Because heart failure is a disease characterized by high mortality rates, frequent hospitalizations, and impaired quality of life, there has been substantial interest in ways in which these various components can be integrated into a single

comprehensive endpoint. In addition, there has been increasing interest in using endpoints that reflect the entire clinical course of the patient. Although Cox proportional hazards analysis—clearly been a useful (and almost universally employed) analysis strategy in chronic heart failure studies—has been used to study time to first event, this technique may lead to “overweighting” less morbid events that occur earlier in the course of follow-up. This potentially introduces major problems in interpretation, in that less severe events happening earlier in the study (such as a brief hospitalization for heart failure) are counted, whereas more severe events (such as death) that happen after an initial event would be ignored in the primary analysis of the trial outcomes. An example of this potential discrepancy is the use of a composite endpoint of time to death or first hospitalization for heart failure, which is standard for chronic heart failure: A patient who is hospitalized for heart failure 2 weeks after randomization but then survives and feels well for 5 years would be viewed as having a worse outcome than one who dies 2 months after randomization. In this sense, the combined endpoint weighs the clinical course in a way that is incongruous with the way it would be viewed by patients and providers.

To deal with this aspect of time to event analysis, various alternative strategies to creating composite endpoints that incorporate the entire follow-up experience have been proposed. One such method is the use of a clinical composite score initially proposed by Packer,<sup>33</sup> in which a patient’s overall status is classified as worsened, unchanged, or improved over the course of follow-up, according to prespecified rules. As it was initially proposed for chronic heart failure, patients are classified as worse if they have experienced any major adverse clinical event (e.g., death, hospitalization for heart failure) or if there was evidence of worsening on the final visit (according to either the patient’s global assessment or the NYHA class determined by the physician). Patients are classified as improved if they have evidence of significant improvement on the final visit (according to either the patient’s global assessment or the physician-determined NYHA class) and did not have any event that would have classified them as worse. If a patient is neither worse nor improved, they are classified as unchanged.

A similar framework has been adopted for acute decompensated heart failure.<sup>34</sup> A more granular method based on similar principles is the global rank method, wherein all patients participating in a trial are ranked on the basis of a prespecified hierarchy of events.<sup>35</sup> For example, in a study of chronic heart failure, all patients who died would be ranked lowest (based on the time to death), patients who did not die but were hospitalized would be ranked second lowest, and patients who did not experience an event would be ranked according to symptomatic status (as measured by a QOL instrument). Another method is to measure “total days alive and out of the hospital” over the course of follow-up. This type of endpoint, which is particularly suited to trials with shorter follow-up periods, incorporates the possibility of frequent hospitalizations and prolonged length of stay into the assessment of efficacy, while also appropriately weighting mortality. This endpoint was used in both the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) study<sup>36</sup> and the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE).<sup>37</sup> Researchers have further refined this approach by adjusting days out of the hospital by using serial measures of health status, creating a global assessment termed the *patient journey score*.<sup>38,39</sup> Although all these approaches have theoretical advantages, they are somewhat more complex to describe and interpret than are traditional endpoints and have thus far not supplanted the traditional endpoint (time to death or hospitalization for heart failure) in studies of chronic heart failure.

### Surrogate Endpoints

A surrogate endpoint is defined by the U.S. Food and Drug Administration (FDA) as “a laboratory measurement or physical sign that is used in therapeutic trials as a substitute for a clinically meaningful end point that is a direct measure of how a patient feels, functions, or survives and is expected to predict the effect of the therapy.”<sup>40</sup> In order to be valid, the surrogate endpoint must have been demonstrated to reliably predict the outcome that it is replacing in terms of four criteria: (1) The biological relevance of the surrogate endpoint must be clearly established through a consistent relationship between it and outcomes in multiple studies; (2) changes in the surrogate endpoint should be predictive of changes in the outcome, independent of treatment; (3) direct proportionality between changes in the surrogate endpoint and in the relevant outcome must be established; and (4) this relationship needs to be replicated in many different patient populations under different conditions.<sup>40</sup> Many physiological variables have been posited as possible surrogate endpoints for heart failure studies, including measures of functional capacity (such as 6-minute walk or peak ventilatory oxygen uptake), ventricular function and volumes, ventricular arrhythmias, hemodynamic changes, and levels of neurohormones or other biomarkers.<sup>41</sup> As currently defined and studied, none of these candidates fulfills the requirements of a true surrogate endpoint, and thus none of these variables is sufficient for the definitive evaluation of the efficacy of a new therapy for heart failure.

In practice, surrogates do serve a useful role in earlier phases of therapeutic development in order to look for signals of efficacy and safety and in selecting the best dose to use in more definitive trials. Whether researchers can identify valid surrogate endpoints that can be used in more definitive trials is a subject of substantial controversy and ongoing interest.<sup>42</sup> Advocates of greater use of surrogate endpoints argue that their establishment would allow for smaller more focused clinical trials and therefore speed the development of new therapies.<sup>43</sup> However, in view of the numerous examples of therapies for which surrogate endpoints proved to be misleading (including inotropic agents,<sup>44</sup> antiarrhythmic drugs,<sup>45</sup> tumor necrosis factor blockers<sup>46</sup>), efficacy studies focused on clinical endpoints such as mortality, morbidity, and symptoms will appropriately remain the definitive approach to establishing efficacy and safety for the foreseeable future.

### Multiple Primary Endpoints

Clinical trials occasionally have two (or, rarely, more) primary endpoints. There are many reasons that investigators might wish to test multiple hypotheses in one trial; multiple questions may be pertinent to the treatment, which endpoint best captures the treatment effect may be uncertainty, or special considerations are needed for regulatory submissions. Multiple hypotheses may be tested with a variety of trial designs, often with active input from regulatory agencies. However, a statistical cost must be paid for these multiple hypotheses, often in some form of “ $\alpha$  allocation,” in which a fraction of the available type I, or  $\alpha$ , error (usually 0.05) is allocated between the multiple endpoints and an adjustment is made for the fact that multiple statistical comparisons are being performed.<sup>47</sup> In addition, allocation of  $\alpha$  to multiple endpoints often necessitates an increase in the trial sample size to maintain the power to detect meaningful differences.

Two trials illustrate methods to deal with multiple primary endpoints and the complexities that they may introduce. The Multicenter InSync Randomized Clinical Evaluation (MIRACLE) had three primary efficacy endpoints (Minnesota Living with Heart Failure score, NYHA class, and

6-minute walk test).<sup>48,49</sup> For the trial to be considered supportive of efficacy, all three endpoints had to be significant at  $P < .05$ , two at  $P < .025$ , or one at  $P < .0167$ . All three endpoints were significantly different at  $P \leq .005$ , and thus the trial met the prespecified criteria for efficacy.<sup>49</sup> In the Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction (CAPRICORN) trial, the original all-cause mortality endpoint ( $\alpha = 0.05$ ) was changed to a coprimary endpoint of all-cause mortality ( $\alpha = 0.005$ ) and a combined endpoint of hospitalizations for cardiovascular events and all-cause mortality ( $\alpha = 0.045$ ). If either of these endpoints had been positive, the CAPRICORN results would have been interpreted as positive. Unfortunately, there was no significant difference in the combined endpoint of mortality and hospitalizations for cardiovascular events ( $P = .297$ ), and although the mortality rate was decreased in the carvedilol recipients ( $P = .031$ ), it did not reach the new, specified level of significance.<sup>50</sup>

### Secondary Endpoints

The multicenter RCT represents a substantial investment of time, energy, and money on the part of subjects, investigators, and sponsors. It is therefore appropriate to gain as much knowledge as possible from the collected database. As a consequence, in addition to the primary endpoint, a variety of other endpoints called *secondary endpoints* are often analyzed. Although the evaluation of secondary endpoints can serve as an important resource for understanding the full impact of a given therapy, their interpretation must be tempered by statistical reality. Specifically, if  $P = .05$  for statistical significance, there is a 5% chance that a “positive” result is actually falsely positive (type I error), which suggests a difference in outcome where none actually exists. Some protocols address this issue by prespecifying only a few secondary endpoints or even a single “primary” secondary endpoint. In the case of trials that yielded negative or neutral results with regard to the primary endpoint, researchers must strenuously avoid the tendency to analyze secondary endpoints (or post hoc subgroups with regard to the primary endpoint) and base claims of efficacy on them.

### Safety Endpoints

The collection and interpretation of adverse effects is essential in determining the safety profile and in assessing the overall value of an intervention, and trials must therefore also be designed with outcome measures that will detect these events. Anticipated adverse events may be related either to the disease process studied or to the known effects of a drug. There is extensive regulatory guidance with regard to the investigator's and sponsor's responsibilities in reporting adverse events, but the basic processes are encompassed by the principle of actively protecting patients' safety and optimizing the information available for the evaluation of possible patterns of adverse events. These data also inform the writing of the package insert for the use of the therapy in clinical practice.

## Sample Size and Statistical Power

The need for clinical trials arises from the practical limitation that not every patient with a given condition can be studied. Consequently, the investigator must use statistical methods to *estimate the probability* that the findings of the study are representative of the whole population of interest. Sample size and statistical power are interrelated concepts that are critical for the interpretation and validity of RCTs. *Sample size* calculations determine how many patients are “enough” to reliably detect the treatment effect under investigation, whereas the *statistical power* is a measure of the ability with a given sample size to detect a real treatment effect if one exists. Detailed discussions of issue and methods of sample size calculations

and methods can be found in statistical textbooks and have been reviewed in detail elsewhere.<sup>51</sup>

The hypothesis of the study influences the sample size in two important ways. First, the type of hypothesis selected affects the power of the study. In general, sample sizes for a noninferiority trial are larger than those for a superiority trial. In addition, hypotheses can be defined as one-sided or two-sided, which affects the sample size. One-sided hypotheses test only one direction of the effect of the therapy (e.g., only improvement); two-sided hypotheses test both directions. Although most investigators may be interested in demonstrating only that an intervention is better than control conditions, they must always recall that therapies can also be harmful. An important example is the Cardiac Arrhythmia Suppression Trial (CAST), which was initially designed with a one-sided hypothesis ( $\alpha = 0.025$ ) for improvement in survival; because these drugs were already marketed and widely assumed to be safe, no harm was expected. In what has become a case study for many issues in RCT design in heart failure, CAST was terminated early because of excess mortality.<sup>45</sup> Consequently, most contemporary trials now use a two-sided hypothesis for sample size determination.

A clinical trial is an approximation of the “truth” in the entire population of interest, and investigators must decide how precise an approximation the clinical trial should be. Two major types of errors can limit the validity of a trial. *Systematic errors* are inherent in the design of the study and usually arise from some type of bias, which can be addressed by randomization, blinding, and appropriate control groups, as described previously. *Random errors* are the result of chance and are classified as type I or type II errors.

Type I error represents the probability that the null hypothesis is incorrectly rejected, so that the alternative hypothesis is accepted (false-positive result). The probability that this will occur is referred to as the *statistical significance level*, or  $\alpha$ . Typically,  $\alpha = 0.05$ , which means that there is a maximum of a 5% chance of incorrectly rejecting the null hypothesis, but other  $\alpha$  levels may be considered more appropriate in a specific clinical circumstances. For example, if the investigators wished to be very confident that a therapy was better than a control condition, perhaps with regard to dangerous side effects, then a more stringent  $\alpha$  might be selected (e.g.,  $\alpha = 0.01$ ), whereas in a study of a disease for which there is no therapy, investigators might be willing to accept an  $\alpha$  of 0.10. Although it has become standard for the great majority of RCTs, there is nothing “magical” about an  $\alpha$  of 0.05; it simply represents a broad consensus of the chance of a false-positive result that is “acceptable” in the conduct of clinical research.

The type II error represents the probability of failing to reject the null hypothesis when it is actually false (false-negative result). The type II error is called  $\beta$ , and it is typically set by investigators to be between 0.05 and 0.20. The type II error is more commonly expressed as the *statistical power*, which represents the probability of correctly rejecting the null hypothesis and is represented mathematically by the relation  $[1-\beta]$ . Type II error is generally associated with “underpowered” clinical trials, in which “no difference” is claimed between two conditions of a study on the basis of  $P > .05$ , even though the study had insufficient power for the investigators to make such a conclusion. Such underpowered clinical trials remain unfortunately common in the literature, and they present a variety of problems in clinical research. Patients in underpowered studies experience the risks of being in the study but may not contribute to the generalizable knowledge and care of future patients. Underpowered trials have been deemed unethical by many investigators.<sup>52</sup>

Sample size and statistical power are profoundly affected by factors that can be estimated only before the conduct of the trial: the *effect size* (how much better the intervention will be than control conditions with regard to the primary

endpoint) and the *event rate* (how frequent events will be in the control group). With regard to effect size, the investigators cannot know what the magnitude of the real difference is, if any, before performing the study, and therefore must select the effect size in which the study should be able to reveal differences. Determining the effect size of a study is a daunting task: What reduction in an endpoint is important enough to detect? For mortality, the answer would be “as small a difference as possible,” but for other endpoints, such as hospitalizations or symptom scores, the decision can be much less clear. Evidence from previous similar studies tends to be very limited, with large uncertainty in the point estimates (especially in pilot studies); published studies are highly selected, and investigators may themselves be overly optimistic. Because extremely large effect sizes (50% or greater) are exceedingly unlikely for new therapies for heart failure, a reasonably conservative estimate of effect size is required in planning the trial in order to avoid an underpowered trial that leaves the underlying hypothesis unaddressed. For example, the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial of ICD therapy enrolled 229 patients on the basis of an optimistic anticipated treatment effect of 50%.<sup>53</sup> The results of the trial showed a 35% reduction in events with ICD therapy, but this did not reach statistical significance ( $P = .08$ ) because the study was not powered to detect this degree of effect.

For typical studies in which clinical events (such as death or hospitalization) serve as endpoints, the primary determinant of statistical power is not the total number of subjects enrolled but the total number of events experienced. For this reason, estimation of both the anticipated treatment effect and the event rates in the control group is critical for the planning of clinical trials. Because baseline event rates are typically lower in clinical trials than in the community samples, such estimates of event rates are often derived from previous clinical trials in which a similar population was enrolled. One alternative approach to ensure a desired statistical power is to predetermine the number of events necessary to demonstrate the effect size and to enroll and monitor patients until this predetermined number of events is reached; thus, estimates of the control event rate would be eliminated as a major determinant of sample size (although they would be a major determinant of the study timeline). Alternatively, the sample size could be reestimated during the course of the trial, when interim evaluations of the event rate (with treatment assignment masked) are performed and the study sample size adjusted accordingly.<sup>54</sup> Ultimately, investigators may be forced to work backward from the number of available patients, which may be constrained by demographics, accessibility, or finances, to the effect size that the study can detect.

The statistical tests used to determine whether one group is significantly different from another are sensitive to the variability within the groups. The smaller the variation within the groups, the smaller the groups can be to detect a difference between them. This facet of statistical analysis has three main implications. First, because measurement error contributes to the variability in the groups, investigators are constantly searching for more precise instruments to capture the full treatment effect reliably. Second, study protocols are usually designed to enroll more homogeneous patient populations to limit another source of variation in the samples. Third, an estimate of the anticipated variability in the groups needs to be established before the study begins, so as to determine the sample size. For many endpoints, the degree of uncertainty in the group estimate can be approximated by analysis of previous heart failure trials, but for novel endpoints or nonvalidated instruments, the variability must also be determined by an informed guess.

Many other factors are important to consider once the inputs just described are determined. The effect size must be adjusted for the possibility of crossovers in therapy, including patients who discontinue therapy, thereby switching from active therapy to a “control” condition (“dropouts”) and patients who switch from the control group to active therapy during the conduct of the trial (“drop-ins”). Drop-ins are particularly problematic if the therapy being tested (or a similar therapy) becomes clinically available during the follow-up period. In the COMparison of Medical Therapy, Pacing, AND Defibrillation in Heart Failure (COMPANION) trial of cardiac resynchronization therapy (CRT) and CRT defibrillator (CRT-D) devices, more than 20% of patients assigned to receive the pharmacotherapy devices had ICDs or CRT-D devices implanted clinically over the course of follow-up; this substantially complicated the interpretation of the final study results.<sup>55</sup> In general, both drop-ins and drop-outs tend to decrease the statistical power of a study, and this development must be adjusted for appropriately in the planning of clinical trials (especially trials with very long follow-up periods or in which problems with compliance can be reasonably anticipated). For example, in the HF-ACTION study of chronic exercise training in heart failure, sample size estimates included adjustment for anticipated numbers of drop-outs (attrition resulting from nonadherence to exercise training) and drop-ins (control patients undertaking an exercise training regimen).<sup>22</sup>

## Data Analysis and Reporting

To protect the integrity of the trial, an analysis plan should be prospectively written; it defines the primary and secondary endpoints, the statistical procedures that will be used to analyze them, and the significance level to be tested. Such a plan protects against the temptation to change the way the data is analyzed once the results are known, and it greatly enhances the validity of the findings. Several important concepts in data interpretation are discussed in the following sections, including the intention-to-treat principle, the interpretation of the significance testing, and subgroup and post-hoc analyses.

### Intention-to-Treat Analysis

Intention-to-treat analyses are counterintuitive. In an *analysis by treatment received (as-treated analysis)*, the effect of a therapy is judged only in patients who actually receive the therapy; in an *intention-to-treat analysis*, patients are evaluated on the basis of the group to which they were randomly assigned, regardless of whether they actually received the therapy. Although as-treated analyses may seem more intuitive, they have the potential to introduce significant biases. Patients who do not adhere to a given therapy may differ significantly from those who do and often have higher event rates than do adherent patients. In addition, compliance may not be balanced between groups, particularly for therapies with significant side effects. Thus, the exclusion of subjects who do not continue the assigned therapy for whatever reason tends to bias the interpretation toward a conclusion of greater efficacy of the therapy being evaluated because only compliant patients are studied. Such an approach may confirm biological efficacy but does not establish real-world effectiveness; in clinical practice, the overall performance of a given therapy must take into account patients who cannot or will not adhere.<sup>56</sup> Intention-to-treat analysis provides an estimate of treatment effect that tends to be more conservative, and it remains the “gold standard” for the interpretation of RCTs. In studies with high rates of noncompliance, as-treated analyses may be performed as a secondary analysis in order to investigate biological efficacy, but such analyses should be seen as supplementary to the intention-to-treat analysis.

The statistical analysis of the primary and secondary endpoints should be described in detail in the analysis plan, and these analyses should be performed per protocol on the cleaned data in an unblinded manner. The interpretation of the results is often a complicated process; the power of the study must be assessed first, and the results must be interpreted in that context. The interpretation of study results should incorporate an analysis of the point estimate of the effect size, the confidence intervals around that point estimate, and the degree of statistical certainty (as reflected in the probability [ $P$  value]) of that result. Often, the clinical trial results are inappropriately interpreted in relation to a single value (the  $P$  value), and the trials are dichotomized as “negative” or “positive” on the basis of the  $P$  value. Data should be interpreted in the context of overall study power, as well as in comparison with other studies in similar populations. For example, in the DEFINITE study,<sup>53</sup> ICD therapy was associated with a 35% reduction in mortality (hazard ratio = 0.65; 95% confidence interval, 0.40 to 1.06;  $P = .08$ ), which did not meet the prespecified criteria for statistical significance ( $P = .05$ ). Technically, this was a “negative” study in that it did not meet its prespecified criteria to establish efficacy. However, a more nuanced interpretation would be that the results suggested the possibility of a 35% reduction in mortality with ICD therapy (on the basis of the point estimate), but the study was not powered enough to conclusively prove this effect with 95% probability (it was “proved” with a 92% probability). In the context of other studies in which ICD therapy was proved efficacious for primary prevention in patients with left ventricular dysfunction, DEFINITE can be seen as a highly supportive but ultimately underpowered study, rather than simply a “negative” one.

For studies that are used to conclusively demonstrate efficacy and support regulatory approval, the focus is typically on only the prespecified primary endpoint; if the primary endpoint is not met at the level prespecified, the study results cannot support the assertion of efficacy. This discipline in endpoint interpretation has many advantages: it interprets the trial in the manner in which the investigators felt was optimal, it is the tenet around which the trial was designed, and it is independent of any post-hoc data-driven bias, thus protecting the type I error of the trial. For example, in the CAPRICORN trial,<sup>50</sup> the primary endpoint was originally all-cause mortality ( $\alpha = 0.05$ ). During the study, the data and safety monitoring committee (DSMC) noted a low overall mortality rate in an early masked analysis and believed that power might have been insufficient to detect a difference with the mortality endpoint. The steering committee then decided to adopt two coprimary endpoints. Both—combined morbidity and mortality ( $P = .30$ ) and all-cause mortality ( $P = .03$ )—were “negative” according to the revised definitions and  $\alpha$  allocation, and so CAPRICORN, a study in which mortality was reduced 23%, was technically a negative trial. However, the challenge to clinicians and regulatory agencies is to interpret this trial for application in clinical practice. Despite some debate, carvedilol had beneficial effects in patients with NYHA classes II to IV heart failure (U.S. Carvedilol Program and COPENICUS) and  $\beta$ -blockers had a recognized benefit in other postmyocardial settings; thus, the reduction in all-cause mortality was thought to be sufficient to warrant the FDA’s approval of carvedilol for heart failure.

#### Subgroup Analysis and Other Post Hoc Testing

Subgroups may be defined in a number of ways, ranging from protocol-specified to purely post hoc analyses. Protocol-specified subgroups are the least susceptible to bias but

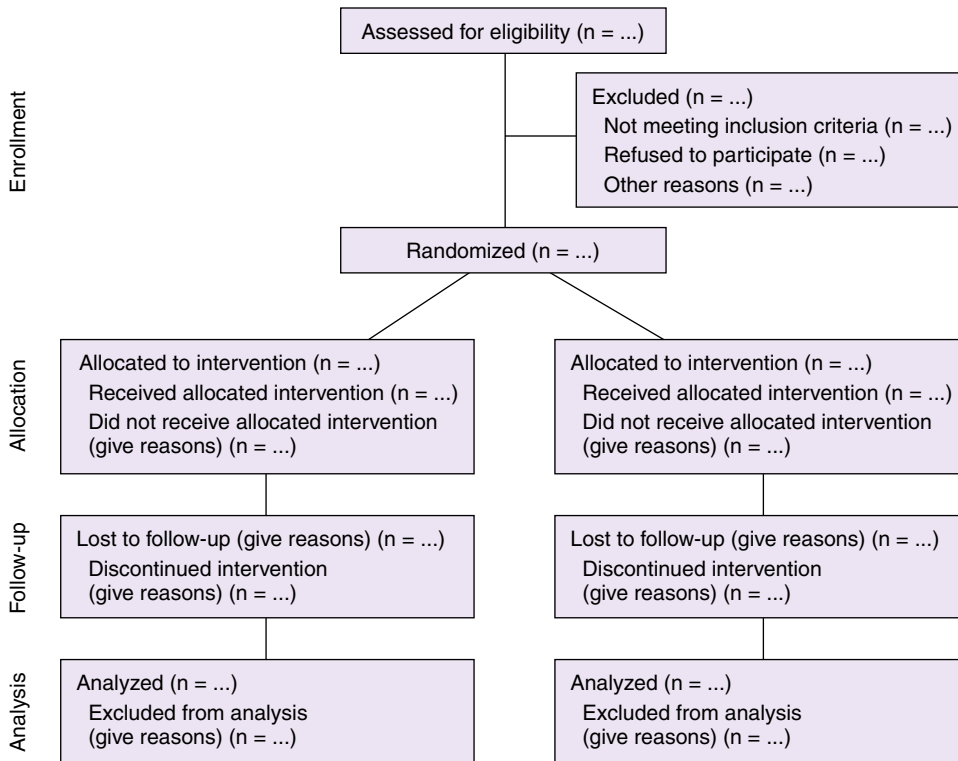

must be interpreted cautiously because of their low statistical power and the increased chance of type I error (false-positive results) inherent in multiple comparisons. The MERIT-HF trial<sup>20</sup> prospectively defined subgroup analyses to be performed in the data analysis plan, including prespecifying the subgroups, stating that they were to be performed only for safety concerns, specifying the endpoints that were to be studied, and mandating that each had at least 180 events. These subgroup analyses demonstrated broad and consistent safety of metoprolol in all of the prespecified subgroups. Other subgroup analysis may not be prespecified but may be highly relevant to the biological properties of the disease or treatment. The OPTIME-CHF study<sup>57</sup> of the inotropic drug milrinone, which is known to increase myocardial oxygen demand, revealed that the drug was particularly harmful in patients with ischemic causes of heart failure, in comparison with patients with nonischemic causes. Although such analyses should be interpreted with caution, their validity is supported by a high degree of biological plausibility. In evaluating the validity of such subgroups analyses, researchers should assess the statistical interaction between the treatment and the subgroup (e.g., subjects with ischemic vs. nonischemic causes) in the total population, and analysis should proceed only if there is evidence of a statistically significant differential response between subgroups (as reflected in the  $P$  value for the interaction term). Other alternative and more robust statistical methods have also been proposed for improving the statistical validity of subgroup analyses.<sup>58</sup> Unfortunately, many subgroup analyses are data-driven post hoc tests that are extraordinarily biased and susceptible to substantial type I error. These analyses are often performed after the data have been perused for “interesting” trends and these trends are then selected for “statistical” testing. Such data-driven subgroup analysis and other post hoc analyses should be limited as much as possible and, when performed, interpreted with the utmost caution.

#### Publication Issues

Clinical trials in heart failure often involve thousands of patients and hundreds of investigators and study personnel. The results of these studies have important effect on the care and management of patients with heart failure, and there is therefore an ethical mandate that these results are published fully and in a timely manner. Unfortunately, a number of major heart failure studies that did not meet their primary endpoint to some extent either have never been published or were presented only as brief papers without supporting details.<sup>59</sup> Part of this publication bias is inherent in all negative reports (it is much more difficult to publish a negative finding than a positive one), but many trials do not even make it to the manuscript peer-review stage. However, intellectual honesty and a responsibility to the participating patients necessitates that negative findings be clearly and objectively presented. In order to facilitate transparency and increase the publication of negative trial results, the Food and Drug Modernization Act (passed in 1997) requires all clinical trials of “experimental treatments for serious or life-threatening diseases” to be registered on an appropriate public registry (such as <http://www.clinicaltrials.gov>).

Publication of RCTs should include detailed descriptions of the patient population, study intervention, procedures for control and blinding, follow-up, study endpoints, and calculations of sample size and power. Standardized criteria for reporting of RCTs have been created in order to improve the consistency of reporting the results of RCTs. Flow diagrams showing the number of patients screened, enrolled, randomly assigned, and analyzed in a standardized manner (Figure 39-2) are useful.<sup>60</sup>

## OPERATIONAL ASPECTS OF RANDOMIZED CONTROLLED TRIALS

A large multicenter RCT is a monumental endeavor, the success of which requires the combined efforts of investigators, study coordinators, project leaders, statisticians, data managers, study monitors, study sponsors, and (of most importance) research subjects. The organizational structure of a clinical trial serves to “operationalize” the scientific principles outlined in the previous section, and it is a critical aspect of a successful clinical trial. As clinical trials have grown in size and complexity and as regulatory requirements have become more complex, the operational structure necessary to perform large clinical trials has expanded as well. Although the organizational structure for a clinical trial must be tailored to the specific needs of that study, many general operational components are relevant to almost all large trials: the presence of a sponsor, a coordinating center, a leadership body, and a DSMC. **Figure 39-3** is a generalized representation of the operational components of a typical large RCT in heart failure, which are discussed in detail in the following sections.

### Study Leadership

Multicenter clinical trials are typically led by a steering committee of investigators who provide guidance on the scientific and operational aspects of the trial. For large or complicated studies, study leadership may be divided between a smaller executive committee (charged with making day-to-day operational decisions) that meets frequently (often weekly or biweekly) and a larger steering committee (charged with making larger decisions about the overall trial conduct) that meets less often (e.g., quarterly). Ideally, study committees ensure the scientific validity of the trial. Study committees are typically involved in all phases of study conduct, from protocol development to making decisions during the course of the study to preserve the trial’s integrity and the patient’s safety and to analyzing and presenting study results. The

**FIGURE 39-3** Generalized organizational scheme of a clinical trial. CEC, clinical event committee; DSMC, data and safety monitoring committee; IRB, institutional review board.

independence of the study committees is essential, and conflicts of interest should be minimized.

### Study Sponsor

The study sponsor is the entity that funds the clinical trial; it may be governmental, a foundation, a commercial entity, or some combination of the three. The responsibilities of the sponsor are clearly delineated for studies involving investigational drugs and devices by the Food and Drug Administration. The sponsor of an Investigational New Drug (IND) application

is responsible for “selecting qualified investigators, providing them with the information they need to conduct an investigation properly, ensuring proper monitoring of the investigation(s), ensuring that the investigation(s) is conducted in accordance with the general investigational plan and protocols contained in the IND, maintaining an effective IND with respect to the investigations, and ensuring that FDA and all participating investigators are promptly informed of significant new adverse effects or risks with respect to the drug”. These important responsibilities require multiple areas of expertise and an intimate role in the daily activities of the trial. For many sponsors, this intimate involvement can give the appearance of a conflict of interest for the sponsor, and some sponsors do not have the time, expertise, or personnel to perform such functions. Therefore, for large clinical trials, study sponsors typically engage another entity to serve as the coordinating center and thereby provide some or all of these functions.

## Coordinating Center

The coordinating center, which may be an academic or commercial organization, is crucial in the operational aspects of the clinical trial. As the name implies, the coordinating center serves as the operational hub of activities related to the clinical trial, including the selection, training, and monitoring of sites; collection and monitoring of adverse events; randomization of study subjects; supplying of the investigational drug; and collecting, cleaning, analyzing, and summarizing study data. Coordinating Center staff typically include project leaders, clinical research associates, data managers, medical monitors, regulatory personnel, and biostatisticians. Because of its central role in the clinical trial, the coordinating center must maintain the utmost integrity and must prevent conflicts of interest. In very large trials, the roles of the clinical coordinating center and the data coordinating center may be split between different entities, or regional coordinating centers may serve to coordinate activities in individual regions or countries in a “hub and spoke” model.

## Data and Safety Monitoring Committee

The DSMC is an essential component of any large RCT of a new treatment. These committees comprise individuals who are independent of the investigators and the sponsor—and in view of the power of DSMCs in clinical trials, a complete lack of any real or apparent conflict of interest is critical. DSMC membership typically includes individuals with expertise in biostatistics, clinical trial methodology, and the field under investigation (e.g., heart failure). DSMCs usually have charters that very specifically delineate their relationship to the sponsor, their operating procedures, their meeting schedules, and either the guiding principles for their duties or explicit statements of the tasks and the procedures that they will use to complete them. DSMC meetings are scheduled at regular intervals either chronologically or on the basis of numbers of events or enrollment. These meetings often have an open session portion, in which the principal investigator, steering committee, or sponsor can address any questions that DSMC members might have, but the data are reviewed in closed sessions with only DSMC members present. As discussed in the next section, the DSMC is often responsible for developing, implementing, and interpreting statistical “stopping rules” for the trial, which may terminate a trial before completion because of undue harm, efficacy, or futility. DSMCs may also be responsible for reviewing unmasked data and making recommendations on altering sample size of the study or changing entry criteria for safety issues. Unless extraordinary reasons can be presented, a DSMC is an ethical necessity for any significant RCT of a new therapy.

In very early phase trials or confirmatory studies of approved therapies, alternative methods may be used, as opposed to a formal DSMC, but ongoing attention to patient safety is critical in all clinical trials.<sup>61</sup>

### DSMC Responsibilities: Administrative Analyses and Safety Analyses

Administrative analyses are the evaluations of the data by the DSMC that are related to the integrity and conduct of the trial. The DSMC may be given the responsibility to perform analyses to assess the validity of the design assumptions or to make recommendations regarding recruitment and thereby possibly make changes in the entry criteria. The DSMC can analyze the baseline data and check for any randomization imbalances in important variables that may suggest problems with the randomization scheme. An important role of administrative analyses and the DSMC is in assessing the event rate in view of the planned sample size and statistical power. If the DSMC members believe that the initially planned sample size would be inadequate to address the hypothesis, they may make recommendations to the study leadership and the sponsor to enroll more patients, extend the follow-up period, or both.

The DSMC has primary ethical responsibility for the safety of the patients and, consequently, has access to unmasked data on all adverse events. If there is evidence of an increased rate of adverse events among the treatment recipients, further analysis might be performed to determine correlates or predictors of the unfavorable outcome, and recommendations can be made to modify the entry criteria or trial procedures. These forms of safety analyses can be performed with minimal impact on the overall power of the trial, but repeated testing of the primary efficacy endpoint can have significant implications, as discussed in the next section.

One of the most important potential activities of the DSMC is to make recommendations to study leadership regarding the premature discontinuation of a clinical trial. Trials may be stopped early because of evidence of harm, conclusively established efficacy, or futility. Definitive evidence that the new therapy being tested is unsafe is a self-evident reason for stopping a trial prematurely. Conversely, if there is clear evidence of a beneficial effect of the treatment, it is in the best interest of the general population that the therapy be made available to all qualified patients. Finally, if a trial has minimal chance of producing any meaningful result, it is important to be able to inform the subjects of this futility and stop the trial. The recommendations of the DSMC are therefore complex decisions that integrate a multitude of inputs; consequently, strict stopping rules are not practical. However, predefined statistical procedures for assessing negative and positive trends, as well as futility in continuing a trial, are essential for providing the basis for these decisions. The statistical tests used in interim analyses have a number of challenges: First, they must address the issue of the statistical cost of repeated testing. Second, they must be designed to address the specific question; tests that may be applicable to the decision to stop a study may not be the most appropriate for assessing the futility of continuing a trial. Third, there must be a method for extrapolating from an incomplete data set.

Repeated testing of a hypothesis increases the probability of a false-positive result.<sup>62</sup> This fundamental principle of statistics has important ramifications for interim analyses in trials. For example, if five interim analyses are conducted with  $\alpha = 0.05$ , then the false-positive error is almost 15%, or three times greater than the standard acceptable  $\alpha$  error. Thus, to account for these repeated tests of the study hypothesis, multiple methods have been developed. The general procedure in these interim analyses is to create, either arbitrarily or by statistical modeling, a critical boundary against which to compare the study's test statistic value at the interim analysis ( $Z_i$ ). If the study's  $Z_i$  has crossed the boundary, then the null hypothesis may be rejected (Figure 39-4).<sup>63</sup> The most commonly used

statistical methods for DSMCs in RCTs are group-sequential procedures and conditional power (or stochastic curtailment) methods, which are discussed briefly as follows.

A number of group-sequential procedures have been used, ranging from the ad hoc selection of a high critical value arbitrarily selected so that when final adjustments are made for repeated testing, the final  $\alpha$  level is protected (Haybittle-Peto method<sup>64</sup>), to more precise methods of guaranteeing a precise type I error (see Figure 39-4). The O'Brien-Fleming group-sequential method has a very low likelihood of accepting the null hypothesis early in the trial, but the  $\alpha$  at the interim test point ( $\alpha_i$ ) increases with subsequent analyses to be nearly equal to the overall  $\alpha$  at the last analysis.<sup>65,66</sup> For example, if the overall  $\alpha$  is selected to be 0.05 and there are five interim analyses, the first interim  $\alpha$  ( $\alpha_1$ ) is 0.00001, and the  $\alpha_5$  is 0.046. This method has the advantage of protecting against premature discontinuation of the study at early interim analyses, for which there are relatively few events, and yet allowing the possibility of termination for decidedly negative results. Other approaches have been developed to allow for greater flexibility in the timing and frequency of the interim analyses and still limit the overall type I error.<sup>67</sup>

Conditional power analysis, or stochastic curtailment, is an attempt to predict the probability that the null hypothesis will ultimately be rejected if the desired sample size is attained, according to the accumulated data up to that point.<sup>68</sup> If the probability that the trial will be either positive or negative is very low, the decision may be made to stop the study before completion. In practice, however, such futility stopping rules apply most frequently to the ability of the trial to demonstrate a significant benefit.

These approaches often employ symmetrical stopping boundaries (i.e., the same boundaries are applied for both a negative result and a positive result), but clinical decisions may be asymmetrical. Many investigators and DSMC members are willing to enroll more patients to clearly establish the effectiveness of a new therapy (a relatively high upper boundary) but are less comfortable allowing a trial to continue if there is a strong suggestion of harm (a lower threshold for discontinuation). Asymmetrical stopping boundaries are an attempt to take into account the investigators' level of concern about the safety of the new therapy.<sup>69</sup> For example, in the MERIT-HF study of metoprolol XL—which was performed at a time when there were significant concerns about the safety of giving  $\beta$ -blockers to patients with heart failure—the researchers used asymmetrical boundary procedures from the onset of the study.<sup>70</sup>

The statistical methods just described provide a foundation upon which a DSMC can build their decision as to whether to recommend continuation or termination of a trial, but they are only one contribution to a very complicated structure. Other elements important to consider include evaluating the comparability of the groups for baseline variables; ensuring that evaluation of the endpoint was unbiased; verifying patient adherence; searching for internal consistency by looking for concordance with other outcomes and among subgroups; checking for external consistency in comparison to known mechanisms of action and results from other similar trials or agents in the same class; ensuring that the length of follow-up has been adequate for making a decision; and considering the potential public effect of either terminating or continuing the trial. Once all of these factors are integrated, the DSMC attempts to make a decision on the basis of protecting patient safety and respecting the scientific integrity of the clinical trial.

## Endpoint or Clinical Events Committee

The endpoint committee, or clinical events committee, is meant to address the considerable variability that exists between the treating physicians, hospitals, regions, countries, and continents with regard to clinical practice and event definitions. The major advantage of a clinical events committee is

**FIGURE 39-4** Asymmetrical stopping boundaries (solid symbols) for the standardized normal statistic with five interim analyses in which two group sequential methods were used [O'Brien-Fleming (solid purple squares) and Haybittle-Peto (solid orange triangles)]. The fifth analysis is the final analysis of the study, and in this example, the boundary for rejecting the null hypothesis ( $H_0$ ) for benefit (a positive  $Z_i$  value) is more stringent than the boundary for demonstrating harm. Dashed lines A, B, and C (open symbols) represent hypothetical trials. In trial A (open circles, blue line), the early suggestion of benefit rapidly disappears, so that at the third or fourth interim analysis, a data and safety monitoring committee (DSMC) might consider terminating the study early to avoid harm. In trial B (open diamonds, red line), outcome also nears a boundary at the third interim analysis, but this time for benefit. The study might be continued after the third analysis, but it is discontinued for benefit after the fourth analysis. Results of trial C (open squares, green line) remain neutral during the course of the entire study; it is possible that a conditional power analysis would suggest at the fourth interim analysis that there was little chance for the trial to produce a meaningful result and the trial could be stopped for futility, depending on the prespecified definitions. (Adapted from Friedman LM, Furberg CD, DeMets DL. *Fundamentals of clinical trials*, ed 3, New York, 1998, Springer-Verlag. With kind permission of Springer Science+Business Media.)

that it can standardize the definitions for and interpretation of clinical events, which increases the validity and comparability of the trial results. The ability to validate endpoints in a blinded manner is very important in assessing endpoints that are difficult to adjudicate (e.g., mode of death) or "softer" endpoints (e.g., myocardial infarction or hospitalization for heart failure).<sup>24,25</sup> Of course, the definitions that the clinical events committee uses for an event may not effectively encompass the variability of clinical practice in different regions. For example, the endpoint of the OVERTURE study<sup>28</sup> included only hospitalizations for heart failure in which the patients required intravenous medications, as a means of mandating higher severity of illness for the disease-specific hospitalization event. Unfortunately for the trial, aggressive oral diuretic therapy is the standard of care in some regions, and consequently, some admissions for heart failure did not count toward the endpoint. Although some study sponsors prefer not to have blinded event adjudication by a clinical events committee because of the extra expense involved, there is clear evidence of the positive effects of clinical events committees on overall trial validity.<sup>71</sup>

## Site Investigators

The site investigators and nurse coordinators are the people who make the study work, by enrolling patients, caring for and following them, completing case report forms, and observing

for important adverse or other effects. As with the sponsor of a trial, the site investigators also have specific responsibilities defined by the FDA, which include ensuring that an investigation is conducted according to the signed investigator statement, the investigational plan, and applicable regulations; protecting the rights, safety, and welfare of subjects under the investigator's care; control of drugs under investigation; and obtaining informed consent from study participants. Investigators must also have a high degree of integrity, especially in the face of financial incentives and continual pressure from the study leadership, coordinating center and sponsor to enroll as many patients as rapidly as possible.

Maximizing study enrollment is a substantial and ever-increasing challenge. To yield useful results, a large RCT in heart failure must enroll a large number of patients who have a chronic and often debilitating disease in a human experiment that may result in significant inconvenience or discomfort, with no guarantee of individual benefit. Almost invariably, initial projections about the rate of enrollment are overly optimistic, in comparison with when the trial is actually conducted. For the study to finish successfully, the investigators', study coordinators', and other clinical personnel's efforts at the study site must be sustained and ongoing. Increasingly complex regulatory requirements and diminished reimbursement for clinical research have exacerbated the difficulty in enrolling patients in heart failure trials in the United States and Western Europe. The proportion of patients in large international trials enrolled in other parts of the world, especially Eastern Europe, South America, India, and China, has accordingly increased dramatically. Although this increasing globalization of clinical trials potentially enhances the generalizability of results, it also introduces substantial concerns. For regulatory agencies such as the FDA, there is uncertainty in how to interpret clinical trial data that were collected primarily from patients with different genetic backgrounds, different comorbid conditions, different health behaviors, and different medical care. In addition, ethical considerations mandate that the developing world not be used to provide research subjects to investigate therapies that are then marketed primarily in the United States at prices that would make them difficult to obtain in the developing countries. This issue has received substantial attention in both the media and the scientific community.<sup>72,73</sup>

## Study Subjects

Patients who consent to participate in RCTs agree to undergo possible inconvenience, discomfort, and often poorly defined risks for the purpose of obtaining generalizable knowledge. The motivations for patients to participate in clinical research have been studied extensively.<sup>74</sup> Many patients who participate in clinical trials do so with the expectation that participation will be of benefit to them, either through the study intervention itself or through the greater medical attention associated with being a study participant; others do so primarily because of a sense of altruism.<sup>75,76</sup> Whatever their motivation for participation, clinical trial participants should be treated with the utmost respect and gratitude. Their willingness to participate in the human experiment of a clinical trial helps provide the evidence for advancing scientific knowledge and improving the practice of medicine for all patients.

## RANDOMIZED CONTROLLED TRIALS IN THE CONTEXT OF DRUG DEVELOPMENT: TRANSITIONAL STUDIES

Although many of the issues discussed are generalizable to all types of clinical trials, much of the preceding discussion has focused on large, multicenter RCTs with clinical endpoints,

which are the types of pivotal trials that provide evidence in support of the regulatory approval and clinical use of drugs. Of importance, however, is that these definitive trials are the end of a long development process. Development programs of new therapies have traditionally been divided into three phases, each with distinct objectives and potential issues in trial design for each. The purpose of phase I studies is to assess the safety of a new therapy in humans, with the specific objectives to characterize the metabolism, pharmacokinetics, pharmacodynamics, dose-response ratio, tolerability, and possible dose-limiting side effects of the therapy before further investigation. The size of these studies varies greatly but generally ranges from 20 to 80 patients. In phase II studies, the dose and effectiveness of the therapy are evaluated for one or more specific indications in patients who have the condition of interest, and the common short-term side effects and risks associated with the drug are determined. In pragmatic terms, phase II studies are critical in defining the dose to be used in the larger phase III studies and to confirm the proof of concept of the therapy being tested, as well as providing information on the magnitude of effect to be studied. Because of the limited time and financial resources generally available at this phase of investigation, these studies may evaluate a limited number and range of doses and employ surrogate endpoints for clinical outcomes. Phase III trials are large studies designed to convincingly demonstrate the efficacy of the therapy, to provide safety information for a more complete evaluation of its benefit-to-risk ratio, and to ultimately define how the therapy should be used. These trials often include from several hundred to thousands of patients.

Although these phases of investigation are useful for discussing trial design and goals, some points regarding this paradigm must be remembered. These phases do not represent a plan that guarantees regulatory approval of the therapy; rather, they serve as a guideline about the types of information that the regulatory agencies require to assess a new therapy. A therapy may already be known to be effective for a different, often related indication (e.g., hypertension, myocardial infarction), and in this case, its evaluation in heart failure may involve a single phase III trial. Consequently, most pharmaceutical and device manufacturers enter into discussions with the FDA and other regulatory agencies early in the course of development and again before conducting phase III studies, both to ensure that their approaches are likely to be acceptable for approval, if positive, and to minimize risk to the participating subjects. The distinction between phase II and phase III trials has become progressively blurred and new study designs have been developed to transition rapidly from phase II and phase III studies and yet retain much of the study architecture.

The initial steps in the clinical development process are meant to provide a bridge between the basic scientific tenets that suggested such therapies could be useful and the definitive studies that convince investigators that the therapy can beneficially influence outcomes in a patient population. This "bench-to-bedside" transition is complicated by numerous factors, but it ultimately requires the confirmation that the therapy performs in humans in its intended manner (i.e., proof of concept) and the determination of appropriate dosages to allow more widespread testing of hypotheses (i.e., dose selection). These studies have often been considered phase II studies, but for the purposes of this discussion, they are referred to as *transitional studies*, to emphasize their role in serving as a transition from basic discovery to large-scale evaluation of efficacy. Various approaches to these critical steps in the evaluation of new therapies are summarized in Table 39-1.<sup>77</sup>

The selection of patients for these transitional studies is greatly influenced by the endpoints, so as to optimize the possibility of demonstrating meaningful differences between

**TABLE 39–1 Approaches to the Design of Transitional (Phase II) Trials**

Approach	Method	Advantages	Disadvantages
Intuitive	Drug administered by a select group of investigators who observe effects in open-label, unblinded studies and make recommendations	<ul style="list-style-type: none"> <li>• Rapid, cheap, and ease to conduct</li> </ul>	<ul style="list-style-type: none"> <li>• Investigators cannot reliably discern clinical benefit</li> <li>• Purely subjective</li> </ul>
Mechanistic	Administer drug in multiple dosages and select dosage that has optimal biological effect thought to best reflect drug's mechanism of action	<ul style="list-style-type: none"> <li>• Often quantitative</li> <li>• Testable hypothesis</li> <li>• Rational</li> </ul>	<ul style="list-style-type: none"> <li>• Limited ability of preclinical research to reliably identify relationship of importance of mechanism in animals to that in humans</li> <li>• Biological effect of drug may be impossible to measure in patients</li> <li>• Drug may have multiple effects that may supersede its intended actions</li> <li>• Difficult to determine the degree of the biological effect necessary to demonstrate efficacy</li> <li>• Short-term biological effects may not be maintained over long term</li> <li>• No clear relation between mechanistic efficacy and effect on clinical outcomes</li> </ul>
Efficacy-pilot	Administer drug in multiple dosages and select dosage that has optimal effect on an array of clinical endpoints	<ul style="list-style-type: none"> <li>• Clinical relevance</li> </ul>	<ul style="list-style-type: none"> <li>• Usually no single endpoint is selected, so not clear whether results are informative</li> <li>• Differences are typically small, and trends are often conflicting</li> <li>• Does not yield benefit-to-risk information</li> </ul>
Safety-pilot	Administer drug in multiple dosages and select dosage that has optimal safety profile	<ul style="list-style-type: none"> <li>• Clinical relevance</li> </ul>	<ul style="list-style-type: none"> <li>• Mechanism of action and clinical efficacy are assumed to be established</li> <li>• Difficult to determine the correct dose of a new drug on basis of its safety profile</li> <li>• Unlikely that safety can effectively be assessed in intermediate-sized trial (&lt;500 patients)</li> <li>• Does not yield benefit-to-risk information</li> </ul>

Adapted from Packer M. Current perspectives on the design of phase II trials of new drugs for the treatment of heart failure. *Am Heart J* 2000;139:S202-S206.

the therapy and the control group (either placebo or active-control condition). The inclusion and exclusion criteria for these studies are typically much more restrictive than in later, larger trials. Selection is based on the presence of a particularly relevant aspect of the pathophysiological features or mechanism of heart failure (e.g., elevated neurohormonal concentrations), more severe manifestation of a particular symptom or greater probability for an improvement (e.g., limited exercise tolerance), or higher risk for a specific adverse effect or safety-related issue (e.g., ventricular arrhythmias). Many protocols focus on defining the “ideal” patient for the therapy, under the assumption that if the therapy is not effective in this ideal patient, it would not be effective or safe in other patient populations. The advantage of these enriched populations is that the higher event rates may overcome the relatively small sample size of these transitional studies. The disadvantage of these narrowly defined groups is that they are often not representative of the broader population in which the subsequent trial will be performed and thus have limited predictive value for that setting. In addition, selecting the “ideal” patient requires a degree of understanding of the underlying mechanisms of both the drug and the pathophysiological features of heart failure, an understanding that may be unavailable. Despite these limitations, the approach of patient selection directed at including an enriched population is the most favorable for these transitional studies.

### Selection of Dose Range and Endpoints in Transitional Studies

A key goal of transitional studies of new therapies is to identify the most appropriate dosage to use in larger trials. The selection of the appropriate dose range is confined by two limits. The upper limit is typically defined by the safety profile of the drug (the maximally tolerated dosage), and the lower limit is usually defined by efficacy (the minimally effective dosage). A common approach, particularly if little is known about the dose range, is an ascending-dose design. Alternatively, a parallel design may be invoked in which many dose groups are studied in order to determine the optimal dosage.

However, the more numerous the dosage groups are, the more difficult it is to demonstrate meaningful differences in efficacy or safety, unless the sample size is substantial. For many reasons, primarily economic, it is rare that study researchers will investigate a truly broad range of doses. Because of these challenges, newer approaches to study design (discussed in the next section) have evolved to include a wide range of dosages that are based on the best informed extrapolations from both animal data and human pharmacological data (preferably in patients with heart failure) but make provisions for dropping dosage conditions as the study proceeds.

Transitional studies are typically smaller than phase III definitive studies and, as such, rarely have sufficient power to use clinical endpoints. Selection of appropriate surrogate endpoints, as defined previously, is therefore a key aspect of designing transitional studies. The search for useful surrogate endpoints in heart failure has been fraught with difficulty, and at present there are no universally accepted surrogate endpoints for this condition. In general, potential surrogates used in transitional studies may be focused on physiological variables, clinical composites, or safety, each of which is discussed as follows.

In many transitional studies, physiological variables, such as hemodynamic measurements, ejection fraction, or levels of a biomarker (e.g., natriuretic peptides), are used as endpoints. Such endpoints are theoretically attractive because they appear to reflect the underlying mechanism of drug effect; for example, inotropic drugs work by increasing cardiac output, and therefore hemodynamic changes seem to be an appropriate surrogate endpoint. However, this approach presupposes a level of understanding of both the mechanism of drug action and heart failure physiology; this understanding is often lacking. In addition, drug efficacy and drug safety may involve very different mechanisms, and therefore drugs that maximize a physiological effect related to efficacy (e.g., cardiac output) may have an unacceptable rate of adverse effects (e.g., arrhythmias). The history of drug development in heart failure contains numerous examples of drugs that were developed on the basis of maximizing physiological surrogates but failed in larger studies because of unanticipated adverse

effects. For example, blockade of the effects of tumor necrosis factor  $\alpha$  with etanercept had clear biological plausibility and had been shown to increase the physiological surrogate of ejection fraction in transitional studies.<sup>78-80</sup> Despite these very promising early results, this therapy was not shown to be beneficial when tested in larger efficacy trials.<sup>46</sup> It is important to recognize that the failure of these drugs was not necessarily a failure of the concept that these drugs addressed; rather, it was attributable to unrecognized potential adverse effects. Mechanistic endpoints remain attractive in as much as they provide a rationale for the application of the therapy to patients with heart failure. If specific mechanisms are well enough defined in humans and the results are interpreted with appropriate caution, mechanistic transitional studies may still provide a basis on which to select a dose range for subsequent study.

A second category of endpoints in transitional studies are clinical efficacy measures. To the extent to which such measures often reflect patient symptoms and functional status, these are not true surrogate endpoints, but they often serve this purpose in transitional studies. When used in transitional studies, multiple clinical endpoints are often combined in a single composite in order to clarify the overall clinical effect of a given therapy. Such endpoints may include measures of clinical events (especially worsening of heart failure, hospitalizations, and death), supplemented by assessments of exercise tolerance, symptoms, or quality of life. The advantage of these endpoints is that they are clinically relevant. However, the size of such studies, the brief duration of follow-up, and the relatively low event rates usually preclude selection of one of these measures as the primary endpoint for transitional studies, and rarely do they reach statistical significance. In the absence of this statistical rigor, the small differences between groups and nonsignificant trends of these assessments must be carefully interpreted. This subjective interpretation is often complicated by results that demonstrate conflicting trends, which further limits the usefulness of any conclusions regarding dosage and design of the subsequent larger trials. In addition, these studies rely on the assumption that the clinical efficacy measures are predictive of the more important clinical outcome measures, such as morbidity and mortality. Unfortunately, this assumption has been incorrect in numerous instances. For instance, inotropic drugs such as milrinone appear to improve symptoms but have an adverse effect on mortality rate. In contrast, many angiotensin-converting enzyme inhibitors and  $\beta$ -blockers did not improve exercise tolerance but did improve prognosis. Finally, these types of endpoints do not yield any information regarding the ultimate benefit-to-risk ratio of the therapy, which is necessary for truly assessing efficacy.

The third category of endpoints in transitional studies focuses on safety issues. In these studies, either one or many of the potential pertinent safety concerns are selected as the endpoint, with the goal of determining the dosage with the best profile for adverse events. Examples of these endpoints include arrhythmias, hypotension, renal dysfunction, electrolyte abnormalities, and other dose-limiting side effects specific to the therapy. This approach is an attempt to directly address the concern raised by previous drug development programs, in which the failure to recognize serious adverse effects resulted in exposure of thousands of patients to increased risk and in the ultimate termination of the development program. These studies may be able to assist with dosage selection, if there are marked safety issues, and the investigators and sponsor are willing to accept a significant degree of uncertainty about these safety estimates. Unfortunately, these studies also fall prey to the limitations noted previously: The studies are generally too small with brief follow-up durations to provide definitive evidence of either safety or harm. In addition, the clinically effective dose is

presumed to be known already, and no important difference in efficacy is presumed among the dosages selected for the safety study. As discussed previously, these safety studies also do not provide information about the overall balance of the safety and efficacy of the therapy. Regardless of the end-point selected, however, any reasonably sized study should have independent unblinded monitoring to protect the safety of the subjects, such as an independent DSMC.

## NOVEL APPROACHES TO DESIGN OF CLINICAL TRIALS IN HEART FAILURE

A fundamental problem for drug development in heart failure is that, of the drugs that have successfully progressed through phase II studies, few have actually proved effective in larger, more definitive studies. The imperative to develop newer, more effective, and economical development strategies is clear, but the potential solutions are constrained by the nature of heart failure. The pathophysiological processes of heart failure are multifactorial and highly integrated, which results both in considerable difficulty in predicting the response to a therapy and in a high likelihood of unintended effects. This variability increases the difficulty in drawing valid conclusions from small pilot studies. Many patients with heart failure are elderly and have other comorbid conditions; thus, competing risks that may not exist for other disease states are present in heart failure. Furthermore, in view of the proven efficacy of currently available therapies such as  $\beta$ -blockers and angiotensin-converting enzyme inhibitors, overall rate of events in patients with heart failure is declining, which necessitates progressively larger numbers of subjects in order to demonstrate meaningful differences. As with any experimental science in which multiple dynamic factors are present, clinical trials adapt to these changes. Previously, this adaptation was achieved in a less formal manner, which often undermined the ability of a trial to provide valid statistical inference. In contemporary clinical science, there are new approaches to modify trials so that they may be responsive to dynamic information, which may be broadly categorized as adaptive designs.<sup>81</sup>

Adaptive design of a clinical trial is "a design that allows adaptations or modifications to some aspects of the trial after its initiation without undermining the validity and integrity of the trial."<sup>82</sup> Three general types of adaptation may be described. In *prospectively designed adaptation*, there is a protocol-specified plan for using adaptive techniques to modify the study. Examples of prospective adaptation include sequential trial designs, interim analyses to apply predefined stopping rules for benefit, harm, or futility or for sample size re-estimation. Application of contemporary statistical techniques, such as conditional probabilities, allows for the prospective construction of boundaries as the basis for stopping rules, which may not only protect patient welfare but also spare the sponsor and patients further burdens when a trial is futile. *Ongoing or ad hoc adaptation* includes adjustment in the inclusion and exclusion criteria, dose or dosing regimen, and treatment or follow-up duration. These changes may introduce bias, inasmuch as the target population, the intervention itself, or both are altered by these modifications. Although statistical methods to account for these changes may help to preserve scientific validity, substantial changes in midstudy almost always introduce complications into the analysis and interpretation of study results. *Retrospective adaptive design* is the most flexible but also most vulnerable to bias and to undermining the validity of a trial. Examples of retrospective (but before unmasking) adaptation include changing the primary or other endpoints and changing the hypothesis from superiority to noninferiority, or vice versa.

Adaptive methods have been widely applied in the study of oncology but rarely in the study of heart failure. Because of the potential efficiency of these methods, however, they will probably be implemented in heart failure trials more frequently in the future. Some examples include adaptive randomization, adaptive hypotheses, and treatment switching, as well as some specific adaptive trial designs. In *adaptive randomization*, various methods can be used to adjust the probability that a subject will be randomly assigned to a specific condition of the trial according to some characteristic of the patients previously enrolled. This technique can balance variance within the enrolled population with regard to such things as investigational site or covariates such as comorbid conditions, age, and gender. For trials in which there are ethical concerns about the treatment conditions, adaptive randomization techniques can allocate patients to the most appropriate treatment groups on the basis of the response of prior patients.<sup>83</sup> These techniques have implications for subsequent hypothesis testing and sample size determination, but methods exist to adjust for these adaptations in randomization. *Adaptive hypotheses*, in which the hypothesis of the study is adapted to the evolving clinical picture, include the incorporation of data from other studies to guide the study under consideration, to include new dosages of the study treatment, or to make changes according to the recommendations of the DSMC.<sup>84</sup> Finally, adaptive techniques for evaluating *treatment switching* may also prove useful in future heart failure trials. This technique is particularly helpful in parallel-group active control studies, in which the patients are randomly assigned to either the active control condition or the study medication condition and are allowed to switch from one treatment to another for lack of response or evidence of disease progression.<sup>85,86</sup> Potential applications include AHF studies, in which the acuity and severity of symptoms preclude a true no-therapy control and many patients may switch conditions.

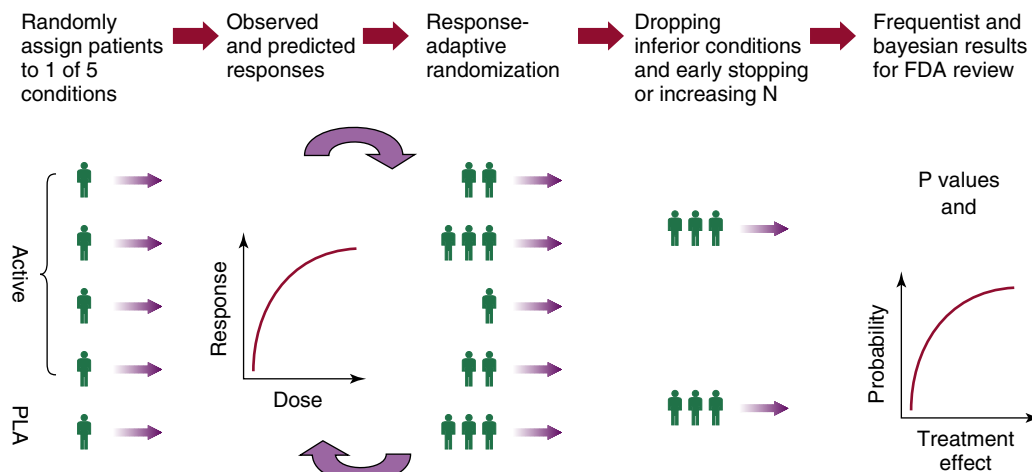

Various adaptive approaches to designing transitional studies of new heart failure therapies have also been used.<sup>87,88</sup> One design that is receiving increased consideration is the “drop-the-loser,” or select-drop, design for dose selection or multicondition phase III trials.<sup>89,90</sup> These designs were initially described in the context of cancer therapy studies and addressed the problem of how to select among multiple different treatment regimens varying in dosages and agents.<sup>91-93</sup> In this design, patients are randomly assigned to one of a few different treatment regimens or to a placebo/standard therapy control condition, and, often with the use of a combined endpoint, each group in which treatment fails in comparison with the control group is dropped sequentially until one regimen is selected. This endpoint can incorporate both efficacy measures and safety or adverse events as stopping rules for the groups. Multiple methods of adaptive allocation of patients in dose-escalation studies can also be used to minimize patients’ exposure to adverse effects while maximizing treatment with potentially efficacious doses. Two of these methods include the continued reassessment method<sup>94</sup> and a hybrid frequentist-bayesian approach.<sup>95</sup> Statistical methods for these sequential group designs have been developed,<sup>96</sup> and statistical research has incorporated bayesian analyses and decision theory.<sup>97-99</sup>

A significant potential limitation of applying this approach to dosage-finding studies is that relevant information about the agent being studied may be unavailable, inasmuch as each group is analyzed independently and so information on the overall pattern of dose-response may be lost. Some investigators have suggested using a prospectively planned combination of active groups for comparisons in transitional studies; others have sought to leverage the data from multiple-dosage groups by developing dose-response curves with regard to outcomes of interest in order

to select appropriate doses. However, the select-drop designs have the advantage of comparing many dosages through the use of clinical endpoints with the potential of producing more clinically relevant information while enrolling fewer patients. These advantages are most evident in trials that are designed to combine phases II and III studies. An example of the combined phase II/III design is the Platelet Glycoprotein IIb/IIIa in Unstable Angina: Receptor Suppression Using Integrilin Therapy (PURSUIT) trial,<sup>100,101</sup> in which a pre-specified interim analysis revealed no significant evidence of an unacceptable safety profile in the high-dose condition, and so the low-dose condition was dropped. The PURSUIT trial had positive efficacy results with the high-dose condition that ultimately led to FDA approval of the drug. A more recent example includes the Placebo-controlled Randomized study of the selective A1 adenosine receptor antagonist KW-3902 for patients hospitalized with acute HF and volume Overload to assess Treatment Effect on Congestion and renal function Trial (PROTECT) phase II/III program, consisting of two sequential studies of the effect of rolofylline in patients with AHF. The PROTECT pilot study<sup>34</sup> demonstrated improved clinical outcomes and provided crucial information for dosage selection and allowed for a relatively seamless transition to the phase III PROTECT trial.

The combined phase II/III trial design has a number of advantages, including continuous enrollment during both phases of the study with the consequent potential time efficiency and the ability to apply outcome data from the patients who were in the phase II stage of the trial to the phase III primary endpoint. In this combined design, however, it may be difficult to perform the study with more than three or four groups, which limits the ability to explore a full dose-response range. In addition, there is less flexibility in the assessment of secondary endpoints, the inclusion and exclusion criteria need to be broad enough for a large-scale phase III trial, and the procedures used to select the appropriate dosage may complicate the assessment of the primary endpoint. If safety assessments are used to guide the selection of the dosage, then the most effective dose may not be selected, whereas if the criteria for dose-selection in the transitional study stage include efficacy assessments, then the sample size of the whole trial needs to be increased, or an adjustment to the overall  $\alpha$  error must be made, or both. It is hoped that these and other newer approaches to the design of transitional clinical trials will help address the specific challenges in establishing proof of concept and selecting the dose for new therapeutic agents in heart failure.

Underlying many of these advances in adaptive design is the application of bayesian analysis.<sup>102</sup> Bayesian approaches differ fundamentally from traditional, frequentist methods. In the frequentist model, parameters must be viewed as fixed so that probabilities of experimental observations can be calculated. This model explains why changing trial design (or parameters of a study) poses such difficulties for frequentist analysis. As soon as parameters are changed, the basis for the statistical inference is undermined. However, in the bayesian approach, all components of the trial, all uncertainty, are measured by probabilities, calculated from the known factors in the trial. Thus, there is more flexibility in these approaches to adapt to changes in clinical trial design. The bayesian approach incorporates continuous updating of the models as information becomes available, but it can require significant computer power and complex mathematical models. The full potential of this statistical approach has not been realized in a clinical development program to date, but there is growing enthusiasm in the both the research community<sup>103</sup> and in regulatory agencies<sup>104,105</sup> for this model. Figure 39-5 provides an example of how a program might be designed to incorporate some of the novel approaches just described.<sup>106</sup>

**FIGURE 39-5** Example of an adaptive trial design involving the use of bayesian statistics. The trial starts as a dose-ranging study, in which four dose levels are compared with placebo; patients are enrolled on the basis of a response-adaptive randomization with an iterative interaction between the responses of those previously enrolled and the random assignment of new patients. As probability thresholds are crossed for selecting groups of different dose recipients, inferior doses are sequentially dropped, leaving the one dose for the phase III trial. The patients continue to be enrolled under the same protocol with whatever amendments are necessitated, and an interim analysis is performed to assess for early stopping or adjustment of sample size. After completion of the trial, frequentist analyses may be performed, but the evaluation by The European Agency for the Evaluation of Medicinal Products (EMA) or the U.S. Food and Drug Administration (FDA) will be based on a bayesian assessment of the totality of the clinical package. PLA, placebo. (Adapted from Chow SC, Chang M. Adaptive design methods in clinical trials—a review. *Orphanet J Rare Dis* 2008;3:11. Permission granted from BioMed central.)

## RANDOMIZED CONTROLLED TRIALS IN SPECIFIC CLINICAL SETTINGS

### Acute Decompensated Heart Failure

Although many of the factors just described are applicable to studies of AHF, AHF trials have specific challenges that are only becoming completely recognized and that have been the subject of extensive discussion in conferences since 2005.<sup>107,108</sup>

The population of patients with AHF is extraordinarily heterogeneous, and entry criteria for a trial must be defined by the mechanism of action of the study medication or device. First, the patient population must actually have AHF, as opposed to other conditions that may imitate AHF, such as an exacerbation of chronic obstructive pulmonary disease or acute coronary syndromes. Because heart failure has traditionally been a clinical diagnosis without clear objective diagnostic criteria, enrollment of “pure” AHF populations in clinical trials has been a major challenge. The use of biomarkers such as natriuretic peptides and troponins to identify patients with AHF and exclude patients with acute coronary syndromes has been a major advance in clinical trials of AHF.<sup>34</sup>

A second important issue in study design is the targeting of appropriate subgroups within the heterogeneous AHF population as a whole. Ideally, studies should target the patients most likely to benefit from a particular intervention and exclude those more likely to be harmed by it. Renal function and blood pressure are very important factors to consider in the selection of patients for given clinical trials. Patients with low blood pressures and those who experience hypotension during hospitalization have poor outcomes,<sup>109</sup> and so interventions with vasodilating properties should be restricted to patients with higher baseline blood pressures. Although researchers in many studies of vasodilating drugs may wish to avoid patients with renal dysfunction, therapies with putative renoprotective properties should target patients at high risk for worsening renal failure, typically patients who already have poor baseline renal function.<sup>34</sup> Enrolling all patients with acute heart failure rather than targeting therapy to a specific group on the basis of the mechanism of action of

the new therapy may be partially responsible for the failure of some AHF trials.

Study procedures in clinical trials of AHF therapies also have some unique aspects. First, because of the dynamic nature of an AHF clinical course, there are multiple distinct times and corresponding clinical conditions at which a patient may be enrolled.<sup>108</sup> During the initial or early-intervention phase, patients are more symptomatic and have received less potentially confounding therapy, which allows for optimal opportunity to demonstrate a symptomatic or other clinical benefit, but there is also greater diagnostic uncertainty. The advent of BNP assays has assisted in considerably limiting this uncertainty, and an emphasis on the early involvement of emergency department personnel has enabled early enrollment in some contemporary trials, with encouraging results.<sup>34</sup> Some agents may be more suitable for treating the patient during the in-hospital phase, in which the goals of therapy are to promote further improvement in the signs and symptoms of AHF, whereas other agents may be more useful in the pre-discharge phase. One study of tolvaptan included patients from all phases of the hospitalization, leveraging the availability of an oral formulation.<sup>110,111</sup> A second issue is the challenge of background therapy in AHF trials. Because no therapy for AHF is currently evidence based, background therapy may vary widely between patients, thereby complicating interpretation of the efficacy and safety of new therapies. Finally, defining the proper follow-up period for acutely administered therapies is also a challenge. Most AHF therapies are given for short durations, often 24 to 72 hours, and so the best time interval over which to assess safety is unknown. In most studies, researchers examine events up to 180 days after randomization, although both investigators and regulators acknowledge that most therapies would probably not continue to have safety effects this remotely. Fortunately, most AHF studies do not have to face difficulties of adherence.

Endpoint selection for AHF studies remains a major challenge in clinical trial design and has been reviewed in detail.<sup>111a</sup> Traditionally, many drug development programs have used demonstration of a hemodynamic benefit as support for efficacy of the therapy; such drugs include nesiritide,<sup>112</sup> levosimendan,<sup>113</sup> and tezosentan.<sup>114</sup> However, there is considerable regulatory skepticism about the ability of improvements in hemodynamics to translate into improved

clinical outcomes, and hemodynamics alone are no longer considered a valid endpoint in AHF studies. Although mortality is of unequivocal importance, many investigators have questioned the likelihood that a 24-hour infusion of an intravenous therapy could have a significant effect after discharge. This has led to a focus on morbidity (e.g., rehospitalization) or symptomatic endpoints (e.g., dyspnea) and has resulted in a disparate array of endpoints and composites that have been used in published phase III clinical trials in AHF (Table 39-2).<sup>34,36,37,110-112,115-118</sup> These can be classified as short-term symptomatic endpoints (e.g., dyspnea improvement), endpoints reflecting events during the index hospitalization (e.g., worsening heart failure that necessitates rescue therapy), or postdischarge endpoints (e.g., death or rehospitalization).

One of the most prominent symptoms that patients report is dyspnea, and dyspnea has been evaluated in many studies as a secondary endpoint; in the pivotal Vasodilatation in the Management of Acute CHF (VMAC) trial, dyspnea was assessed as a coprimary endpoint with change in pulmonary capillary wedge pressure.<sup>112</sup> However, dyspnea is very difficult to evaluate as an endpoint, especially when confounded by the presence of invasive hemodynamics, as in those trials.<sup>119</sup> The Randomized Interventions with Tezosentan (RITZ-1)<sup>120</sup> and Value of Endothelin Receptor Inhibition with Tezosentan in Acute Heart Failure Study (VERITAS)<sup>115</sup> were the first AHF trials in which a symptom (dyspnea) was used as endpoint without the confounding effects of invasive hemodynamics. There are two main instruments for assessing changes in dyspnea. A Likert scale, on which the patient reports a relative change from baseline symptoms with categorical statements ranging from “markedly improved” to “markedly worsened,” is very useful for assessing rapid changes in dyspnea, but the patient must compare current symptoms with those at a previous time, such as when study therapy was initiated. On the Visual Analog Scale (VAS), the patient rates the absolute current level of dyspnea on a scale from 0 to 100 at specific times, which allows comparative assessments over longer time scales. Other approaches to the assessment of dyspnea have also been proposed in an effort to provide more objective evaluations of this important subjective symptom.<sup>31</sup>

Recognizing the subjective nature of the dyspnea assessments and their inability to capture the entirety of a patient’s response to a therapy, other investigators have developed composite endpoints. In the Second Randomized Multicenter Evaluation of Intravenous Levosimendan Efficacy (REVIVE-II),<sup>117</sup> the patient-reported global assessment had to be moderately or markedly improved at 6 hours, at 24 hours, and at 5 days without evidence of clinical deterioration, for the patient’s condition to be considered “improved,” whereas evidence of worsening of heart failure or death categorized the patient’s condition as “worsened”; those meeting none of these criteria were considered “unchanged.” This categorical variable was based on an endpoint developed for chronic heart failure studies.<sup>33</sup> To evaluate the efficacy and safety of newer agents, other clinical development programs are extending this approach to include such effects as worsening of renal function in phase II and phase III trials. As discussed previously, the advantages of using composite endpoints are that the totality of the patient experience can be evaluated and the event rate is increased, but the disadvantage is that they limit differentiation of the severity of events, so that death is weighted similarly to worsening of heart failure. Other approaches, such as a global ranking method, may address some of these challenges in future AHF trials.<sup>35</sup> In general, it seems unlikely that any single endpoint will effectively capture all aspects of the AHF clinical course, and thus it is unlikely that one endpoint will fit all types of RCTs for AHF. This area of clinical trial design for AHF is a topic of very

active debate, and many currently ongoing trials will inform the next generation of studies.

## Clinical Trials with Devices and Surgery

Device-based and surgical therapies for heart failure have proliferated since 2000. Indeed, the majority of advances in heart failure therapeutics have been driven by devices (e.g., ICDs, CRT, and left ventricular assist devices [LVADs]) rather than by new pharmacological therapies. In comparison with traditional RCTs of new drug therapies, the appropriate evaluation of new devices and surgical techniques presents substantial challenges. In particular, issues related to the technical aspects of the procedure, the more pronounced placebo effect, masking and endpoint selection may be uniquely difficult.

One unique challenge of device and surgical trials that is absent from trials of drugs is the extent to which variations in operator technical skill may affect the efficacy and safety of the therapy. Unlike studies of pharmacological therapies, clinical trials of surgical interventions or devices must account for operator skill level and incorporate an assessment of technical success into study design. “Technical success” itself may be quantified, depending on the intervention. For example, in a study of CRT, successful placement of the lead for the coronary sinus can be reasonably assumed to lead to successful delivery of therapy, and this success can be reliably judged at the time of the procedure. More complicated surgical procedures, such as mitral valve repair or surgical ventricular restoration, are likely to have many more gradations of “technical success,” and efficacy may be influenced by small differences in technique that are not readily quantifiable and may not be apparent at the time of the intervention. Various strategies exist for dealing with issues of operator skill level and procedural success. One option, which was used in the MIRACLE study of CRT, is a pilot phase in which operators demonstrate a basic level of technical expertise before being permitted to enroll patients in main trial.<sup>48</sup> Once a procedure is more clinically established (e.g., coronary artery bypass grafting), formal testing of operator skills may be unnecessary, but procedural success rates should be carefully tracked during the course of the trial to the extent possible. For trials of interventions that require a high degree of technical skill, investigators frequently select sites with extensive prior experience and skill (“expert sites”). Although such a strategy may provide the most rigorous evaluation of the efficacy of the procedure or device to be tested, it does raise the issue of generalizability of the results in clinical practice with less experienced operators. This contrast between “efficacy” (the ability of a therapy to improve outcomes in a carefully controlled clinical trial context) and effectiveness (the ability of a therapy to improve outcomes when implemented into broader clinical practice) has been demonstrated for several procedures, most recently with surgical ventricular restoration procedures, in which excellent results demonstrated by expert operators have not been replicated in broader clinical practice.<sup>121,122</sup>

Another issue closely related to the issue of technical success is applying the principle of intention-to-treat analysis in trials of device or surgical interventions. Although it may be appropriate in the initial development of new devices or procedures (i.e., proof of concept) to randomly assign only patients in whom the device implantation is successful (as was done in the MIRACLE study and the Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure [COMPASS] study<sup>48,123</sup>), it is important to recognize that such a design does not fully account for the risks of a given intervention in comparison with usual care. Outside of research trials, patients who undergo a procedure that is not technically successful are exposed to the procedural risks

**TABLE 39–2 Selected Large Phase II and III Acute Heart Failure Trials and Their Endpoints**

Study	Year of Publication	Intervention	Primary Endpoint(s)	Key Secondary Endpoints	Long-Term Clinical Outcomes
Vasodilation in the Management of Acute CHF (VMAC) <sup>112</sup>	2002	48-Hour nesiritide infusion vs. nitroglycerine infusion vs. placebo	Coprimary: <ul style="list-style-type: none"> <li>• <math>\Delta</math> PCWP at 3 hours</li> <li>• <math>\Delta</math> Dyspnea (Likert) at 3 hours</li> </ul>	<ul style="list-style-type: none"> <li>• PCWP at 24 hours</li> <li>• Dyspnea at 24 and 48 hours</li> <li>• Global clinical status</li> </ul>	Tertiary endpoints: <ul style="list-style-type: none"> <li>• 48-hour hypotension, headaches</li> <li>• 30-day mortality, myocardial infarction, readmission, and renal dysfunction</li> <li>• 6-month mortality (not powered for definitive analysis)</li> </ul>
Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) <sup>36</sup>	2002	48-Hour milrinone infusion vs. placebo	Cumulative days of hospitalization for cardiovascular cause or number of days at death within 60 days after random assignment	<ul style="list-style-type: none"> <li>• Proportion of cases failing therapy because of adverse events or worsening heart failure (sustained SBP &lt; 80 mm Hg, myocardial ischemia, arrhythmias, persistent CHF, inadequate diuresis, organ hypoperfusion)</li> <li>• Heart failure score</li> <li>• Global health (VAS)</li> </ul>	Primary endpoint
Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) <sup>37</sup>	2005	Therapy guided by pulmonary artery catheter plus clinical assessment vs. clinical assessment alone	Days alive and out of hospital during the first 6 months	<ul style="list-style-type: none"> <li>• Adverse events related to catheter use</li> <li>• 6-Minute walk duration</li> <li>• Quality of life vs. time trade-off</li> <li>• MLHF</li> </ul>	Primary endpoint

with none of the putative benefits. It is important, therefore, that more definitive trials of new devices or surgical procedures include in the analysis all patients randomly assigned to receive the intervention (intention-to-treat analysis), even if the procedure could not be completed.<sup>55</sup>

Two other major challenges for device and surgical trials are controlling for the placebo effect and masking. There is a significant literature on the increasing magnitude of a placebo effect as it relates to the invasiveness of the therapy (e.g., placebo injections have a much greater treatment effect than do placebo pills).<sup>124</sup> The presence of a strong placebo effect has led to the use of sham procedures for controls, in which control patients undergo some aspects of the procedure to be tested (such as general anesthesia) but do not undergo the actual therapeutic intervention. In studies of implanted devices such as CRT devices, a common strategy is to implant the device in all patients but activate it only in the intervention recipients. For example, in the MIRACLE study, all patients received a CRT device but were randomly assigned to have the device activated or in backup pacing mode.<sup>48</sup> As noted previously for the intention-to-treat principle, such a strategy is useful for proof-of-concept studies but may be less valid in definitive outcome trials, inasmuch as it does not provide complete information about the relative risks and benefits in comparison to usual care (because all patients would be exposed to the risks of the device but only half the patients would be exposed to the benefits). For studies of interventions associated with substantial risk (such as cardiac surgery), random assignment to sham procedures has generally been considered unethical.

Masking of conditions for both patients and providers is considered a hallmark of robust clinical trial design and a solution to the issue of the placebo effect, but it may be impossible with some device or surgical interventions. In some device studies, such as MIRACLE, the researchers have attempted to maintain a double-blind situation by having a separate group of physicians manage the device without masking, whereas the overall care for the patient and assessment endpoints was provided in a blinded manner by the heart failure specialist. As a practical matter, some therapies, such as ventricular assist device therapy, are impossible to mask, a limitation which may be addressed in part by careful selection of the study endpoints and the use of endpoint committees that are unaware of patients' conditions to adjudicate events.<sup>125</sup>

In view of these challenges, careful selection of the primary study endpoint is crucial for the success of trials of surgical and device-based therapy. Use of the most objective possible endpoint (e.g., mortality or mortality plus hospitalizations) is obviously preferable in order to minimize the biases introduced by incomplete masking and the placebo effect. For example, in the COMPANION study, a primary endpoint was the composite of all-cause mortality and all-cause hospitalizations, which was considered robust and less likely to be influenced by the device placebo effect and the lack of masking.<sup>55</sup> The absence of a sham-operated control group and the lack of masking were unavoidable in the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) and were addressed by selecting the most objective endpoint possible: all-cause mortality.<sup>125</sup>

Because the very poor prognosis in end-stage heart failure, the REMATCH study was able to demonstrate a substantial treatment effect on all-cause mortality despite a small sample size. When design considerations make such “hard” clinical endpoints impractical, more objectively measured endpoints (e.g., peak ventilatory oxygen uptake [VO<sub>2</sub>], left ventricular dimensions) should generally be preferred over more subjective ones (NYHA class, quality of life) in order to minimize the extent of the placebo effect and the effect of the lack of masking.

A specific challenge of device-based therapies, such as therapy with mechanical cardiac support devices, concerns how to best assess incremental changes in technology (e.g., improvements in pump design). In contrast to drugs, improvements in device technology tend to be small and incremental, and it is often impractical to perform a new RCT to compare each new improvement to standard therapy. This creates a tension between the desire to introduce new device improvements into clinical use and the need to rigorously evaluate their efficacy and safety. In the case of mechanical cardiac support devices such as LVADs, a variety of alternative approaches to a traditional RCT have been proposed for dealing with this problem, including the use of concurrent non-randomly assigned controls and hybrid designs incorporating both randomly assigned and historical controls (Figure 39-6).<sup>126</sup> The advent of the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS), an ongoing registry of patients who have received destination LVAD therapy in the United States, may help establish appropriate benchmarks that may help to serve as concurrent controls for new devices.

## Clinical Trials of Monitoring Tools and Strategies

In addition to the ongoing development of new therapies, developments in both genomics and device technology have resulted in an increasing array of monitoring tools (both molecular and device based) with potential to improve the diagnosis and treatment of heart failure. Although such diagnostic tools have traditionally been held to a lower regulatory standard of evidence (e.g., simply establishing that they can accurately measure what they claim to measure) than have therapeutic interventions, such tools should ideally undergo the same rigorous evaluation for safety and efficacy before being adopted into clinical practice. There has been an increasing trend toward using RCTs to carefully evaluate monitoring strategies. Trials of such diagnostic tools present specific challenges in terms of trial design that are discussed in detail as follows.

For a diagnostic or monitoring device to be clinically useful, it must meet all of several criteria. Fundamentally, a device must be able to make measurements that are accurate, are reproducible, and can be delivered to clinicians in a timely and understandable manner. Although necessary, this criterion is not sufficient; for a diagnostic device to be of proven clinical use, that information must be actionable in a way that can be demonstrated to improve patient outcomes. In clinical trials of monitoring strategies, researchers should therefore evaluate not only whether a monitoring tool can accurately measure something but also whether the knowledge of such data by clinicians leads to therapeutic decisions that improve patient outcomes. In this sense, monitoring trials help evaluate both the tool itself and the therapeutic strategy tied to this information.

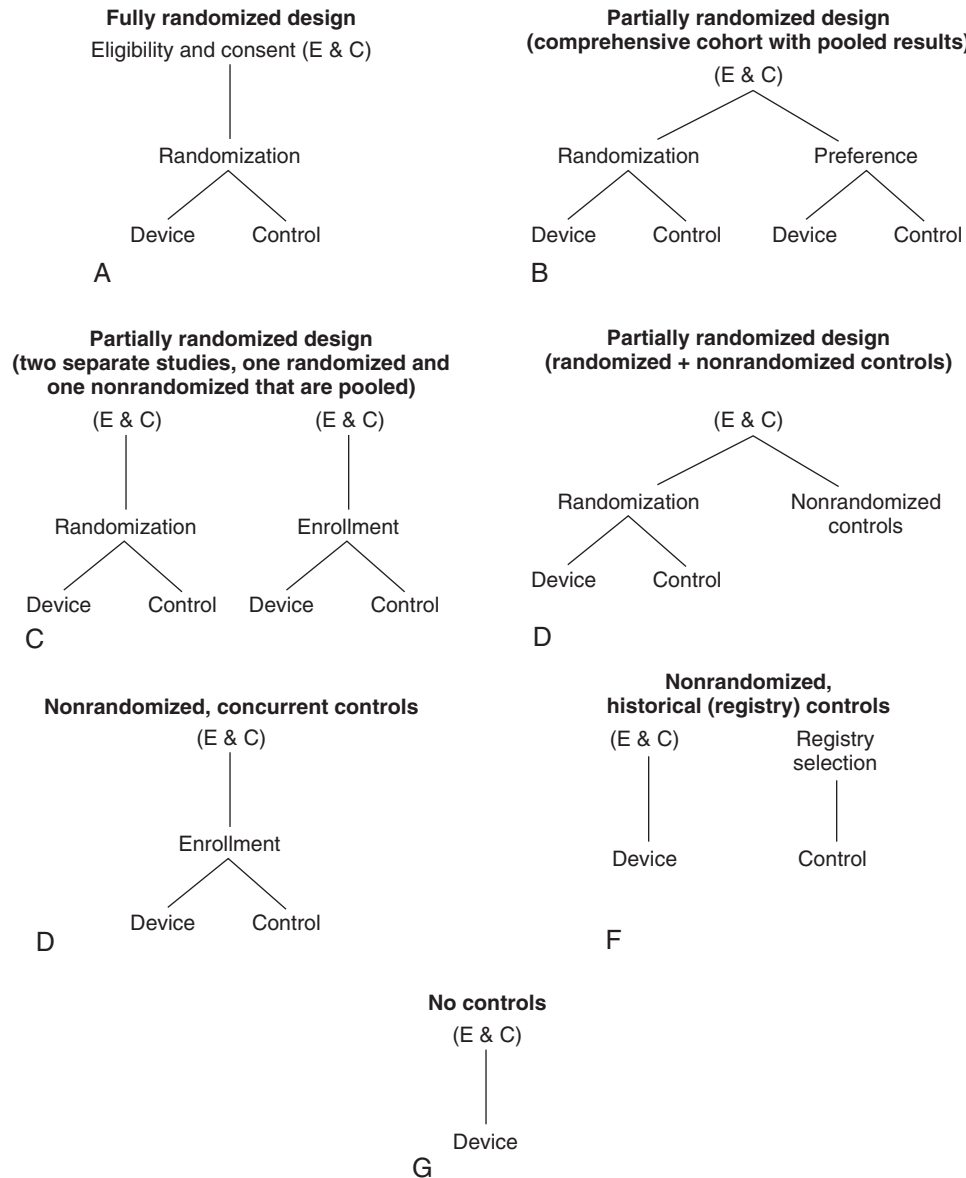

Numerous important clinical trials have been designed to rigorously evaluate a variety of monitoring devices and strategies, pulmonary artery catheters,<sup>37</sup> chronically implanted hemodynamic monitors,<sup>123</sup> serial measurements of biomarkers (such as natriuretic peptides),<sup>127</sup> or intensified disease management algorithms based on vital signs and weight.<sup>128</sup>

In general, study protocols have varied in the degree to which they have predetermined how investigators would change therapy according to the information provided. In ESCAPE, specific hemodynamic goals and guidelines for achieving them were defined by protocol for the intervention group.<sup>129</sup> In other trials, such as the Systolic Heart Failure Treatment Supported by BNP (STARS-BNP) study of BNP-guided therapy, interventions based on the provided diagnostic information were left to the discretion of individual physicians.<sup>127</sup> Both approaches have obvious advantages and disadvantages. Providing specific guidance limits variability (all investigators respond to the diagnostic information in a similar way) but also ties the efficacy of the monitoring device to a specific treatment paradigm, which creates the possibility that the monitoring device could be useful but the treatment algorithm could be incorrect. Conversely, by leaving clinical decisions solely to the individual investigator, the study is a more direct evaluation of the utility of the diagnostic information per se, but it also introduces substantial heterogeneity that may complicate analysis, particularly in smaller trials.

Particularly challenging in this type of trial are issues of appropriate control groups and masking. Ideally, the experience of control subjects in RCTs is identical to that of the intervention recipients, with the exception of the intervention itself. Monitoring trials present a significant challenge to this paradigm. For some interventions, such as pulmonary artery catheterization or an implanted diagnostic device such as the Medtronic Chronicle, the invasive nature of the monitoring tool itself is associated with specific risks that must be weighed in assessing the balance of risks and benefits. One method for dealing with this potential bias is to have both groups undergo placement of the monitoring device but provide the diagnostics information only to physicians of the intervention recipients. This approach allows for single-blind conditions (i.e., the patients do not know whether they are in the “guided” condition or not). As noted in the “Clinical Trials with Devices and Surgery” section, this approach addresses some problems but creates others. Although such a design provides a more rigorous evaluation of the utility of the diagnostic information provided, it does not address the overall balance of risks and benefits of the device, in particular if the device is invasive or if hospitalization is required for implantation. As an example, in the COMPASS trial, the Chronicle device was implanted in all study patients, but only patients in whom implantation was successful were randomly assigned to have the information from the device available to their physician (intervention group) or not (control group). Although such a design provides a rigorous evaluation of the utility of *information* from a diagnostic device, it does not elucidate the overall risks and benefits of a strategy based on implanting such a device and on using data generated from the device to guide therapy. To clarify this distinction, in COMPASS there were three patients who could not undergo the implantation and therefore were not randomly assigned, 277 elective hospitalizations for device implantation, and 15 hospitalizations for complications related to the device. A true evaluation of the overall safety and efficacy of a monitoring strategy based on an implanted device would have to “count” all adverse events related to the intervention.<sup>130</sup>

A related issue in all monitoring studies is the frequency of interaction with patients in the intervention group versus those in the control group. More frequent interaction with health care providers alone appears to decrease event rates in chronic heart failure,<sup>131</sup> which potentially confounds the extent to which any observed benefit is related to a greater frequency of health care interactions or to the monitoring tool itself. To improve the rigor of monitoring strategy studies, the intensity of follow-up between the intervention and control groups should generally be as identical as possible;

**FIGURE 39-6** Possible modifications of traditional design for randomized controlled trials of mechanical cardiac support devices. (Adapted from Neaton JD, Normand SL, Gelijns A, et al. Designs for mechanical circulatory support device studies. *J Card Failure* 2007;13:63-74.)

this may involve “sham” contacts. For example, in the COM-PASS trial, it was recognized that more frequent contact with intervention recipients might risk unmasking the condition to patients and might also have a more direct effect on outcomes; therefore, control patients received calls in a random schedule designed to match the frequency of contacts with the intervention recipients.<sup>123</sup>

## NEW DIRECTIONS

Best practices for RCTs in general continues to evolve, and improvement in clinical trial methodology and education is an important part of the National Institutes of Health Roadmap Initiative.<sup>132</sup> Interestingly, this has resulted in an increase in “meta-research”: that is, research into the methodology of research. In view of the extent to which cardiovascular medicine has been at the forefront of evidence-based medicine research, it is not surprising that cardiovascular trials will continue to drive innovation in the field of clinical trials. As described in this chapter, a variety of novel

developments—including greater use of adaptive designs, bayesian statistical methods, novel endpoints, and new operational structures such as clinical trials networks—will continue to alter the landscape of clinical trials in heart failure. Developments in pharmacogenomics will also have substantial effects on clinical trial methodology. The next steps in expanding the concepts of “personalized medicine” will be prospectively incorporating such genomic or phenotypic markers into inclusion and exclusion criteria rather than confining them to ancillary studies or retrospective analyses. The use of genetic polymorphisms to better target anticoagulation therapy with warfarin has also come into mainstream clinical practice and is now part of the FDA labeling for warfarin.<sup>133</sup> These types of “pharmacogenomic” indications for drugs will become more numerous and will create both substantial opportunities, as well as significant challenges, for both researchers and regulatory bodies. Clinical trial methodology will need to continue adapting to new scientific and regulatory developments, in order to continue providing a robust foundation of evidence to guide clinical practice and improve the care of patients with heart failure.

## Conclusion, 607

The rapid growth of medical knowledge since the 1970s has created many advances in the treatment of chronic illness, and the treatment of cardiovascular disease has been at the center of this advancement. Unfortunately, timely translation of this progress into everyday care of patients with cardiovascular disorders remains problematic. Development of practice guidelines has emerged as a major strategy for optimizing the use of new and existing therapeutic modalities of proven benefit. To be effective, these guidelines must not only clearly delineate which therapies are efficacious but also account for the many practical aspects necessary to fully implement specific treatments in the care of patients. When professional groups address these two issues, both the art and science of medicine can be employed to obtain better patient outcomes in cardiovascular diseases long associated with high mortality rates, severe morbidity, and poor quality of life.

This chapter describes in detail the theoretical aspects of guideline development and discusses how they have evolved since 1990. The principles and methods of guideline development, which are closely linked to the evidence-based medicine movement, continue to change as the discipline matures. In addition, the process by which these abstract principles and methods are applied to generate practice guidelines for a specific clinical problem, heart failure, is examined.<sup>1-10</sup> Review of key guidelines for heart failure illustrates the difficulties inherent in formulating a clinically useful document to translate new advances into standard care. The condition of heart failure—a complex syndrome with many clinical manifestations and therapeutic alternatives that vary from very well established to uncertain—is well suited for the guideline approach.

## RATIONALE FOR GUIDELINE DEVELOPMENT

### Justification

Many rationales can be presented to justify the development of clinical practice guidelines. Three particularly cogent arguments are as follows: (1) Medical knowledge

continues to accumulate at such a rapid pace that individual clinicians cannot readily and adequately synthesize the new information and adapt more effective strategies of care for the many diseases they confront in practice; (2) accepted standards for care are needed for even the simplest monitoring of practice to occur; and (3) translation of clinical trials into day-to-day practice is often difficult because of gaps in knowledge of how to apply therapies in actual practice. These three specific justifications for development of practice guidelines are discussed in detail as follows.

The rapid growth in medical knowledge, both physiological and therapeutic, is commonly acknowledged, but the effects of the this growth remain underappreciated. The constant appearance of new advances in medical knowledge has created the expectation that disease outcomes will improve not only in a commensurate way but also rapidly after research developments. Novel methods of care are developing simultaneously in many different fields, and so the burden of processing new medical knowledge has become immense. Individual practitioners cannot rapidly synthesize these developments into their daily practice unaided.

Frequently, guidelines are used as standards for quality or process control; this application has remained controversial for many health care providers. A more universally accepted rationale is that a practice guideline will accelerate and make more uniform the application of advances in medical care and thus improve health care delivery and outcomes. Substantial variation in medical practice for the same disease process in various geographic areas has long been recognized.<sup>11</sup> This variation may be somewhat justified on the basis of true regional differences in expression of a clinical condition. However, careful review of utilization data versus clinical profile suggests that much of the existing variation cannot be accounted for on this basis. Well-prepared guidelines offer an excellent basis for standards of care in the monitoring process.

Many clinicians believe that clinical trial results alone are sufficient to dictate practice standards and to provide adequate rationale

### BOX 40-1 Inherent Assumptions Underlying Practice Guidelines

Clinical decisions must be made.

- Lack of action is not an option
- Correct course of action is not readily apparent

There exists a reasonably valid method to address knowledge base and evaluate medical evidence.

There exist data beyond randomized clinical trials that enhance medical decision making.

Uncertainties remain with regard to approaches to treatment after review of totality of medical evidence. Expert opinion has a role in management decisions.

Experts with interest and commitment to the clinical problem and guideline process must be available.

and direction for implementing new therapies (see Chapter 39). However, as outlined in detail in this review, translating advances in medical knowledge into changes in clinical practice is quite complex for many conditions. Many considerations beyond interpretation of a particular clinical trial as positive or negative come into play. Practice guidelines offer one strategy to bridge the gap between clinical trial results and implementation of new therapeutic modalities in community practice.

### Inherent Assumptions

The creation of these position documents can be justified cogently; however, the feasibility of developing a valid and useful practice guideline depends on certain inherent assumptions that are often as much a belief system as verifiable facts (Box 40-1). Whether these assumptions are met or not depends on the clinical condition under consideration. Guidelines are most justified (1) when certain decisions clearly must be made about the specifics in the care of the patient and (2) when potential approaches to care are either certain (need widespread adoption) or uncertain (need clarification). Practice guidelines offer particular utility for disease processes that have serious consequences for individual and public health, in which failure to act has obvious consequences. There must be an acceptable method for evaluation of medical evidence related to the disease state. Data on therapeutic options should be more complex than rigorous clinical trials that are easy to interpret. Experts who focus on the study and care of the clinical problem and who can act with independent integrity must be available to execute the guideline process. These underlying assumptions appear to be valid for the syndrome of heart failure.

## ROLE OF EVIDENCE-BASED MEDICINE

Since 1990, evidence-based medicine has evolved as a significant alternative to traditional approaches to medical decision making and has become a critical underpinning of the methods for guideline development.<sup>12</sup> Traditional medical decision making certainly involves use of scientific principles, including the pathophysiological basis of disease, and integrates clinical experience with the results of clinical studies, especially randomized trials. Despite elements in common with evidence-based medicine, traditional approaches reach therapeutic decisions in a fundamentally different way, on the basis of evaluation of advantages and disadvantages in individual encounters with patients. Such ad hoc decision making does not arise from a plan considered in advance and is not a consequence of a predefined approach; instead, it occurs on spontaneously. In contrast, evidence-based medicine stresses the need for medical decisions to be based on

the best scientific data, particularly results from randomized controlled trials and systematic observational studies, which are typically beyond the individual physician's experience.<sup>13</sup> But where do clinical experience and the individual patient fit into the evidence-based medicine decision making? Interestingly, even cursory examination of key papers prepared during development of this discipline reveals the importance of applying the "best evidence" with regard to the peculiarities and particulars of the individual case.<sup>14,15</sup> Perhaps the best way to resolve this apparent fusion of two contradictory approaches is to recognize that medicine is an applied science rather than a natural science.<sup>16,17</sup> The understanding of medical heuristics remains incomplete and must advance only if decisions about care are to be optimized.<sup>18</sup>

Evidence-based medicine has been linked to guideline development from the beginning of this discipline, inasmuch as the principles of this approach apply not only to the actions of individual physicians but also to the creation of practice policies or codified documents to define patient management.<sup>19</sup> Archie Cochrane, among many other authors, recognized that formal methods were needed to evaluate multiple studies of the same medical problem.<sup>20</sup> Systematic reviews complement practice guidelines and represent another important aspect of evidence-based medicine.<sup>21</sup> As expected, the emphasis of evidence-based medicine on objective analysis of randomized clinical trial results and on general adherence to formalized methods has created conflict concerning the quality of practice guidelines that have been developed.<sup>22,23</sup> A detailed discussion of the nature of medical evidence is presented later in this chapter; debate rages concerning the relative value and, even for some clinicians, the usefulness of certain forms of medical evidence. Traditional approaches depend heavily on observational data that have tainted this form of evidence for many clinicians. A major conceptual point concerns specifying the nature of observational or nonrandomized data that are evaluated. Traditionally, decision making depends heavily on personal observational data that are rarely collected systematically or by a prospective method, are not subject to rigorous statistical analysis guided by prespecified goals, and are not replicated in any formal way. If rigorous methods are applied in the collection of observational data, however, substantial information can be obtained about drug efficacy, and the results of randomized and nonrandomized approaches are often complementary and additive to use of therapies in real patients.<sup>24-29</sup> The concepts of a practical clinical trial and restricted cohort design provide novel examples of bridging design methods that can advance the discipline of evidence-based medicine.<sup>30-33</sup> Guideline-creating bodies continue to address potential methodological issues and effectively voice counterarguments in seeking to balance the inherent tensions and conflicts described previously.<sup>34,35</sup>

## PROCESS OF GUIDELINE DEVELOPMENT

### The Role of Experts

Guidelines are developed by groups of committed individuals judged to be experts on a particular clinical problem; that is, they have special skill and knowledge gained from training and experience related to the clinical focus of guideline development. Experts are identified on the basis of visible accomplishments, such as publication of clinical and research activities linked to broad clinical experience.

Experts on a panel influence every aspect of guideline development. Some of their key roles include defining the clinical focus of the guideline, delineating the specific evidence to be considered, providing access to key data that may not be published or fully reported, creating a synthesis of the

available evidence, developing a hierarchy of and weighing the evidence gathered, and determining the strength of recommendations made in the guideline.

Experts must define the scope of the clinical problem to be studied according to their clinical experience and their sense of the important aspects of the problem. Experts guarantee access to the broadest possible knowledge base. Medical evidence published from a variety of sources is frequently incomplete. Negative results of clinical trials might not be written in manuscript form or accepted, especially in a timely manner, even if they are prepared for publication. Details concerning important negative findings may be available only through experts. In some instances, critical aspects of important clinical trials are not adequately represented in trial publications. Access to this information may be limited to opinion leaders.

Experts synthesize the available evidence in a way that cannot be done by nonexperts. They evaluate the biological plausibility of a particular therapy. Biological plausibility is an important determinant of the ultimate weight of evidence or strength of conclusion for a particular therapeutic strategy. Although drug efficacy for cardiovascular disease is commonly not understood precisely, a therapy grounded in well-established basic pathophysiological theory is accorded more support. Expert opinion must particularly address gaps in therapeutic evidence, because for many important aspects of patient care, even cohort data are unavailable. Evidence from properly constructed expert opinion is indispensable in translating scientific evidence into actual clinical practice. Experts are responsible for the tone and effect of the final guideline document. Their ability to create a cogent, literate, user-friendly publication with practicality based on a sound science foundation is crucial.

## Overview of Guideline Development

Numerous steps are involved in the development and implementation of a practice guideline (Box 40-2). Key points in this process are discussed as follows both as abstract concepts and through concrete examples from experience gained in the development of the Heart Failure Society of America (HFSA) practice guideline<sup>7</sup>.

The initial step is to define the scope of the specific clinical problem. This first part of the process is typically problematic, and its successful completion should be the initial goal of the guideline group. For example, heart failure is a syndrome with a number of distinct clinical manifestations and pathophysiological processes that necessitate many different treatment strategies that are established in varying degrees. The resources at hand, adequacy of evidence for specific aspects of the disease process, and likelihood of developing a consensus may determine the scope of the guideline. The initial HFSA guideline, published in 1999, had a narrow focus concentrating on the pharmacological treatment

of chronic, symptomatic left ventricular dysfunction. Other distinct subsets of the clinical syndrome of heart failure (i.e. acute, decompensated heart failure and “diastolic dysfunction”) were not considered. After this first effort, the HFSA completed development of a second, comprehensive practice guideline that included most aspects of heart failure and was published in 2006. Guideline content evolves when the commissioning body is a society, and this continuity and progression are strengths of practice guidelines developed by such groups.

The second essential step in guideline development is to identify the key evidence to be considered in formulating the document. In the case of the HFSA guideline, this process was heavily dependent on the committee members involved. Other guideline groups have been more complex, consisting of committee members teamed with a research staff to ensure that a more formal and systematic review of all available evidence is produced.<sup>36</sup> Systematic efforts help ensure the completeness and adequacy of the review process. Systematic reviews can be a costly process and are probably best targeted at specific areas with particularly rich or complex data. Dedicated research staff associated with the committee or contract research organizations are generally essential to the systematic review process. However, the responsibility for interpreting the results of any systematic review rests ultimately on the clinical experts commissioned to develop the guideline.

The third step involves establishing a strategy for evaluating the medical knowledge concerning treatments and care plans that may be applied to a particular condition. Substantial effort has been expended to define the role that particular types of evidence should play and to establish rules to assess the quality of available evidence.

The fourth step of guideline development concerns the process of writing and reviewing the guideline before its acceptance by the commissioning body. The development of a written document is the essential part of this phase. It provides a mechanism for precision of thought and a means to elicit careful review, criticism, and refinement of controversial and problematic issues. Ideally, during this important phase, exchanges among reviewers in a point and counterpoint process can be applied to specific aspects of the guideline to further clarify and enhance the final document. Style and language concerning specific recommendations must be consistent. This aspect of the guideline process is labor intensive, inasmuch as the writing process is difficult and should be done by the health care experts on the guideline committee or writing group.

Robust internal and external reviews during finalization of the practice guideline are crucial as well. Reviewers can be external to the committee or organization, and their comments can be assimilated to a variable extent. These reviewers offer fresh perspectives and added expertise to the developmental process. Different perspectives usually provide balance and focus to the effort. In the HFSA guideline process, the organization's executive council served as the primary reviewers (Figure 40-1). This allowed integration of a substantial amount of additional expertise and experience into the final guideline. However, reviews confined within the organization commissioning the guideline may have certain limitations related to biases of the group. Both internal organizational review and the different medical perspectives of outside experts constitute the best approach.

The fifth step in guideline development and implementation is dissemination of the document. Many avenues are available, and media exposure should be diverse. Comprehensive guidelines are typically lengthy in full format but can be condensed to a series of pocket cards and made available online by hypertext links from recommendations to background sections in order to furnish more detail and reference materials. Web-based documents that can be downloaded to portable computing devices have become popular; they

### BOX 40-2 Steps in the Development of a Practice Guideline

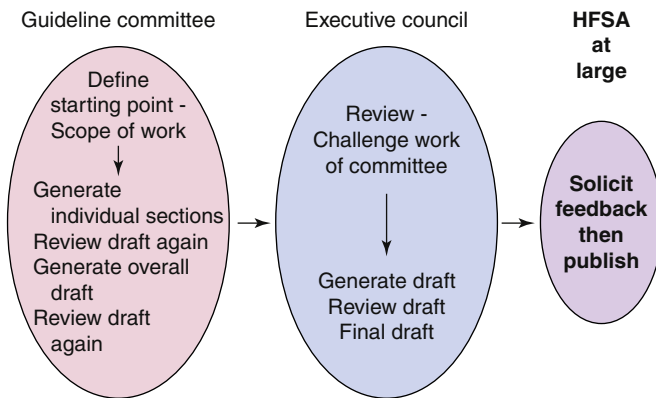

- Determining the scope of the practice guideline
- Identification of the medical evidence relevant to the guideline
- Specifying type of evidence and relative weight of evidence
- Formulating strength of evidence in recommendations
- Establishing therapeutic justification for recommended therapies
- Formulating strength of recommendations for specific therapies
- Creation of document, including establishment of structure
- Developing a review process for the document
- Dissemination of the practice guideline
- Determining the life cycle of the document

## Development of HFSA Guide

Proposed as an annual process

**FIGURE 40-1** The series of steps involved in the development and review of the practice guideline produced by the Heart Failure Society of America (HFSA). Two unique features of this guideline process were the active involvement of the executive council of the society and the relative lack of external review.

present the opportunity for point-of-care use, and they ease the search for specific information.

Another important aspect of the guideline development process focuses on minimizing the impact that conflicts of interest may have on the formation of the guideline document. Although conflicts of interest rightly focused on financial issues, they may arise for many reasons and should include any type of individual bias that will render unobjective the evaluation of medical evidence or declaration of recommendations. Information concerning sources of support, whether personal or for research purposes, should be collected periodically during the development process and available for scrutiny after publication of the document. The individual members of the guideline group should be the most aware of potential conflicts and should recuse themselves from aspects of the guideline development in which they believe they may be biased. Presence of some degree of conflict of interest is inevitable because of the necessary composition of guideline groups. Prospective recognition and awareness of the potential for conflicts of interest is critical.

The final step of guideline development concerns the life cycle of the document produced. In most instances, it is advantageous to have the guideline evolve as a “living” document, of which subsequent revisions are based on new advances in knowledge and on responses from practitioners who attempt to use the guideline in everyday practice. For example, because of new knowledge about heart failure from ongoing randomized clinical trials and other research, information about new advances must be incorporated into guideline documents. Even a yearly review of critical aspects of the heart failure guideline is not unrealistic, in view of the pace of new advances. Development of a “living” document has clearly become a major goal for the societies formulating heart failure guidelines, but substantial commitment by society members is necessary to sustain it.

## APPROACHES TO MEDICAL EVIDENCE

Review of medical evidence is naturally the most essential process in guideline development; it ensures that accurate and useful recommendations concerning the efficacy and use of particular treatment strategies are formulated<sup>37,38</sup> (Box 40-3). Ongoing efforts aim to improve this process by

- Dosing
- Monitoring for side effects and efficacy
- Duration of therapy
- Adjustment of concomitant prescriptions

iterative experience with guideline formulation and better definition of key aspects.<sup>39-41</sup> This complex process can be subdivided into a series of critical elements: (1) the method for identifying key evidence and determining types and strengths of evidence of interest, (2) evaluation of the scientific validity of each piece of evidence reviewed, and (3) construction of a strategy for weighing the different types of evidence to reach a conclusion or recommendation in favor of or against a particular therapeutic intervention. These three major milestones are discussed in detail as follows so that the nuances inherent in this part of the guideline process can be better understood.

## Identification of Evidence

A variety of techniques are used to identify the key medical evidence to be reviewed in the guideline process. The widespread availability of computerized databases of medical literature (e.g., PubMed) that can be searched in an organized manner has facilitated this process. Literature searches are designed to identify key articles or reports through the use of appropriate search terms. Other methods to identify evidence, however, are essential to complement this process. Reviews of references compiled for key articles or reports of trials and other clinical research may be additional sources of evidence. Members of the guideline writing group should review results of searches performed and provide input, because they may be aware of additional important references.

### Types of Evidence

Some details concerning the specific types of evidence applicable to the development of practice guidelines and the assignment of relative merit for this evidence are of interest (Table 40-1). Evidence derived from cohort studies is increasingly consulted in guideline development, because the accumulation of clinical trial data enables guideline committees to address issues important in practice, rather than the primary focus of the trial work. Cohort studies consist of both prospective and retrospective subgroup analyses of clinical trials, case-control or propensity analyses in which matched subsets of trial populations are used, and analyses of dose-response studies that may involve all or a portion of the clinical trial population. This type of evidence has well-recognized

**TABLE 40-1** Relative Weight of Evidence Used to Develop Practice Guidelines

Category	Types of Evidence (Highest to Lowest)
Category A	Randomized controlled clinical trials
Category B	Cohort and case-control studies Post hoc analysis, subgroup analysis, and meta-analysis
Category C	Expert opinion: <ul style="list-style-type: none"> <li>• Observational studies and epidemiological findings</li> <li>• Registry studies</li> <li>• Safety reporting from large-scale use in practice</li> </ul>

inherent limitations. Studies of this type are usually post hoc in nature and involve subgroups of the study population that were not created by a random process. Whenever possible, these analyses should be based on pre hoc hypotheses. Prospective stratification of the randomization process may be included to help provide balance for anticipated subgroup comparisons or to avoid bias in the comparison of therapy. Often a series of subgroup analyses are performed; this raises the potential for a chance finding that results from errors that arise from multiple hypothesis testing. In addition, there are often issues related to the power of such studies to detect treatment differences and to the generalizability of any positive or negative results. Despite these limitations, studies in this category often have a significant influence on guideline development because they address issues of great clinical importance that frequently cannot be resolved on the basis of classical randomized clinical trial data. Rather than relying solely on expert opinion, guideline developers can use cohort analyses as a formalized way to address some of these issues.

Observational evidence may take the form of epidemiological studies or expert opinion. Epidemiological studies by definition cannot establish the relationship between a particular treatment and any beneficial or detrimental effects. However, these studies can suggest the strength of association between a specific treatment and important clinical outcomes (see also Chapter 22). Expert opinion, discussed later in this chapter, is another form of observational data that makes up the body of evidence considered in the guideline process. It is typically a critical part of any guideline that has merit in clinical practice. The guideline document should clearly identify the nature of the evidence for specific recommendations, so that those areas covered by expert opinion can be clearly identified.

### Strength of Evidence

The practice guideline document should indicate the strength of evidence for each specific recommendation through the use of a grading system similar to that shown in Table 40-1. This allows practitioners to better understand the nature of the evidence that underlies particular recommendations. Precise characterization of strength of evidence is classified by expert analysis and varies to some extent between guidelines. Some practice guidelines are more conservative with regard to criteria to qualify evidence most highly (strength of evidence level A in Table 40-1); at least two positive clinical trials are necessary to achieve this level of evidence. As experience with the application of guidelines accumulates, it will be clearer whether the current system is accurate in predicting long-term trends in accepted therapy and new knowledge about treatments.

## Interpretation of Randomized Clinical Trials

Much effort has been expended in the development of specific criteria by which randomized trials should be evaluated. How trials are reported must be reviewed in detail. Was the

design of the trial reported prospectively? Are the statistical methods fully detailed, and were they followed in the analysis of the trial data? Were the key data revealed in the primary or pivotal report of the trial results?

### Issues Specific to Statistical Analysis

A full description of issues related to statistical analysis of clinical trial data is beyond the scope of this chapter. However, several points seem to arise frequently when data from specific trials are used for guideline development. A key question is whether a trial met its primary endpoint. Positivity, as defined in the analytical plan for the study, should be determined clearly from the study report. Although controversy may arise over the mathematical definition of statistical significance, the clinical trial design should allow ready determination of the primary endpoint and the significance level specified for achievement of the primary endpoint. Some heart failure trials have featured multiple primary endpoints, identified either prospectively or retrospectively. Multiple primary endpoints require some decision about the distribution of the probability values necessary to minimize type I or  $\alpha$  error at the level of  $P < .05$ .

Another important concern is the interpretation of results concerning secondary endpoints, such as hospitalization for worsening heart failure. These are often of significant interest, as in the case of the prevention condition of the Studies of Left Ventricular Dysfunction (SOLVD) trial, and are translated into guideline recommendations even though the primary endpoint of the trial was not met. Consistency of favorable results for secondary endpoints is important as well. For instance, the total number of hospitalizations may be unaffected or increased, whereas heart failure–related hospitalizations are reduced.

### Limitations of Positive Randomized Clinical Trials

Aspects other than the dichotomous outcome of a study must be considered when results from a particular clinical trial are used in everyday practice. Two important aspects to consider are the sample size and the generalizability of the study findings.

Large-scale clinical trials with many events generally provide the most accurate evidence for guideline development, especially for evaluating the effect of therapies on endpoints such as mortality and morbidity. Studies whose designs require a specified number of events, rather than achievement of a prespecified sample size that is based on estimates of event rates, are more likely to achieve this aim. Numerous small to moderate-sized heart failure trials have yielded findings that have not been replicated by additional larger studies. Various explanations have been offered for this failure to replicate initial studies. These explanations, however, have essentially reinforced the concept that a large number of events in patients with heart failure are necessary to ensure that a positive finding on mortality and morbidity endpoints is not spurious.

Clinical trials always involve selected patients from within a population with the diagnosis of a particular disease or syndrome. Selection bias takes many forms and may significantly restrict the implications of positive trial results. Inclusion and exclusion criteria may result in too narrow a study population to have wide clinical applicability. Although the screening process is generally not well reported, it is important to review what was used to obtain the population studied, as well as the inclusion and exclusion criteria. Requirements for a certain degree of illness or the absence of specific comorbid factors are typical and may restrict application of the trial results. The monitoring process necessary to ensure safety is another aspect that may influence generalizability of the study results. Because of concerns about generalizability despite positivity of specific trial results,

restrictions may be placed on the recommendations given in the practice guideline.

## Weighing the Evidence: Hierarchy of Relative Value

Traditionally, the process of weighing the evidence begins with the development of a hierarchy concerning the scientific validity and value of different types of medical evidence. This allows the objective assessment of the relative weight of arguments for and against a particular treatment.<sup>42</sup> Results of randomized clinical trials continue to be accorded the highest rating among the types of evidence available. However, the known limitations of results from clinical trials and the value of other types of evidence have caused guideline development to engage in a much more complex process concerning the evaluation of medical evidence. This process is probably best described as an integration of many types of evidence, including expert opinion that results in formulation of a consensus in support of or against particular therapies or management strategies.

### Expert Opinion as Evidence

The value of expert opinion of evidence useful in guideline development remains a point of controversy. For critics, expert opinion is simply another form of observational evidence derived from clinical work in day-to-day patient care. This experience is subject to the known biases and limitations of experience of individual practitioners caring for a small number of patients in a specific practice setting. For proponents of expert opinion, this type of evidence represents the expert's complex synthesis of disease pathophysiology, direct study of patients, and interchange of experience and ideas with colleagues. Ideally, the nature of the patient care experience for most experts should be fundamentally different from that of individual practitioners in most care settings. Clinical experts should have substantial experience, derived from direct care for many patients, that is the focus of the practice guideline under development. In addition, as thought or opinion leaders, they should also be exposed to the experiences of many practitioners in a variety of practice settings. Through contact with numerous health care providers who may refer or discuss patients' cases with them, experts can encounter rare safety issues and assess efficacy of particular treatments across a very wide spectrum of cases.

The guideline process requires a team of experts acting in concert, not a series of isolated individuals. At best, expert opinion is built up from the experience of many experts involved in development of the guideline. When committee members work together, their collective experience is stronger than that of an individual practitioner. When the composite experience of experts consistently either does or does not favor a particular therapy, the evidence is heavily weighted.

Inclusion of evidence based on expert opinion sets the stage for potential conflicts between the subjective assessments of experts and the objective evidence from trials and other data. These conflicts appear to take two forms. One concerns the assessment of clinical trial results by the experts. In particular cases, flaws may be evident to one expert and not another. Reservations regarding the generalizability of trial results and the gaps in knowledge left by trial data may differ between panel members. The second area of potential conflict concerns the expert's experience with particular therapies from his or her own practice. In ideal circumstances, the assessment of clinical value by the panel experts is congruent with the highest quality of objective evidence available, typically results of randomized clinical trials. Thus, the expert's view of the value of a therapy in daily practice outside the confines of a clinical trial and the potential implications of

the trial results for patient care is contrasted to the evidence-based approach.

When subjective expert opinion is not congruent with more objective scientific evidence, either for or against a therapy, how is the discrepancy resolved? Subjective opinion should focus on cogent arguments based on known potential issues with objective evidence. Unfortunately, there are no absolute rules for discarding trial results or deciding that the limitations of the trial are sufficient to countermand a traditionally positive statistical result. Most guidelines are intended to resolve these very difficult issues through a consensus opinion of the panel members involved. Strategies for reaching consensus on recommendations based on expert opinion are not well defined. However, an open, dynamic discussion seems crucial in order to prevent consensus from being driven by one or more experts with strong opinions. Working from written documents facilitates this process and provides the opportunity for feedback to the group. When expert opinion reaches a strong consensus, it may override positive or negative results from pieces of evidence of any type (including data from individual clinical trials). In contrast, the evidence in a few instances may be so controversial that it prevents the attainment of consensus. When a clear consensus cannot be reached, one action is to present more than one possible approach concerning application of a particular therapy. This may take the form of a majority-minority report or the form of two alternatives valued equally by the panel. Addressing controversial issues is critical for the practical success of a guideline, because the struggles encountered by the panel will be like those faced by clinicians in their everyday practice. A belief inherent to the guideline process is that considered judgment by credible experts in these controversial areas is more likely to be correct than ad hoc decisions made "on the spot" by physicians in practice.

## EFFICACY IN BROADER CONTEXT

The press that reports novel medical findings, as well as individual practitioners, often focus solely on whether a trial's results were interpreted as positive or negative. Evaluation of trial data in the development of practice guidelines should go beyond whether the results meet a particular statistical definition of significance for the trial's primary endpoint. The additional elements analyzed from clinical trial data tend to refine and clarify study results.<sup>43</sup> The major elements in this evaluation process typically include (1) the endpoints studied, (2) degree of positivity or negativity of trial results, (3) whether key findings have been replicated by other work or whether the trial was conducted on the basis of results of a series of studies, and (4) how the trial results fit into the totality of evidence supporting or contraindicating a particular therapy.

### Endpoints Studied

For heart failure, the strength of recommendation has tended to be influenced significantly by the effect that therapies have on morbidity and mortality. Drugs or procedures that reduce the risk of these outcomes are strongly recommended, whereas therapies that only reduce symptoms and improve quality of life receive less support. This orientation can be attributed to the profound effect that heart failure has on these clinical events of major interest. In addition, some clinicians perceive that these endpoints, particularly mortality, have the advantage of objectivity needed to clearly establish efficacy even in the setting of controlled clinical trials. Other endpoints, such as symptom scores or quality of life, are sufficiently subjective to make measurement difficult. The tools used to quantitate these endpoints are often hard to apply to

how patients seem in clinical experience. Because these factors generate a degree of uncertainty about the endpoints, the recommendations are more conservative.

## Degree of Positivity or Negativity

CH 40

Randomized studies may have sufficient power to be statistically positive, but therapy may produce only mild clinical benefit that hardly mandates a change in standard practice. In contrast, therapeutic trials may, in rare cases, demonstrate a profound clinical benefit that merits particular focus in a practice guideline.  $\beta$ -Blockade for heart failure (see Chapter 46), in which the magnitude of clinical benefit is great, is one example.

## Replication and Modification

Replication is the key to advancement in basic science. The results of many well-conceived single experiments are confirmed in this manner, and “failed experiments” with unusual results may be substantiated and may lead to new insights and discoveries. Fortunately, for many favorable therapies, data from a series of clinical trials are available to strengthen evidence for efficacy. Strict replication is, of course, much more difficult to achieve in clinical trials, even with the best of intent; for example, in trials performed sequentially in time, both the patient populations studied and the concomitant therapies given may be different. Despite these limitations, it is important that clinical studies with similar populations and comparable background therapy yield concurrent results. Unfortunately, because medical science involves human subjects, replication is often difficult, and evaluation of a treatment may depend on the result of a single randomized trial. Failure to consistently replicate a finding is less problematic if there are a sufficient number of clearly positive trials.

Experience in the basic laboratory suggests that another strategy—conducting serial studies with the results of previous work to optimize future study designs—should be applied more frequently in clinical research. Unfortunately, because of the time typically necessary to organize and complete human studies, this helpful strategy is less frequently used in clinical science than is replication. Because of current limitations in funding, it is very difficult to continue investigation when initial results regarding therapy are negative, even if the dose selected or the patient population is eventually understood to be incorrect.

## BEYOND EFFICACY: IS TREATMENT JUSTIFIED?

Practice guidelines must, from the available evidence, determine more than whether a treatment is efficacious or not. Treatment may have salutary effects on certain aspects of a clinical problem but still be difficult to justify as part of standard care. Therapeutic justification is one way to conceptualize how net clinical benefit and practicality are evaluated against a practice guideline. Several characteristics of therapy significantly affect how widespread the application of new treatments can and should be. Increasingly, committees carefully consider not only the risk-benefit ratio but also the cost effectiveness of novel therapies. Safety considerations may not be completely straightforward. In the case of certain desperately ill patients, greater risk for adverse reactions may be acceptable, and the quality of evidence for efficacy may be less rigorous.

Cost and cost-benefit analysis have not been major considerations during most guideline development, whether for heart failure or in other areas. However, because of the increasing recognition of the financial burden of new therapies and the crisis looming in Medicare as the number of recipients

increases dramatically, financial issues have become a major focus in cardiovascular medicine. In practice guideline development, committees cannot generally ignore this aspect of care much longer.

Safety is evidently a priority, but tolerability and practicality are also important considerations when advances in care are applied in actual practice. A therapy may be safe but still associated with bothersome minor side effects. These side effects may not produce significant medical problems, but they may be sufficient to cause patients to stop being compliant with therapy. Practicality is of particular concern for pharmacological therapy that often must be taken over a prolonged period on an outpatient basis. Convenience of administration becomes a critical test in this setting; once-a-day therapy is a common goal.

## DETERMINING STRENGTH OF RECOMMENDATION

The analytical process used to determine the strength of recommendations in a practice guideline is difficult to present in clear-cut way.<sup>44</sup> Determining value on the basis of the totality of available evidence seems to be critical when the strength of recommendations is formulated. *Totality of evidence*, as discussed in detail in the next section, refers to the impression gained about a treatment on the basis of a synthesis of all types of scientific data, favorable and unfavorable, concerning a therapy. The goal of therapeutic development is to achieve the best solution to problems of cost, convenience, and safety while ensuring that the treatment is efficacious. Formulating strength of recommendations takes all these aspects of therapy into account.

### Totality of Therapeutic Evidence

The full body of scientific evidence for a therapy includes not only results of human experimentation but also expert opinion and findings from epidemiological and basic science studies. It is accepted that agreement between various types of evidence, especially from studies with different methods, adds weight to the likelihood that a particular therapy is of value. Evidence-based medicine is often equated with the summary evaluation of a few clinical trials. However, best judgment seems to result from integration of available trial data with information from the basic laboratory and the findings of observational and epidemiological studies. Therapies supported by multiple lines of evidence are perceived as necessary components of disease management. In contrast, treatments shown to be effective only by limited clinical trial data and lacking other supporting evidence are often recommended more weakly. Similar situations arise when therapies are supported by studies with small sample sizes or by trials in which subjects were selected in such a way that it is difficult to extrapolate results to everyday clinical practice. Clinical trial results concerning treatment may be conflicting in different studies for the same or related endpoints. Issues of whether a drug class effect is present may be problematic as well because even drugs with similar mechanisms can produce different side effects, or dose requirements may differ in a way that may reduce or prevent positivity in randomized clinical trials.

### Scale of Strength

There is no uniform system for specifying strength of recommendations, but guidelines usually have three levels of favorable recommendation: for example, “is recommended,” “should be considered,” or “may be considered.” The rating system is usually asymmetrical, with several degrees

of favorable recommendation but only a single category for therapies not thought to be effective. The phrase “is recommended” is generally taken to mean that the therapy specified should be used in as many patients as possible with the disease process in question. Exceptions to use should be carefully delineated in the guideline document. Less positive recommendations can take the form of “should be considered” or “may be considered”; these indicate that the therapy can be applied in the majority of patients or on an individual basis, respectively. Language and the review of evidence related to strength of recommendation should be as consistent as possible within the guideline document.

## GUIDELINE DEVELOPMENT: PRACTICAL ASPECTS OF DRUG THERAPY

As noted previously, despite the intent to rely on data derived from clinical trials in the creation of a practice guideline, the findings from these studies have important limitations. Many elements required for the actual implementation of a therapeutic strategy are often not addressed (Figure 40-2). For example, key factors for practicing physicians include ideas about dosing and duration of therapy, familiarity with the class and with a particular drug within the class, convenience of drug administration, side effect profile (as distinct from safety), and cost.

### Practical Aspects of Drug Administration

Optimal dosing is not generally defined for cardiovascular pharmaceutical agents by clinical trial data. Trial designs usually have specific target dosages, but invariably many patients fail to reach these dosages during the course of the trial. Dose-response studies are very rare for important clinical endpoints such as morbidity and mortality. The duration of therapy necessary may not be evaluated, and the methods for upward titration and therapeutic monitoring may not be established easily from available clinical trial data. In heart failure in particular, information on how the new therapy fits with previously established treatment may be uncertain. These issues become less abstract when the fundamental aspects of pharmacological treatment are considered. When administering pharmaceutical therapy, practitioners must write a specific prescription for a defined dose, taken at a specific frequency, and taken for a designated period of time. Practitioners must also carefully consider how the new medication will interact with other drugs the patient may be taking. In many instances, clinical trial data does not provide any of this information.

A number of other factors affect ease of use of pharmacological therapy. In some cases, physicians may be familiar with a drug for one use and will more readily accept the agent for another application. Convenience of administration is an important determinant of whether an agent is adopted. The complexity of dosing, the route of administration, and the nature of the monitoring process all affect individual therapeutic decisions in clinical practice. Cost continues to be an important factor in many practice settings, especially in managed care organizations.

## IMPLICATIONS OF PRACTICE GUIDELINES FOR CARDIOVASCULAR PRACTICE

Crafting a guideline is difficult enough; achieving adherence is even more problematic. Individualized treatment based on personal observation has been a touchstone of medical practice for several millennia. According to this concept, individual variation in disease expression and in

**FIGURE 40-2** Estimated frequency of types of evidence available to guide specific aspects of pharmacological therapy for heart failure. Many issues that face practitioners who prescribe medication must be resolved with observational data and expert opinion. *RCT*, randomized controlled trial.

response to therapy is of more therapeutic importance than basic pathophysiological processes and mechanisms of drug action. Patients with a given disease are seen as being more different from than similar to one another. Arising with the origin of medical practice, the philosophy of individualizing therapy on the basis of personal physician experience may have been easier to accept when knowledge was scant; diseases that could be diagnosed often had a significant spontaneous recovery rate, and there was little understanding of how to identify favorable treatments. After a long period of profound uncertainty, the circumstances of medical practice that promoted extreme individualization of care have been substantially altered since the 1970s, certainly in the field of cardiovascular medicine. Application of the scientific method to clinical medicine has provided objective evidence and reproducible understanding of the effects of therapies, particularly pharmacological treatments. In addition, individualization of therapy on the basis of personal observation is especially likely to be incorrect because of several characteristics of cardiovascular disease, including heart failure: (1) Drug effects may be modest and yet important in a condition with high mortality and morbidity rates, (2) the medical problem is chronic, and the outcomes of treated patients vary widely and are difficult to quantitate from experience in practice, and (3) the drug may effect a complex array of favorable outcomes, wherein the pattern of benefit varies from one patient to the next. Because using observations from an individual's practice is a problematic way to assess therapeutic value in cardiovascular medicine, standards of care and practice guidelines are needed.

A number of treatment strategies are now sufficiently well established that it is simply not up to an individual practitioner to deviate from their use. This conclusion does not detract from the art of medicine. In some clinical situations, certain nuances in disease manifestation and response to therapy should influence the application of treatment in particular patients. Optimizing care in these situations may well stress individual practitioner experience over clinical science derived from experimentation. The main challenge facing practitioners today is to be able to distinguish these situations: when knowledge is insufficient to set exact standards versus when practice guidelines are not recommendations but requirements. Resolution of this dilemma will be difficult, but it is imperative because of the continuous advance of medical knowledge and the proper expectation on the part of patients that their care will be optimized.

Developers of a clinical practice guideline must confront this central issue—recommending versus requiring—when they envision translation of their recommendations into everyday practice. The definition of the word *guideline* serves to illustrate this controversy: an indication or outline of policy or conduct, in which *indication* means that certain actions are advisable (suggested or recommended) or necessary (required). The critical word *or* represents the nature of this dilemma. Most clinicians, of course, prefer not to consider practice guidelines as absolute standards. With the continued refinement of clinical trial methods and the ability to develop a totality of evidence, however, many are suggesting that these documents should be perceived that way.

## EVOLUTION OF RECOMMENDATIONS ABOUT $\beta$ -BLOCKERS

In the treatment of heart failure caused by left ventricular systolic dysfunction, the evolution of  $\beta$ -adrenergic blockade as a major therapeutic modality provides an excellent case study of therapeutic concepts developed over time during guideline development.<sup>45,46</sup> A review of the recommendations concerning these agents illustrates how the guideline process has resolved some difficult dilemmas even for a very efficacious therapy.

### $\beta$ -Blockade for Symptomatic Left Ventricular Systolic Dysfunction (see Chapter 46)

The HFSA guideline in 1999 was limited to pharmacological therapy and was the first heart failure guideline to recommend  $\beta$ -blockade as routine therapy for patients with symptomatic heart failure caused by left ventricular systolic dysfunction. This recommendation was accompanied by a level A strength of evidence (see Table 40-2), but the decision to provide this strength of recommendation was based on the profound overall body of knowledge supporting the role of  $\beta$ -blockers in treating heart failure. Use of these agents exemplifies how guideline care is closer to required rather than merely recommended. Both the totality of evidence and the quality of the clinical trial data available to support this therapy are striking. There is ample evidence from basic laboratory studies that  $\beta$ -adrenergic receptors are downregulated in response to sympathetic activation and that chronic sympathetic activation is harmful to cardiac structure and function.<sup>45-47</sup> Epidemiological data also link excess adrenergic activity to poor prognosis in patients with left ventricular systolic dysfunction.<sup>48</sup> Many small mechanistic trials have demonstrated convincing evidence that  $\beta$ -blockade enhances ventricular function in patients with heart failure.<sup>49,50</sup> These small-scale trials were eventually followed by several large-scale mortality trials, which documented the striking ability of  $\beta$ -blockade to lower risk of death and hospitalization in patients with symptomatic left ventricular systolic dysfunction.<sup>51-53</sup> Available clinical trial data contain excellent information concerning safety and tolerability and illustrate the justification for this therapy, in part by showing that the rates of mortality and morbidity remained high despite conventional therapy with angiotensin-converting enzyme (ACE) inhibitors and other agents as given to the “placebo” recipients. This total weight of medical evidence and knowledge concerning cost versus benefit, convenience, and safety provides very strong support for routine use of these agents in as many patients as possible who have heart failure and left ventricular systolic dysfunction.

However, gaps are present even in the rich body of evidence supporting  $\beta$ -blockade. Studies to help understand dose, initiation of therapy, and method of titration in clinical

practice settings are limited.<sup>54</sup> Dose titration is reasonably well defined from trial data for surrogate endpoints, but no definitive results concerning the dosages needed for optimal outcomes are available. Information is available about target dosages, and moderate-size prospective trials with surrogate endpoints suggest some benefit at low dosages and greater benefit at target dosages.<sup>55</sup> Retrospective studies have suggested that heart rate response may help guide therapy with  $\beta_1$  selective agents.<sup>56</sup> Withdrawal trials, designed to study the response of patients after discontinuation of ongoing therapy, provide a few data, but their results strongly suggest that therapy should be indefinite as long as ventricular dysfunction persists.<sup>57,58</sup> Data from available trials and expert experience were sufficient to outline approaches to titration and the course that should be taken if patients' conditions worsen while they receive therapy.

A major clinical issue concerning  $\beta$ -blockade is when to initiate therapy in patients with known systolic dysfunction. Hospitalization for cardiovascular disease provides an excellent opportunity for the initiation of life-saving therapy, and strategies based on this approach have been developed for lipid-lowering agents and other drugs. Fortunately, data are available concerning the potential effectiveness of this approach with  $\beta$ -blockade for heart failure. The Initiation Management PredischARGE process for Assessment of Carvedilol Therapy for Heart Failure (IMPACT-HF) trial demonstrated convincingly that this approach resulted in higher likelihood of  $\beta$ -blocker use at 60 days after discharge, and patients treated this way were more likely to achieve target dosages.<sup>59</sup> This moderate-sized randomized clinical trial ( $n = 382$ ) could not provide reliable outcomes data, but it did provide solid information about the safety of this approach. On the basis of these results, the 2006 HFSA guideline recommended institution of  $\beta$ -blockade at discharge after successful treatment of an episode of acute heart failure. Results of a subsequent large-scale observational study strongly suggest that institution of  $\beta$ -blockade in hospital results in better short-term outcomes.<sup>60</sup>

Another important clinical issue not fully addressed by trial results concerns the use of  $\beta$ -blockers in elderly patients. Investigators in the Cooperative Cardiovascular Project used proportional-hazards modeling to examine the likelihood of 2-year survival in patient subgroups when  $\beta$ -blockers were prescribed at the time of hospital discharge after an acute myocardial infarction.<sup>61</sup> Results of adjusted analysis indicated a substantial reduction in mortality at 2 years among patients aged 80 years or older who were treated with  $\beta$ -blockade. Analysis of subgroup data from the Metoprolol CR/XL Randomized Intervention Trial in congestive Heart Failure (MERIT-HF) also yielded support for the efficacy of  $\beta$ -blockade in older patients.<sup>62</sup>

### $\beta$ -Blockade in Patients with Severe Heart Failure

When the initial HFSA guideline was formulated, information concerning  $\beta$ -blockade in patients with severe heart failure caused by left ventricular systolic dysfunction was very limited. It was known that decompensation of heart failure during initiation of  $\beta$ -blockade was more common in these patients and that some patients had to be permanently withdrawn from therapy. Because of these difficulties and the limited amount of available data, even in view of observational experience, the recommendation was for such patients to avoid  $\beta$ -blocker use.

After publication of the original HFSA guideline, results from the large-scale Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) study, which enrolled patients with severe heart failure, were reported.<sup>63</sup> Patients in this trial had severe left ventricular dysfunction (ejection fraction < 25%) and symptoms of heart failure at rest or on minimal exertion despite attempts at diuresis and optimization of medical therapy. Interestingly, New York Heart Association

**TABLE 40–2 Structure of Recommendations and Grading of Evidence Among Major Heart Failure Guidelines**

HFSA 2006	ACC/AHA 2009	ESC 2008	CCS 2006
<b>Strength of Recommendation (Highest to Lowest)</b>			
Is recommended	Class I: Procedure or treatment should be performed or administered	Class I: Evidence or general agreement that a given treatment or procedure is beneficial, useful, or effective	Class I: Evidence or general agreement that a given procedure or treatment is beneficial, useful, and effective
Should be considered	Class IIa: It is reasonable to perform procedure or administer treatment; additional studies with focused objectives are needed	Class II: Conflicting evidence or a divergence of opinion about the usefulness or efficacy of the given treatment or procedure Class IIa: Weight of evidence or opinion is in favor of usefulness or efficacy	Class II: Conflicting evidence or a divergence of opinion about the usefulness or efficacy of the procedure or treatment Class IIa: Weight of evidence is in favor of usefulness or efficacy
May be considered	Class IIb: Procedure or treatment may be considered; additional studies with broad objectives are needed; additional registry data would be helpful	Class IIb: Usefulness or efficacy is less well established by evidence or opinion	Class IIb: Usefulness or efficacy is less well established by evidence or opinion
Not recommended	Class III: Procedure or treatment should not be performed or administered because it is not helpful and may be harmful	Class III: There is evidence or general agreement that the given treatment or procedure is not useful or effective and in some cases may be harmful	Class III: There is evidence or general agreement that the procedure or treatment is not useful or effective and in some cases may be harmful
<b>Strength of Evidence (Highest to Lowest)</b>			
A: At least one RCT	A: Multiple populations evaluated; data derived from multiple RCTs or meta-analyses	A: Data derived from multiple RCTs or meta-analyses	A: Data derived from multiple RCTs or meta-analyses
B: Cohort and case control studies; post hoc analysis, subgroup analysis, and meta-analysis; prospective observational studies or registries	B: Limited populations evaluated; data derived from a single RCT or nonrandomized studies	B: Data derived from a single RCT or large nonrandomized studies	B: Data derived from a single RCT or nonrandomized studies
C: Expert opinion; observational studies and epidemiological findings; safety reporting from large-scale use in practice	C: Very limited populations evaluated; only consensus opinion of experts, case studies, or standard of care	C: Consensus of opinion of the experts or small studies, retrospective studies, registries	C: Consensus of opinion of experts or small studies

ACC/AHA, American College of Cardiology Foundation/American Heart Association; CCS, Canadian Cardiovascular Society; ESC, European Society of Cardiology; HFSA, Heart Failure Society of America; RCT, randomized controlled trial.

The guidelines all have the same number of categories for grading recommendations which correlate well overall. The second category (labeled should be considered in the HFSA 2006 guideline) is the most difficult to describe and is the most dissimilar among the guidelines. Hopefully the reader can use the examples given in future tables to understand the nuances among the guideline for this strength of recommendation.

functional class was not assigned to these patients, but the mortality rate among the placebo recipients was close to 20% at 1 year, which confirmed the severity of the heart failure in the study population. Despite this degree of heart failure,  $\beta$ -blockade with carvedilol was well tolerated by the study patients and was associated with a marked reduction in all-cause mortality, a reduction comparable with that achieved in studies of patients with less severe symptoms. The study was stopped early by the data and safety monitoring board because of the highly significant benefit of  $\beta$ -blockade. Of note, this study did not include patients with severe heart failure and persistent congestion. Patients were treated to relieve congestive symptoms before randomization. A retrospective analysis of the MERIT-HF data in patients with a comparable degree of ventricular dysfunction and 1-year mortality rate also revealed a similar mortality benefit from extended-release metoprolol.<sup>64</sup> These favorable results led to a revision in the HFSA guideline in 2006 to include use of  $\beta$ -blockade in patients with severe heart failure who were thought to be adequately decongested.

### $\beta$ -Blockade for Asymptomatic Left Ventricular Dysfunction

In contrast to the strong recommendation for use of  $\beta$ -blockade in patients with symptoms, the initial HFSA guideline in 1999 gave a much more subdued recommendation for

patients with no symptoms. The difficulty for guidelines in this area arose from the lack of data from randomized clinical trials to support the use of  $\beta$ -blockade. This illustrates a common problem for the guideline process: How accurately can the findings from one part of the disease spectrum be extrapolated to another? In contrast, in the ensuing 2001 guidelines from the American College of Cardiology Foundation/American Heart Association (ACC/AHA)<sup>4</sup> and the 2006 HFSA heart failure guidelines, a recommendation, about as strong that for patients with symptoms, was given in regard to  $\beta$ -blocker therapy in patients with asymptomatic left ventricular dysfunction.<sup>4</sup> Interestingly, no data from new randomized, controlled trials were available to support this strength of recommendation. This illustrates a case in which a very strong recommendation was given despite a low level of evidence. More recently, a prospective, randomized controlled trial demonstrated a favorable effect of  $\beta$ -blockade on left ventricular remodeling in this patient population, at least providing surrogate endpoint data in favor of this approach.<sup>65</sup>

### Summary

These specific issues regarding the practical aspects of  $\beta$ -blocker therapy amply illustrate the beneficial effect that consideration of all forms of scientific data can have on guideline development. This approach makes it possible to provide

## INTEGRATION OF AVAILABLE GUIDELINES

Increasing enthusiasm for practice guidelines in heart failure has led to the creation of several detailed documents by major cardiovascular societies, including the HFSA, the European Society of Cardiology (ESC), the ACC/AHA, and the Canadian Cardiovascular Society (CCS) (Table 4-2). Many authorities worry that this development adds unnecessary complexity and confusion by producing sets of guidelines that may differ meaningfully and even contradict one another. Another perspective considers multiple guidelines as an advantage, because many recommendations rest on less-than-ideal evidence (observational studies or expert opinion). In this setting, multiple guidelines by groups substantially independent of one another help address other important concerns about the role of experts. Similarities and differences among the individual guidelines help health care providers more effectively individualize management decisions. Finally, when the guidelines are concordant on key therapy, their consistency provides a much more convincing foundation for quality-of-care indicators and assurance programs.

To illustrate these points, positions taken by the individual guidelines on several common clinical scenarios in heart failure are presented in tabular form and reviewed in detail in the following sections. These guidelines share a sufficiently similar approach to formulating position statements (providing a strength of recommendation and a strength of evidence), and so comparison is possible. There are some differences in how evidence is graded and assessed in the various guidelines, but results of randomized clinical trials are considered best, whereas expert opinion is assigned the lowest value.

### Left Ventricular Systolic Dysfunction

One area that illustrates substantial agreement among the guidelines concerns the medical treatment of left ventricular systolic dysfunction (Table 40-3). ACE inhibitor and  $\beta$ -blocker therapy are recommended on the basis of high-grade evidence for all patients with reduced ejection fraction, whether symptoms are present or not. Aldosterone antagonists are uniformly considered a standard of care in patients with severe heart failure, and digoxin is recommended for patients who remain symptomatic despite ACE inhibitor and  $\beta$ -blocker therapy as tolerated. Loop diuretics are recommended even though the evidence is less than desirable. Exercise training represents an evolving area of care and is likely to be more uniformly recommended on the basis of clinical trial results. In contrast, the recommendations for hydralazine-nitrate therapy are more variable, but both U.S. guidelines now recommend this therapy as a standard of care in African-American patients with symptomatic systolic dysfunction.

### Cardiac Resynchronization

Clinical improvement after cardiac resynchronization pacing is variable and provides a good illustration of how guidelines may include specific criteria for therapy to increase the likelihood of a favorable response (Table 40-4). The guidelines are in agreement about key characteristics of candidates for this device, with emphasis on QRS duration, presence of significant symptoms, and severe left ventricular systolic dysfunction in the setting of aggressive pharmacological treatment. The guidelines also indicate that strength of evidence is high for appropriate candidates according to data from randomized clinical trials that focused on outcomes. Contrasting strengths of recommendation among the guidelines also

may be of benefit when this treatment is considered in broad patient populations. The HFSA guideline is the most conservative, with a “should be considered” strength of recommendation, similar to class IIa in the other guidelines. The HFSA device section begins with caveats concerning comorbid conditions and the likelihood of rapid death from severe underlying heart failure. This approach allows for more flexibility in decision making for individual patients than “is recommended” or a class I indication.

### Inotropic Therapy in Acute Heart Failure (see Chapter 43)

The value of inotropic therapy (defined as dobutamine or milrinone) in patients with decompensated heart failure has long been hotly debated as appropriate attention has focused on the potentially harmful aspects of this drug class. A combination of results from the basic laboratory and prospective observational studies enabled the guideline committees to make a strong recommendation concerning this treatment, even though data from randomized trials are limited (Table 40-5). Their recommendations identify the potential for harm from this therapy and highlight the lack of convincing clinical benefit in broad populations of patients with acute heart failure.<sup>66</sup> Nevertheless, heart failure specialists who care for critically ill patients with acute heart failure, including those in cardiogenic shock, rely on these drugs. These agents may provide a bridge to recovery or surgical intervention (left ventricular assist device or cardiac transplantation). Committees agreed that the key to making a recommendation was to define the appropriate patient population in which this treatment may be considered, which is done in a very similar way in all the guidelines. Lack of enthusiasm even in the patient population identified is evident from the low strength of recommendation given by three of the four guidelines. This sends a strong message for careful consideration before this therapy is applied even in the recommended patient population, a conclusion that remains unchanged by results with newer agents in this class.<sup>67</sup> This element of the acute heart failure guideline illustrates the significant role that observational data can play, especially when combined with evidence from the basic laboratory and clinical trials.<sup>68-70</sup>

### Polypharmacy

The use of multiple medications is recognized as critical in the treatment of systolic heart failure and is part of management in essentially all patients. However, this approach is problematic because of the relative lack of evidence from randomized controlled trials in which the benefits of specific combinations of therapy are tested (Table 40-6). Background therapy differs in various placebo-controlled trials; this leads to subgroup analysis and extrapolation, which weaken strength of evidence. In contrast, pathophysiological considerations and the available data on certain combinations of medication prompt interest in combination treatment. To add to the controversy, the major heart failure guidelines demonstrate both consensus and disagreement about the relative values of specific combinations of life-saving drugs. Careful review of the various guidelines reveals differences in regard to strength of evidence and target patient populations for specific combinations.

Recommendations concerning aldosterone antagonists illustrate how some of these significant issues play out among the key guidelines (see Table 40-6). These agents have been shown to be life-saving in patients with severe heart failure treated with ACE inhibitors, but essentially not in such patients treated with  $\beta$ -blockers, and convincing data about less symptomatic patients are not available. This creates dilemmas regarding strength of recommendation and evidence when clinicians consider prescribing these drugs in

**TABLE 40-3 Recommendations Concerning Key Therapeutic Areas for Heart Failure Caused by Left Ventricular Systolic Dysfunction**

combination with β-blockade and in combination with other drugs in patients who do not have severe heart failure. Recommendations concerning aldosterone antagonists as part of combination therapy are restricted because of persistent concern about their adverse effects on serum potassium level and renal function in this setting.<sup>71</sup> Risk of serious hyperkalemia has led all the guidelines to specifically not recommend the triple combination of angiotensin receptor blocker, ACE inhibitor, and aldosterone blocker. This reaction could be excessively conservative inasmuch as some patients have low potassium levels despite oral replacement and may need aldosterone blockade to achieve adequate serum concentrations.

## TRANSLATING CLINICAL TRIAL DATA INTO PRACTICE

### Problem of Perspective

The application of new therapies in practice is generally a slow process. Many practitioners ascribe to the tenet “First, do no harm.” Most respond to and evaluate medical advances from the traditional perspective of medical decision making rather than the perspective of evidence-based medicine (Table 40-7). It is clear that practitioners in direct daily contact with patients, many of whom have symptoms not related to organic disease or self-limited acute conditions, often rely on a hierarchy of medical evidence different from that used in guideline development. This perspective continues to

limit the rapid application of new treatments that might be expected from favorable clinical trial results alone.

### Specific Issues

Three other translational problems also contribute to the fact that clinical gains are often less than expected in accordance with favorable clinical trial results. First, knowledge gained concerning disease states and results from clinical trials often do not as easily improve outcomes in general populations of patients. Selection bias for trial enrollment may avoid issues of safety and side effects that may be more common in general medical populations. Second, medical practitioners are inherently resistant to change. Unexpected problems related to new therapeutic approaches may arise, and so many practitioners adopt a conservative approach to novel treatment. Third, therapeutic advances often necessitate new methods of care for a particular disease state; these methods may or may not be easy to adapt to outpatient or inpatient practice and are frequently expensive to implement. Some new therapeutic advances require fundamental changes in physicians’ perception of disease processes that are simply hard to accept.

Strategies for implementing changes in practice processes and implementing new standards of care have not been well studied or understood. Unfortunately, the changes necessitated by many therapeutic advances are significant in terms of practice organization, facilities, and personnel. Funding to support the necessary adaptations often does not accompany the change in expectations regarding treatment, particularly

**TABLE 40–4 Similarity and Contrast Among Guidelines in Recommendations for Cardiac Resynchronization Therapy**

General Considerations	HFSA 2006	ACC/AHA 2009	ESC 2008	CCS 2006				
Specific recommendations	Intervention made in view of functional status and prognosis on the basis of severity of underlying heart failure and comorbid conditions (recommended, C)	Not mentioned	Not mentioned	The decision to implant a device in a patient with heart failure should be made with assessment and discussion between the heart failure and arrhythmia specialists (class I, level C)				
Criteria for use								
QRS duration	≥120 msec	≥120 msec	≥120 msec	≥120 msec				
LVEF criteria	≤35%	≤35%	≤35%	≤35%				
Optimize medications	Required 3-6 months	Required	Required	Required				
Clinical Scenarios	SoR	SoE*	SoR	SoE*	SoR	SoE*	SoR	SoE*
Class III	Should be considered	A	Class I	A	Class I	A	Class I	A
Class IV	May be considered Selected ambulatory patients	B	Class I Ambulatory patients	A	Class I Any class IV	A	Class I	A
Classes I to II	Not recommended	C	Insufficient evidence		Insufficient evidence		Insufficient evidence	

\*For definition of A, B, and C, see Table 40-2.

ACC/AHA, American College of Cardiology Foundation/American Heart Association; CCS, Canadian Cardiovascular Society; ESC, European Society of Cardiology; HFSA, Heart Failure Society of America; LVEF, left ventricular ejection fraction; SoE, strength of evidence; SoR, strength of recommendation.

**TABLE 40–5 Recommendations for Inotropic Therapy (Dobutamine or Milrinone) for Acute Heart Failure**

Aspect	HFSA 2006	ACC/AHA 2009	ESC 2008	CCS 2006
Indications for use	Intravenous inotropic agents (milrinone or dobutamine) may be considered to relieve symptoms and improve end-organ function in patients with advanced heart failure characterized by LV dilation, reduced LVEF, and diminished peripheral perfusion or end-organ dysfunction (low-output syndrome), particularly if these patients have marginal systolic blood pressure (<90 mm Hg), have symptomatic hypotension despite adequate filling pressure, or are unresponsive to or intolerant of intravenous vasodilators. These agents may be considered in similar patients with evidence of fluid overload if they respond poorly to intravenous diuretics or manifest diminished or worsening renal function.	Patients with either predominantly low-output syndrome (e.g., symptomatic hypotension) or combined congestion and low output may be considered for intravenous inotropic agents such as dopamine, dobutamine, and milrinone. Inotropic agents are of greatest value in patients with relative hypotension and intolerance of or no response to vasodilators and diuretics.	Inotropic agents should be considered in patients with low-output states, in the presence of signs of hypoperfusion or congestion despite the use of vasodilators or diuretics, or both, to improve symptoms. Inotropic agents should be administered only in patients with low SBP or a low measured cardiac index in the presence of signs of hypoperfusion or congestion. Therapy should be reserved for patients with dilated, hypokinetic ventricles.	Patients with low cardiac output and SBP less than 90 mm Hg should be given a positive inotrope (e.g., dobutamine, 2-5 µg/kg/min, or milrinone, 0.275 µg/kg/min). Depending on the hemodynamic profile, treatment should include combined intravenous diuretics and inotropic agents. Once SBP is improved by inotropic agents, vasodilator therapy can be added to lower filling pressures further.
Strength of recommendation	May be considered	Class III	Class IIa	Class I
Strength of evidence*	C	C	B	B

\*For definition of B and C, see Table 40-2.

ACC/AHA, American College of Cardiology Foundation/American Heart Association; CCS, Canadian Cardiovascular Society; ESC, European Society of Cardiology (2008); HFSA, Heart Failure Society of America (2006); LV, left ventricular; LVEF, left ventricular ejection fraction; SBP, systolic blood pressure.

**TABLE 40–6 Strategy for Addition of Medical Therapy to ACE Inhibitor and  $\beta$ -Blocker\***

In Addition to ACE Inhibitor and $\beta$ -Blocker	HFSA 2006		ACC/AHA 2009		ESC 2008		CCS 2006	
	SoR	SoE†	SoR	SoE†	SoR	SoE†	SoR	SoE†
<b>Clinical Scenario: NYHA Class II</b>								
ARB	Should be considered	A	Class IIb	B	Class I	A	Class I	A
Aldosterone antagonist	Should be considered	C	Class IIb	B	Insufficient evidence		Insufficient evidence	
Hydralazine nitrate: African American patients	Should be considered	B	Class IIa	A	Class IIa	B	Class IIa	A
Hydralazine nitrate: non-African American patients	Should be considered	C	Class IIa	A	Class IIa	B	Insufficient evidence	
<b>Clinical Scenario: NYHA Class III</b>								
ARB	Should be considered	A	Class IIb	B	Class I	A*	Class I	A
Aldosterone antagonist	Should be considered	A	Class I	B	Class I	B	Class I	B
Hydralazine nitrate: African American patients	Is recommended	A	Class IIa	A	Class IIa	B	Class IIa	A
Hydralazine nitrate: non-African American patients	Should be considered	C	Class IIa	A	Class IIa	B	Insufficient evidence	

\*Order in which agents are added is not well delineated by the guidelines. The triple combination of ACE inhibitors, ARB, and aldosterone antagonist is not recommended by each of the guidelines because it heightens risk of hyperkalemia and worsening renal function.

†For definition of A, B, and C, see Table 40-2.

ACC/AHA, American College of Cardiology Foundation/American Heart Association (2009); ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CCS, Canadian Cardiovascular Society; ESC, European Society of Cardiology; HFSA, Heart Failure Society of America (2006); NYHA, New York Heart Association; SoE, strength of evidence; SoR, strength of recommendation.

**TABLE 40–7 Factors That Affect Concerns About Therapy Among Various Groups in the Medical Care System**

Group	Concerns
Clinical trialists	Results of randomized trials
Guideline makers	Randomized trials, cohort results Observational data, expert opinion
Process reviewers	Absolute consensus on therapy Clear-cut criteria to identify patients to be treated
Practicing physicians	Absence of side effects, cost, convenience Familiarity, safety Efficacy

when advances are related to pharmacological therapy. The practicality of making process changes is often ignored by guideline makers and by professionals who monitor compliance with guidelines.

### Clinical Example: $\beta$ -Blockade

$\beta$ -Blockade for heart failure is a striking example of a therapy once contraindicated that is now indicated. A number of barriers have prevented the use of  $\beta$ -blockade for heart failure from becoming widespread. In addition to barriers that characterize many new therapies, such as necessary changes in practice processes and the need for education concerning the therapy, a number of unique challenges have been associated with the use of  $\beta$ -blockade (Table 40-8). Many strategies have been used to overcome these latter barriers to the translation of new advances into clinical practice. Creation of practice guidelines has emerged as one of the principal strategies and is a seemingly effective approach.

**TABLE 40–8 Unique Barriers to the Use of  $\beta$ -Blockade for Heart Failure**

Traditional Approach	Treatment Approach with $\beta$ -Blockade
Treat for immediate improvement in symptoms	Give $\beta$ -blocker for long-term benefit, not for immediate symptom relief
Use new approaches in sickest patients first	Do not use in sickest patients (those with active class IV heart failure with fluid or in hospital)
Do not add drugs to regimen when patients experience improvement in symptoms	Add $\beta$ -blockade as a part of a multiple-drug regimen for heart failure

## CONCLUSION

Development and promulgation of practice guidelines seem to be fixtures of modern medical care.<sup>72</sup> Considerable consensus supports the idea that a systematic process is necessary to evaluate new approaches to management, especially when patients suffer from debilitating, expensive, and fatal diseases such as heart failure. Despite many landmark studies that promote reliance on evidence-based medicine, significant gaps in knowledge persist, especially from the point of view of the health care provider, who, for example, must write a highly specific prescription for pharmacological therapy that details dose, frequency, and duration of a specific medication, with or without adjustment of other therapies. Many specific decisions were traditionally made on an ad hoc basis by physicians and other health care providers. In most cases, there was observational experience, but given that individual physicians were making these decisions, the nature of the observational experience was biased and often of limited value for many diseases.

## BOX 40-4 Humanistic Principles Critical for Guideline Development

Achieve consensus  
Avoid a single dominant voice  
Maintain independence  
Remain humble  
Show up for work consistently

Development of specific practice guidelines is emerging as a critical part of translational strategy. The understanding of the strengths and limitations of clinical trial data as agents of change in clinical practice has deepened, and the importance of the thought process inherent in guideline development has become more evident. Effective long-term guidelines are living documents with short life cycles that accelerate along with the understanding of the steps necessary to translate advances in heart failure into clinical care. Properly conceived, these standards should significantly enhance the applications of advances in medical science to the actual day-to-day care of patients. As the economic reality increasingly clashes with rising patient and provider expectations for quality and success, novel approaches to care delivery will be paramount to avoid loss of morale and the practice of inferior medicine on a large scale.<sup>73,74</sup>

Although in this setting the justification for guidelines is apparent, the developmental process for these standards of care needs continued investigation and refinement. External pressures and emphasis on timeliness will increasingly complicate an already very difficult academic challenge. To quote Sackett, "Truth is not often best determined by scheduling a press conference."<sup>75</sup> A number of humanistic principles have become as critical to guideline development as scientific acuity and discipline (Box 40-4). Dedication to the art and science of medicine and the spirit of cooperative endeavor is more necessary than ever for success in guideline development.

## Disease Prevention in Heart Failure

Viorel G. Florea and Jay N. Cohn

Despite advances in the therapy of cardiovascular disorders, heart failure remains a challenging disease process with a high prevalence (Figure 41-1) and a dismal long-term prognosis (see Chapter 22).<sup>1</sup> Although the rate of fatal events in patients with heart failure has been declining,<sup>2</sup> the crude number of deaths attributed to the condition has been increasing,<sup>1</sup> primarily because the incidence of the condition has increased (Figure 41-2). The aging of the population and improved length of survival of patients with acute myocardial infarction are believed to be some factors contributing to the growing burden of chronic heart failure. More than 500,000 new cases of heart failure are diag-

retention, vascular remodeling), this discussion is an attempt to characterize the specific mechanisms of the effect of the comorbid conditions and their treatment on the development of heart failure.

### DIASTOLIC AND SYSTOLIC HEART FAILURE

Although the existence of diastolic heart failure, as distinguished from systolic heart failure, was recognized before 1940,<sup>10</sup> the mechanisms that ultimately produce these two phenotypes of chronic heart failure remain, at present, largely unknown.<sup>11</sup> Furthermore, whereas diastolic dysfunction is common in systolic heart failure,<sup>12</sup> left ventricular systolic performance, function, and contractility in general remain normal in diastolic heart failure.<sup>13</sup> The myocardium and left ventricle of most patients with heart failure have, in fact, many similarities and are abnormal during both systole and diastole, regardless of ejection fraction. The myocardium in patients with ischemic cardiomyopathy or hypertensive heart disease is similarly characterized by increased left ventricular mass, myocyte hypertrophy, and increased interstitial collagen.<sup>14,15</sup> Hypertrophic myocardium in these and other conditions exhibits similar abnormalities of calcium handling and similar functional abnormalities of contraction and relaxation,<sup>16</sup> regardless of ejection fraction. Myocardium from patients with dilated cardiomyopathy and from those with hypertrophic cardiomyopathy demonstrates similar delay in diastolic cytosolic calcium reuptake, in association with delayed relaxation.<sup>16</sup>

Although classifying systolic and diastolic heart failure has been challenging,<sup>17</sup> the key element differentiating the two types of heart failure is the presence or absence of ventricular dilation and remodeling.<sup>7</sup> The presence of conditions that are considered risk factors, such as hypertension or diabetes, leads to myocyte apoptosis and necrosis.<sup>18</sup> The resultant fibrosis forms the basis of impaired ventricular relaxation and reduced ventricular compliance.<sup>19</sup> When this process is slow and chronic, the ventricle may maintain its size and shape (does not remodel) and therefore preserves its ejection fraction.<sup>20</sup> In acute insults to the ventricle, as in myocardial infarction, alterations in the topography of

nosed each year, and this incidence is expected to rise to 772,000 new cases per year by 2040.<sup>3</sup> The burden of heart failure will obviously not be eliminated by an improvement in the survival of patients who are already affected with the disease; instead, a drastic reduction in the incidence of heart failure is necessary to prevent an increase in the burden. It is therefore important that a population-level strategy be developed to prevent the lifetime risk of heart failure that applies to the large number of individuals at risk. Such a strategy would complement the current approaches that are aimed at intensive management of patients with manifest heart failure (Figure 41-3).

Because of the sizable public health burden posed by heart failure and the limitations in health care resources, it is crucial that the primary drivers of this problem be identified. In 2001, a new approach to the classification of heart failure was adopted by the American College of Cardiology/American Heart Association; this approach included stage A, characterized by no structural disorder of the heart or heart failure symptoms but risk factors that clearly predispose carriers toward the development of heart failure.<sup>4</sup> It is estimated that 74 million people in the United States are living with risk factors for heart failure (i.e., are in stage A of heart failure).<sup>5</sup> The new classification scheme adds a useful dimension to the understanding of heart failure: the recognition that there are established risk factors and structural prerequisites for the development of heart failure and that therapeutic interventions performed even before the appearance of left ventricular dysfunction or symptoms can prevent the development of heart failure. In 2008, the American Heart Association published a scientific statement on heart failure prevention.<sup>6</sup> The progression of heart failure mandates that an all-out effort be made to prevent its development in the first place, and the best time to intervene would be before or at stage A.

A number of risk factors have been identified that may lead to heart failure. These exert their adverse effects through functional and structural influence on the left ventricle, characterized as ventricular remodeling and defined as progressive ventricular hypertrophy, enlargement, and cavity distortion over time.<sup>7,8</sup> These risk factors include hypertension, diabetes mellitus, atherosclerotic disease, metabolic syndrome, obesity, chronic obstructive pulmonary disease (COPD), and the use of many therapeutic and recreational agents that can exert important cardiotoxic effects. Hypertension and myocardial infarction together account for approximately 75% of the population-attributable risk of heart failure,<sup>9</sup> and both are generally preventable with currently known and available strategies. The burden of heart failure risk factors, and comorbid conditions and their treatment on incident heart failure are examined in this chapter. As the primary mechanisms of the development of heart failure may be cardiac (structural remodeling, decreased compliance, impaired contractility) or peripheral (fluid

**FIGURE 41-2** Incidence of heart failure by age and gender. (From Rosamond W, Flegal K, Furie K, et al. Heart disease and stroke statistics 2008 update. A report from the American Heart Association Statistics Committee and Stroke Statistics Subcommittee. *Circulation* 2007;117[4]:e25-e146.)

both the infarcted and noninfarcted regions of the ventricle may lead to progressive ventricular enlargement.<sup>21</sup> The decrease in global left ventricular ejection fraction results largely from ventricular dilation and remodeling (Figure 41-4).<sup>22</sup>

The distinctive features of remodeling in diastolic heart failure and systolic heart failure are illustrated in Figure 41-5 (see also Chapter 14).<sup>23,24</sup> In systolic heart failure, the left ventricular cavity size is increased, the ventricular shape and geometry are altered with a greater increase in transverse than in long axis, the wall stress is increased, and the ejection fraction is reduced. The mass is increased, but the mass-to-cavity ratio remains unchanged or is decreased. In diastolic heart failure, the cavity size remains unchanged or may even decrease, and there is usually an increase in wall thickness and mass; however, mass-to-cavity ratio is substantially increased, the end-diastolic wall stress is increased, systolic wall stress remains normal, and the ejection fraction remains normal or may even be higher than normal.<sup>13,23</sup>

Ejection fraction provides no information regarding functional capacity.<sup>25</sup> Rather, in patients with normal ejection fraction<sup>26</sup> and in those with low ejection fraction,<sup>27</sup> functional status is linked partly to the ventricular capacity for diastolic distention and preload recruitment during exertion. Konstam and associates<sup>27</sup> observed that among patients with low ejection fraction, diastolic distention during exercise, accompanied by associated stroke volume augmentation, distinguishes asymptomatic patients from those with symptoms of heart failure. Therefore, in both patients with heart failure and low ejection fraction and those with heart failure and more normal ejection fraction, the myocardium and left ventricle function abnormally during both systole and diastole. Ejection fraction in patients with chronic heart failure, rather than signifying distinct pathophysiological processes, principally distinguishes the pattern of hypertrophic left ventricular remodeling: hypertrophic cavity dilation versus hypertrophic concentric thickening without cavity dilation.

## DISTINGUISHING FLUID RETENTION FROM ABNORMALITIES IN VENTRICULAR PERFORMANCE

The clinical syndrome of heart failure usually results from both impaired left ventricular performance and circulatory congestion (see Chapter 18). This congestion is aggravated

**FIGURE 41-3** The pyramid of heart failure (HF) in the population and the potential effect of a range of preventive and treatment strategies in lowering age-specific mortality rates. A lifetime of prevention: the case of heart failure. *Circulation* 2002;106:2997-2998.)

## Hypertension and Heart Failure

Considerable evidence from experimental and clinical studies and epidemiological investigations indicates the critical role of hypertension in the pathogenesis of heart failure (see Chapter 28). Elevated levels of diastolic and especially systolic blood pressure are major risk factors for the development

of heart failure.<sup>28,29</sup> Also, hypertension is frequently accompanied by metabolic risk factors and obesity, which themselves increase the risk of heart failure. On the basis of the 44-year follow-up data of the Framingham Heart Study, 75% of patients with heart failure have antecedent hypertension.<sup>1,9</sup> The population attributable risk for heart failure associated with hypertension is 39% in men and 59% in women.<sup>28</sup> Because nearly 33% of adults in the United States have hypertension,<sup>30</sup> strategies to control blood pressure are an integral part of any effort to prevent heart failure.

Both acute and chronic hypertension have been linked to the risk of heart failure. Sudden elevation of blood pressure (such as in hypertensive emergencies) can lead to acute left ventricular strain and acute heart failure<sup>31</sup> and is a common precipitating cause for decompensation in a patient with chronic heart failure.<sup>32</sup> Progression from chronic hypertension to structural ventricular changes and then to asymptomatic diastolic and systolic ventricular dysfunction is well established by natural history investigations in longitudinal epidemiological cohort studies, such as the Framingham Heart Study.<sup>28</sup>

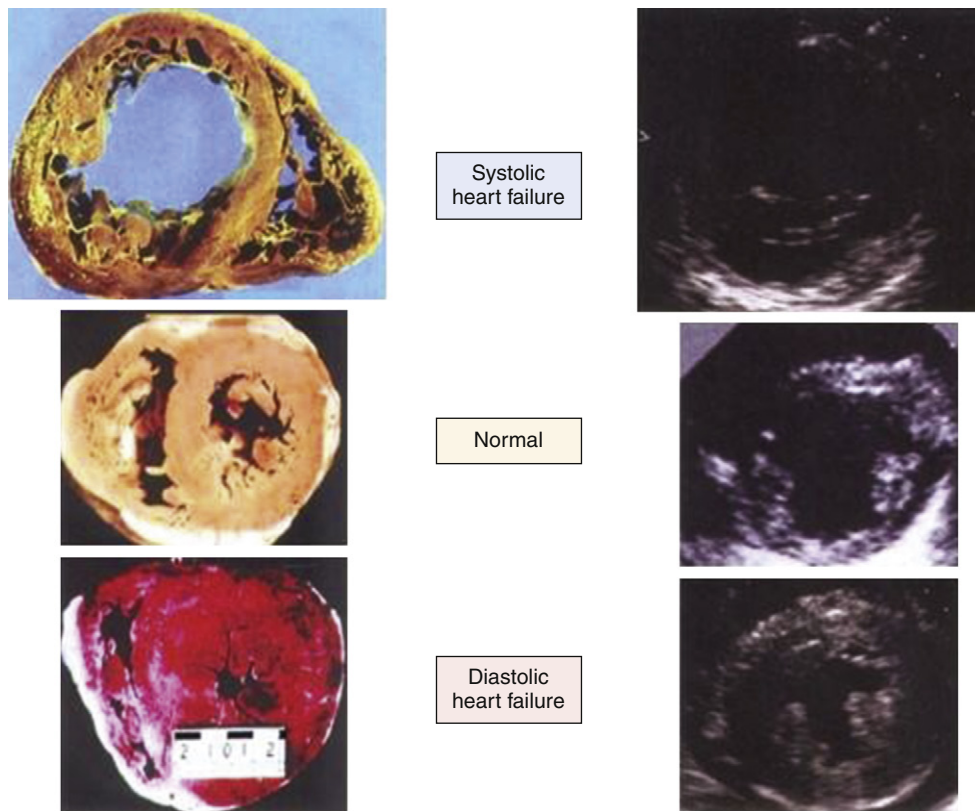

Elevated blood pressure places greater hemodynamic burden on the myocardium and leads to left ventricular hypertrophy<sup>33,34</sup> (Figure 41-6). Left ventricular hypertrophy is associated with increased myocardial stiffness and decreased compliance, initially during exercise and subsequently at rest.<sup>35-37</sup> The initial concentric hypertrophy (thick wall, normal chamber volume, and high mass-to-volume ratio) helps keep wall tension normal despite high intraventricular pressure (Figure 41-7). Because systolic stress (afterload) is a major determinant of ejection performance, normalization of systolic stress helps maintain a normal stroke volume despite the need to generate high levels of systolic pressure.<sup>38</sup>

Because the impedance load facing the left ventricle is dependent on pressure at all pressure levels, the benefit of lowering this vascular load may be demonstrated in all

**FIGURE 41-4** Relationship between left ventricular end-diastolic volume and ejection fraction (EF) at three levels of cardiac index and at a constant heart rate of 70 beats/minute. In chronic heart failure, a low EF indicates little about contractility or left ventricular load; it mostly identifies a left ventricle that has remodeled with dilation. (From Konstam MA. "Systolic and diastolic dysfunction" in heart failure? Time for a new paradigm. *J Card Fail* 2003;9:1-3.)

**FIGURE 41-5** Ventricular remodeling in systolic and diastolic heart failure. *Left*, Autopsy samples; *right*, cross-sectional 2-dimensional echocardiographic views of systolic (*top*) and diastolic (*bottom*) heart failure, in comparison with normal heart function (*middle*). In systolic heart failure, the left ventricular cavity is markedly dilated, and wall thickness is not increased. In diastolic heart failure, the cavity size is normal or decreased, and wall thickness is markedly increased. (From Chatterjee K, Massie B. Systolic and diastolic heart failure: differences and similarities. *J Card Fail* 2007;13:569-576.)

patients with left ventricular dysfunction, regardless of the absolute pressure level. Furthermore, changes in brachial artery pressure may not serve as an adequate guide to reductions in impedance load on the left ventricle. Constriction and stiffening of small arteries at branch points and in the microcirculation augment reflected waves that may impose a late systolic aortic pressure load on left ventricular emptying that is not detectable in the arm. Therapy that relaxes these small arteries may therefore exert a greater benefit than is apparent from standard blood pressure measurement. In addition, however, some of the benefits of antihypertensive therapy on the development of heart failure may be mediated by nonpressure mechanisms. Improved endothelial function may favorably affect coronary perfusion, and some drugs may inhibit structural changes in the left ventricle independent of pressure reduction.

Aggressive control of blood pressure is the most effective approach to reduce the incidence of heart failure in a hypertensive population.<sup>39</sup> A number of clinical trials have demonstrated the benefit of treating hypertension in the prevention of heart failure (see also Chapter 28).<sup>40-44</sup> Primary prevention trials have demonstrated up to a 50% reduction in the incidence of heart failure in patients with hypertension who are treated with blood pressure-lowering agents.<sup>45,46</sup> The Hypertension in the Very Elderly trial achieved a 64% relative risk reduction in heart failure with the diuretic indapamide, with or without the angiotensin-converting enzyme (ACE) inhibitor perindopril (Figure 41-8).<sup>47</sup>

**FIGURE 41-6** Prevalence of left ventricular hypertrophy (LVH), demonstrated by echocardiography (ECHO), as a function of 30-year average systolic blood pressure (SBP). (From Lauer MS, Anderson KM, Levy D. Influence of contemporary versus 30-year blood pressure levels on left ventricular mass and geometry: the Framingham Heart Study. *J Am Coll Cardiol* 1991;18:1287-1294.)

Inhibition of the renin-angiotensin system with ACE inhibitors or angiotensin receptor blockers (ARBs) appears to exert a greater benefit on left ventricular hypertrophy and remodeling than would be predicted from their pressure-lowering effect. Their effectiveness in reducing morbid events in nonhypertensive patients with atherosclerotic disease may involve pressure-independent as well as pressure-dependent mechanisms.<sup>48,49</sup>

$\beta$ -Blockers are also effective in preventing heart failure in hypertensive patients, partly through pressure reduction and partly through inhibition of structural remodeling of the left ventricle. Diuretic therapy also is effective in preventing heart failure, not only through blood pressure reduction but also by intravascular volume contraction, which reduces the risk of congestion. Diuretics are not known to affect remodeling directly. Calcium channel antagonists, especially amlodipine, contribute to prevention of heart failure by their powerful vascular effects that reduce blood pressure and diminish reflected waves. These drugs probably do not directly inhibit left ventricular remodeling. The failure of  $\alpha$ -blockers to prevent heart failure or to slow its progression is consistent with the lack of effectiveness of these drugs in inhibiting structural cardiac remodeling.

## Diabetes Mellitus and Heart Failure (see Chapter 26)

The number of patients with diabetes mellitus continues to rise in industrial societies, mainly because of changes in lifestyle (excessive calorie and fat intake and decreased physical activity). Among Americans 20 years of age or older, 9.6% have diabetes, and among those 60 years of age or older, 21% have diabetes mellitus.<sup>1</sup> Since 1990, the prevalence of patients with a diagnosis of diabetes increased 61%.<sup>50</sup> Data from the Framingham Heart Study indicate a doubling in the incidence of diabetes since 1980, most dramatically during the 1990s. Most of the increase in absolute incidence of diabetes occurred in individuals with a body mass index (BMI) of 30 kg/m<sup>2</sup> or higher.<sup>51</sup> Researchers at the Mayo Clinic found that the prevalence of diabetes increased 3.8% per year since 1990. Among patients in whom heart failure was first diagnosed in 1999, the odds of having diabetes were nearly four times higher than for those with heart failure diagnosed 20 years earlier.<sup>52</sup> Worldwide, the prevalence of diabetes for all age groups was estimated to be 2.8% in 2000 and is projected to be 4.4% in 2030.<sup>53</sup> The total number of people with diabetes mellitus is projected to rise from 171 million in 2000 to 366 million in 2030.<sup>53</sup> In developing nations, the prevalence of diabetes is expected to increase between 2000 and 2010; rates in African and Asian countries are projected to rise by two to three times their current levels.<sup>54,55</sup>

Diabetes and insulin resistance are important risk factors for the development of heart failure.<sup>56</sup> The presence of

**FIGURE 41-7** LaPlace's law. The larger the vessel radius (R) is, the higher the wall tension (T) must be to withstand a given internal fluid pressure (P). For a given vessel radius and internal pressure, a spherical vessel has half the wall tension of a cylindrical vessel.

clinical diabetes mellitus markedly increases the likelihood of heart failure in patients without structural heart disease<sup>57</sup> and adversely affects the outcomes of patients with established heart failure.<sup>58,59</sup> In a study of patients with type 2 diabetes mellitus, older than 50 years, and whose urinary albumin was greater than 20 mg/L, 4% of patients developed heart failure over the study period, of whom 36% died.<sup>60</sup> The Framingham Heart Study showed that the prevalence of heart failure was twice as high among diabetic men and five times as high among diabetic women aged between 45 and 74 years as in age-matched nondiabetic controls.<sup>61</sup> After the age of 65 years, the association became even stronger, with a fourfold higher prevalence in diabetic men and an eightfold higher prevalence in diabetic women.<sup>61</sup> A study of the predictors of heart failure among women with coronary disease revealed that diabetes was the strongest risk factor.<sup>62</sup> Diabetic women with elevated BMI or depressed creatinine clearance were at highest risk. Diabetic patients with fasting blood glucose levels higher than 300 mg/dL had an adjusted risk of developing heart failure three times higher than that of diabetic patients with controlled fasting blood glucose levels.<sup>62</sup>

The occurrence of heart failure represents a major and adverse prognostic turn in a diabetic patient's life. Heart failure is the most common admission diagnosis for diabetic patients, and more than one third of patients with type 2 diabetes die of heart failure.<sup>61,63-65</sup> Of patients requiring hospitalization for heart failure in the United States, 44% have diabetes; this percentage seems to be increasing with time.<sup>66</sup> In a community-based cohort of 665 subjects with heart failure in Olmsted County, Minnesota, the 5-year survival rate was 46% among patients with heart failure alone but only 37% among those with heart failure and diabetes mellitus.<sup>52</sup>

The basic reason for the increased prevalence of heart failure among diabetic patients is the presence of a distinct diabetic cardiomyopathy that is structurally characterized by cardiomyocyte hypertrophy, microangiopathy, endothelial dysfunction, and myocardial fibrosis.<sup>18,67</sup> At the cellular level, diabetic cardiomyopathy is associated with defects in

subcellular organelles and downregulation of catecholamine receptors as a result of chronically elevated catecholamine levels.<sup>68,69</sup> Also, in animal models with the onset of hyperglycemia, changes in myocardial calcium transportation and alterations in contractile proteins occur, both of which lead to systolic and diastolic dysfunction that worsens as the collagen content of the myocardium increases.<sup>68,70,71</sup> Doppler imaging studies have been used to provide load-independent assessments of cardiac relaxation. These studies not only have confirmed evidence of diastolic dysfunction in asymptomatic patients with diabetes but also have demonstrated a direct relationship between the extent of diastolic dysfunction and glycemic control (Figure 41-9).<sup>72</sup> Although diastolic dysfunction is the hallmark of diabetic cardiomyopathy, concomitant subtle systolic dysfunction is present even at earlier stages of the disease.<sup>63</sup>

Although neither the Diabetes Control and Complications Trial in type 1 diabetes nor the U.K. Prospective Diabetes Study (UKPDS) in type 2 diabetes showed a reduction in cardiovascular events with intensive glycemic control,<sup>73,74</sup> a prospective, observational component of UKPDS revealed a continuous relationship between glycemic exposure and the development of heart failure with no threshold of risk, so that for each 1% absolute reduction in glycosylated hemoglobin (HbA<sub>1c</sub>), there was an associated 16% decrease in hospitalization for heart failure (Figure 41-10).<sup>75</sup> Similar findings were also reported in a large cohort study in the United States.<sup>76</sup> Another study revealed that fasting glucose levels are predictive of hospitalizations for congestive heart failure, with a 10% increase in the risk of heart failure–related hospitalization for each 18-mg/dL (1-mmol) increase in fasting glucose level.<sup>77</sup>

Attaining optimal glycemic control should be a goal in both the prevention and treatment of heart failure in patients with diabetes. The Action to Control Cardiovascular Risk in Diabetes (ACCORD) study indicated a previously unrecognized harm of intensive glucose lowering in patients with type 2 diabetes at high risk<sup>78</sup>; however, these results were not confirmed in the Action in Diabetes and Vascular disease: PreterAx and DiamicroN-MR Controlled Evaluation (ADVANCE) trial<sup>79</sup> and should not necessarily be interpreted as diminishing the importance of glycemic control.<sup>80</sup>

**FIGURE 41-8** Kaplan-Meier estimates of the rate of heart failure according to study group in the Hypertension in the Very Elderly trial. For subjects receiving active treatment, in comparison with those receiving placebo, the unadjusted hazard ratio was 0.36 (95% confidence interval, 0.22 to 0.58). (From Beckett NS, Peters R, Fletcher AE, et al. Treatment of hypertension in patients 80 years of age or older. *N Engl J Med* 2008;358:1887-1898.

**FIGURE 41-9** Relationship between glycosylated hemoglobin (HbA<sub>1c</sub>) and left ventricular diastolic function in patients with type 1 diabetes and without overt heart failure ( $r = .68$ ,  $P < .0002$ ).  $E/E_M$  = relation of peak early diastolic transmitral flow (E) to myocardial relaxation velocity during early diastole ( $E_M$ ). (From Shishehbor MH, Hoogwerf BJ, Schoenhagen P, et al. Relation of hemoglobin A<sub>1c</sub> to left ventricular relaxation in patients with type 1 diabetes mellitus and without overt heart disease. *Am J Cardiol* 2003;91:1514-1517, 1519.)

Association of glycaemia with macrovascular and microvascular complications of type 2 diabetes (UKPDS 35): prospective observational study. *BMJ* 2000;321:405-412.)

The choice of oral hypoglycemic agent that may be used is restricted. For instance, metformin is contraindicated in the presence of either heart failure or renal impairment, and precautions also apply to the use of the thiazolidinediones.<sup>81,82</sup> In addition to treating hyperglycemia, it is crucial to control all other cardiovascular and metabolic risks and to prevent complications in patients with diabetes. ACE inhibitors or ARBs can prevent the development of end-organ disease and the occurrence of clinical events in diabetic patients, even in those who do not have hypertension.<sup>48,83</sup> Long-term treatment with several ACE inhibitors or ARBs has been shown to decrease the risk of renal disease in diabetic patients,<sup>84,85</sup> and prolonged therapy with the ACE inhibitor ramipril has been shown to lower the likelihood of heart failure, myocardial infarction, and cardiovascular death.<sup>48</sup> Likewise, the use of ARBs in patients with diabetes mellitus and hypertension or left ventricular hypertrophy has been shown to reduce the incidence of first hospitalization for heart failure, in addition to having other beneficial effects on renal function.<sup>86-88</sup>

### Atherosclerotic Disease and Heart Failure (see Chapter 23)

Patients with known atherosclerotic disease (e.g., of the coronary, cerebral, or peripheral blood vessels) are at increased risk of developing heart failure. The role of coronary artery disease and myocardial infarction as a major antecedent of heart failure has been well established.<sup>89,90</sup> Both in Europe and in the United States, coronary artery disease has been reported to be the most common cause of heart failure.<sup>91,92</sup> Autopsy series indicate that 33% of patients with heart failure have prevalent but undetected major coronary artery disease.<sup>93</sup> Even in patients with heart failure classified clinically as “nonischemic cardiomyopathy,” up to 25% may have evidence of coronary artery disease at autopsy.<sup>94</sup> Indeed, patients with “nonischemic cardiomyopathy” may develop clinical ischemic events, which suggests that coronary artery disease may not be just an “innocent bystander” in these patients.<sup>95</sup> The presence of underlying coronary artery disease contributes to the morbidity and mortality of patients with heart failure.<sup>96</sup> In addition to epicardial disease, microvascular coronary disease is also both widespread and often underrecognized.<sup>97</sup> Clinically silent coronary atherosclerosis is highly prevalent in the general population,

including children and young adults.<sup>98,99</sup> These data suggest that coronary atherosclerotic disease (epicardial or microvascular, clinically overt or silent) can lead to acute or chronic ischemia, thereby predisposing to left ventricular dysfunction and symptomatic heart failure. According to the 2008 update of heart disease and stroke statistics,<sup>1</sup> the proportions of persons with a first myocardial infarction who develop heart failure in 5 years are 7% of men and 12% of women at 40 to 69 years of age and 22% of men and 25% of women at 70 years of age or older.

The risk of coronary artery disease and myocardial infarction can be reduced by modification of classic risk factors (e.g., controlling hypertension).<sup>45,46</sup> The risk factors can be modified favorably through lifestyle changes, including reduction of weight and cessation of tobacco use. Several large trials of patients with myocardial infarction have shown a reduction in the incidence of heart failure with several treatment strategies.<sup>100-104</sup> ACE inhibitors reduce incidence of heart failure by 23% among patients who have coronary artery disease and normal systolic function and by 37% among patients who have reduced left ventricular systolic function.<sup>45</sup> In one large-scale trial, long-term treatment with an ACE inhibitor decreased the risk of the primary endpoint of cardiovascular death, myocardial infarction, and stroke among patients with high-risk established vascular disease who had no evidence of heart failure or of reduced left ventricular ejection fraction at the time of randomization, but the incidence of new heart failure was not a primary or secondary endpoint.<sup>48</sup> Among patients with stable coronary artery disease and no heart failure, another ACE inhibitor significantly reduced the incidence of death, myocardial infarction, or cardiac arrest.<sup>105</sup> A more recent large trial of ACE inhibition versus placebo failed to show a reduction in the primary composite endpoint, although a post hoc analysis did show some reduction in hospitalization for heart failure.<sup>106</sup>

Observational studies and small clinical investigations have suggested that hydroxymethylglutaryl-coenzyme A reductase inhibitors (statins) may be beneficial in patients with ischemic and nonischemic heart failure.<sup>107-110</sup> The first prospective randomized clinical outcome trial with statins that focused specifically on heart failure, Controlled Rosuvastatin in Multinational Trial in Heart Failure (CORONA), demonstrated no significant differences in the primary composite endpoint of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke.<sup>111</sup> The role of statins in heart failure thus remains uncertain, and additional trials may be needed to resolve this uncertainty.

### Metabolic Syndrome and Heart Failure (see Chapter 20)

The term “metabolic syndrome” refers to a cluster of risk factors for cardiovascular disease and type 2 diabetes mellitus. According to the National Cholesterol Education Program Adult Treatment Panel III, metabolic syndrome is diagnosed when three or more of the following five risk factors are present<sup>112</sup>: (1) fasting plasma glucose of 100 mg/dL or higher; (2) high-density lipoprotein (HDL) cholesterol level lower than 40 mg/dL in men or lower than 50 mg/dL in women; (3) triglyceride levels of 150 mg/dL or higher; (4) waist circumference of 102 cm or more in men or 88 cm or more in women; and (5) systolic blood pressure of 130 mm Hg or higher or diastolic blood pressure of 85 mm Hg or higher, or the presence of drug treatment for hypertension. The prevalence of metabolic syndrome reaches epidemic levels and ranges from 6.7% among people 20 to 29 years of age to 43.5% for people 60 to 69 years of age and 42.0% for those 70 years of age or older.<sup>113,114</sup> The age-adjusted prevalence of metabolic syndrome is similar for men (24.0%) and women (23.4%).<sup>113</sup>

**FIGURE 41-11** Mortality rates among adults in the United States, 30 to 75 years of age, with metabolic syndrome (MetS), with and without diabetes mellitus (DM) and preexisting cardiovascular disease (CVD). CHD, coronary heart disease; w/, with; w/o, without. (From Malik S, Wong ND, Franklin SS, et al. Impact of the metabolic syndrome on mortality from coronary heart disease, cardiovascular disease, and all causes in United States adults. *Circulation* 2004;110:1245-1250.)

Although the designation of metabolic syndrome as a unique pathophysiological condition and as a predictor of disease has been questioned,<sup>115</sup> most clinicians and researchers have long maintained that certain metabolic risk factors are prone to occur in clusters and that this clustering increases the risk of diabetes,<sup>116</sup> heart failure,<sup>117</sup> and overall cardiovascular morbidity and mortality.<sup>118</sup> According to the National Health and Nutrition Examination Survey (NHANES) data, people who did not have metabolic syndrome had the lowest risk for cardiovascular events, those with metabolic syndrome had an intermediate level of risk, and those with diabetes mellitus had the highest risk (Figure 41-11).<sup>119</sup>

Mechanisms underlying elevated cardiovascular risk associated with metabolic syndrome appear to involve subclinical organ damage.<sup>120</sup> Among patients with hypertension but without diabetes, those with metabolic syndrome seem more likely to have microalbuminuria, left ventricular hypertrophy, and increased carotid intima thickness than did those without metabolic syndrome.<sup>120</sup> In addition, the greater the number of metabolic syndrome components present, the more severe were the microalbuminuria and left ventricular hypertrophy.<sup>120</sup> Alterations in metabolic pathways, inflammatory reactions, and other cellular processes may increase the risk of atherosclerosis in the insulin-resistant state. For example, there is growing evidence for cellular interactions between signaling pathways involved in actions of insulin and the renin-angiotensin system.<sup>121,122</sup> Nuclear peroxisome proliferator-activated receptors (PPARs) also appear to play a role in the atherogenic mechanisms underlying metabolic syndrome. The PPARs regulate the expression of a variety of genes, and they modulate lipid metabolism, glycemic control, and vascular inflammation and tone.<sup>123</sup> Modulation of PPAR-related actions by cardiovascular risk factors, such as obesity and overweight, can lead to promotion of atherosclerotic disease.<sup>123</sup>

Treatment of metabolic syndrome consists of aggressive management of each of its individual components, including impaired fasting glucose concentration, dyslipidemia, and hypertension. The Diabetes Prevention Program Research Group evaluated the benefits of lifestyle intervention (weight loss and increased physical activity) in comparison with the antihyperglycemic agent metformin for prevention of diabetes in persons with elevated fasting and postload glucose concentrations.<sup>124</sup> Both treatments decreased the incidence of new-onset diabetes, but

lifestyle intervention led to a 39% lower incidence of diabetes than did metformin treatment ( $P < .001$ ).<sup>124</sup> Despite public education programs urging adults and children to modify lifestyles by including healthy food choices and more physical activity, most Americans do not follow recommended dietary or exercise guidelines for maintaining health.<sup>125</sup> An analysis of data from more than 153,000 U.S. adults included in the Behavioral Risk Factor Surveillance System revealed that only 3% of adults followed a healthy lifestyle.<sup>125</sup> Moreover, almost 10% followed no weight, dietary, or smoking recommendations.<sup>125</sup>

Drugs targeting PPAR- $\alpha$  (e.g., fenofibrate and gemfibrozil) are used in the treatment of metabolic syndrome. Fibrates decrease triglyceride level, increase HDL cholesterol, and may have some anti-inflammatory effects; however, their effect on cardiovascular disease outcomes continues to be evaluated.<sup>126</sup> Among patients with impaired glucose tolerance and cardiovascular disease or risk factors, the use of the angiotensin-receptor blocker valsartan along with lifestyle modification led to a relative reduction of 14% in the incidence of diabetes but did not reduce the rate of cardiovascular events.<sup>127</sup> A number of other trials are currently in progress to determine the most effective intervention for patients with the metabolic syndrome.<sup>128</sup>

## Obesity and Heart Failure (see Chapter 20)

Obesity continues to be a leading public health concern in the United States.<sup>129,130</sup> The trend toward increasing obesity in this country is alarming.<sup>131</sup> Between 1980 and 2002, the prevalence of obesity doubled among adults aged 20 years or older, and the prevalence of overweight tripled in children and adolescents aged 6 to 19 years.<sup>132,133</sup> The age-adjusted prevalence of overweight and obesity ( $\text{BMI} \geq 25 \text{ kg/m}^2$ ) increased from 64.5% in the period 1999 to 2000 to 66.3% in the period 2003 to 2004. The prevalence of obesity ( $\text{BMI} \geq 30 \text{ kg/m}^2$ ) increased during this period from 30.5% to 32.2%. Extreme obesity ( $\text{BMI} \geq 40.0 \text{ kg/m}^2$ ) increased from 4.7% to 4.8%.<sup>133</sup> The World Health Organization estimates that by 2015, the number of overweight people globally will increase to 2.3 billion, and more than 700 million will be obese.<sup>1</sup> Once considered problems only in high-income countries, overweight and obesity are now dramatically on the rise in low- and middle-income countries, particularly in urban settings.<sup>1</sup>

In several studies, BMI has been evaluated as a risk factor for left ventricular remodeling and overt heart failure. In these investigations, obesity has been associated consistently with left ventricular hypertrophy and dilation,<sup>134-137</sup> which are known precursors of heart failure.<sup>138,139</sup> In the Framingham Heart Study population, overweight and lesser degrees of obesity were associated with an increased risk of heart failure (Figure 41-12).<sup>140</sup> Extreme obesity has also been associated with heart failure.<sup>141</sup> Excess body weight is a strong predictor of mortality<sup>142-144</sup> and is associated with a significant increase in the risk of stroke.<sup>145</sup> Some investigators claim, and rightly so, that if the prevalence of obesity remains unchecked in the United States, the favorable trends in cardiovascular disease morbidity and mortality will probably be reversed.<sup>146</sup>

There are several plausible mechanisms for the association between obesity and heart failure. Increased BMI is a risk factor for hypertension,<sup>147</sup> diabetes mellitus,<sup>147,148</sup> and dyslipidemia,<sup>131</sup> all of which augment the risk of myocardial infarction,<sup>149,150</sup> an important antecedent of heart

failure.<sup>29,57,151,152</sup> In addition, hypertension and diabetes mellitus independently increase the risk of heart failure.<sup>28,29,57,151,152</sup> Elevated BMI is associated with altered left ventricular remodeling,<sup>134-138</sup> possibly as a result of increased hemodynamic load,<sup>153,154</sup> neurohormonal activation,<sup>155</sup> and increased oxidative stress.<sup>155,156</sup> Adipose tissue acts as an endocrine organ, secreting hormones and other substances that create a proinflammatory state and promote formation of atherosclerotic plaques.<sup>157</sup> Recently, Zhou and colleagues<sup>158</sup> raised the possibility of a direct effect of obesity on the myocardium by demonstrating cardiac steatosis and lipooapoptosis in an animal model of obesity.

Efforts to promote optimal body weight are likely to have an effect on a number of manifestations of cardiovascular disease, including heart failure. A number of strategies have been used to treat obesity, including diet, exercise, behavior therapy, medications, and surgery. To select among these treatments, clinicians must evaluate the obesity-related risks to the individual patient and balance those risks against any

**FIGURE 41-12** Cumulative incidence of heart failure according to category of body mass index at the baseline examination. The body mass index was 18.5 to 24.9 in normal subjects, 25.0 to 29.9 in overweight subjects, and 30.0 or more in obese subjects. (From Kenchaiah S, Evans JC, Levy D, et al. Obesity and the risk of heart failure. *N Engl J Med* 2002;347:305-313.)

possible problems with the treatment. Because all medications inherently carry more risks than do diet and exercise, medications should be chosen only for people in whom the benefit justifies the risk.<sup>159</sup> This process of evaluation is particularly important because drug treatment for obesity has been tarnished by a number of problems over the years. Since the introduction of thyroid hormone to treat obesity in 1893, almost every drug that has been tried in obese patients has caused such undesirable outcomes that it had to be terminated. Thus, any new drug for the treatment of obesity must be used cautiously unless the safety profile would make it acceptable for almost everyone. If an individual is to lose weight, he or she must enter a state of negative energy balance, in which the energy taken in as food is less on average than the energy needed for daily activities. Comparatively few drugs are currently available for the treatment of overweight patients.<sup>159-162</sup> Medications for promoting weight loss are indicated primarily as an adjunct in patients who are unresponsive to nonpharmacological methods and who are at substantial medical risk because of their obesity.<sup>163</sup> Gastric bypass surgery is an option in cases of obesity that is highly refractory to therapeutic intervention and in which BMIs are above 40 kg/m<sup>2</sup>. One study attested to the benefits of bypass in selected patients, demonstrating a significant reduction in cardiovascular, cancer, diabetes, and all causes of death.<sup>164</sup>

## Chronic Obstructive Pulmonary Disease and Heart Failure

Although precise statistics on the prevalence of COPD are surprisingly scanty, it is estimated that approximately 14 million people in the United States have this condition.<sup>165</sup> COPD is now the fourth leading cause of death in the United States, and it is the only common cause of death whose incidence is increasing.<sup>165</sup> The importance of COPD as a cause of death is probably underestimated, inasmuch as COPD is probably a contributor to other common causes of death. The prevalence of and rates of mortality from COPD are also increasing.<sup>166</sup> The World Health Organization predicts that by 2020, COPD will be the fifth most prevalent disease worldwide and the third most common cause of death.<sup>167</sup> Reasons for the dramatic increase in COPD include reductions in mortality from other causes, such as cardiovascular diseases in industrialized countries and infectious diseases in developing countries, along with a marked increase in cigarette smoking and environmental pollution in developing countries.<sup>165</sup>

The risk ratio of developing heart failure in patients with COPD is 4.5, in comparison with age-matched controls without COPD, after adjustments for cardiovascular risk factors.<sup>168</sup> Among the comorbid conditions commonly associated with heart failure, COPD is the one that most delays the diagnosis of heart failure and is most often blamed for nonadherence to therapeutic guidelines, especially  $\beta$ -blockade.<sup>169</sup> The rate-adjusted hospital prevalence of heart failure is three times greater among patients discharged with a diagnosis of COPD than among patients discharged without mention of COPD.<sup>170</sup> The Kaiser Permanente Medical Program reported that the age-adjusted relative rate of hospitalization for heart failure was 5.55 and the odds ratio of heart failure as a comorbid condition was 8.48 in COPD patients, in comparison with persons without COPD.<sup>171</sup> The prevalence of COPD ranges from 20% to 32% among patients with heart failure.<sup>172-176</sup> Patients with heart failure and concomitant COPD have more symptoms and worse outcomes that are not explained by poorer left ventricular function (Figure 41-13).<sup>177</sup>

The relationship between COPD and heart failure remains to be elucidated. A working hypothesis to account for the high prevalence of left ventricular systolic dysfunction in patients with COPD is that low-grade systemic inflammation

**FIGURE 41-13** Kaplan-Meier curves of death among the 5010 patients enrolled in the Valsartan Heart Failure Trial according to the presence or absence of chronic obstructive pulmonary disease (COPD). (From Staszewsky L, Wong M, Masson S, et al. Clinical, neurohormonal, and inflammatory markers and overall prognostic role of chronic obstructive pulmonary disease in patients with heart failure: data from the Val-HeFT heart failure trial. *J Card Fail* 2007;13:797-804.)

in COPD accelerates progression of coronary atherosclerosis, which ultimately results in ischemic cardiomyopathy. Such a hypothesis is based on the fact that patients with COPD have higher elevation of inflammatory markers,<sup>177,178</sup> and it fits the clinical observation of a higher incidence of troponin elevation<sup>177</sup> and left ventricular wall motion abnormalities<sup>179</sup> noted in patients with COPD and left ventricular dysfunction. Patients with heart failure and concomitant COPD have higher activation of neurohormones, particularly norepinephrine and plasma renin.<sup>177</sup> COPD may also lead to right ventricular failure from pulmonary hypertension, a common complication of COPD.<sup>180</sup> The cause of pulmonary hypertension in COPD is generally assumed to be hypoxic pulmonary vasoconstriction, which leads to permanent medial hypertrophy.<sup>180</sup>

Although bronchodilators, corticosteroids, and antibiotics in the treatment of acute exacerbations constitute the mainstay of current drug therapy for COPD,<sup>165</sup> smoking cessation is the only strategy that prevents the relentless progression of airflow obstruction<sup>181</sup> and improves the long-term survival in the COPD population.<sup>182</sup> Long-term oxygen therapy was also shown to reduce mortality and improve quality of life in patients with severe COPD and chronic hypoxemia (partial pressure of arterial oxygen <55 mm Hg).<sup>183</sup> The presence of COPD affects the treatment of heart failure, inasmuch as COPD is still viewed as a contraindication to  $\beta$ -blockade. Therefore, patients with heart failure caused by left ventricular systolic dysfunction who also have COPD are often deprived of the most beneficial pharmacological intervention. A large body of data indicates that patients with COPD may tolerate selective  $\beta$ -blockade, and these medications should not necessarily be denied to patients with heart failure and concomitant COPD.<sup>173</sup>

## Rheumatoid Arthritis and Heart Failure

Rheumatoid arthritis is a chronic systemic inflammatory and progressive disease characterized by persistent inflammatory synovitis, joint destruction, and increased mortality.<sup>184,185</sup> Cardiovascular disease has been identified as the underlying cause of a substantial proportion of deaths among patients with rheumatoid arthritis.<sup>186</sup> Heart failure is an important contributory cause of cardiovascular disease—associated

death in patients with rheumatoid arthritis.<sup>187</sup> This excess mortality results primarily from the increased incidence of heart failure among patients with rheumatoid arthritis in comparison with subjects without rheumatoid arthritis.<sup>187</sup> Nicola and associates<sup>188</sup> studied 575 patients with no history of heart failure at the time rheumatoid arthritis was diagnosed and 583 controls with no rheumatoid arthritis; the relative risk of new-onset heart failure during the subsequent 30 years was 1.9-fold higher among the patients with rheumatoid arthritis after adjustment for age, gender, standard cardiovascular risk factors, and the presence of ischemic heart disease.

The most plausible explanation for the increased risk of heart failure in rheumatoid arthritis is the persistent inflammatory state that characterizes the rheumatic state.<sup>189,190</sup> A distinguishing feature of heart failure in rheumatoid arthritis is that it is far more likely to involve diastolic dysfunction than systolic function.<sup>188</sup> Patients with rheumatoid arthritis have a significantly higher risk of coronary artery disease than do subjects without rheumatoid arthritis.<sup>191</sup> Coronary artery disease in patients with rheumatoid arthritis is characterized by less extensive atherosclerotic plaque and greater evidence of inflammation and plaque instability than in subjects without rheumatoid arthritis.<sup>189</sup> Patients with rheumatoid arthritis are less likely than patients without this condition to report symptoms of angina and more likely to experience unrecognized myocardial infarction and sudden cardiac death.<sup>191</sup>

The issues related to inhibition of tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) are particularly complex. TNF- $\alpha$ , an inflammatory cytokine released by activated monocytes, macrophages, and T lymphocytes, promotes inflammatory responses that are central to the pathogenesis and progression of rheumatoid arthritis.<sup>192</sup> TNF- $\alpha$  is also known to mediate cardiac injury through a variety of biological mechanisms, thus contributing to the progression of heart failure.<sup>193</sup> These observations led to several large randomized controlled trials designed to assess the efficacy of TNF- $\alpha$  inhibitor therapy in the treatment of heart failure. Unfortunately, these efforts were unsuccessful; the trials were stopped prematurely because of lack of efficacy and a suggestion of worsening heart failure in the patients treated with TNF- $\alpha$  inhibitor.<sup>194,195</sup> These data suggested that TNF- $\alpha$  inhibitors may promote or worsen heart failure in patients with rheumatoid arthritis. However, high disease activity and systemic inflammation (typically associated with high levels of circulating cytokines) have consistently been shown to increase cardiovascular risk in rheumatoid arthritis<sup>186,196,197</sup>; therefore, inhibition of TNF- $\alpha$  should reduce heart failure risk in patients with rheumatoid arthritis. Therein lies the dilemma: it is biologically plausible that by dramatically reducing systemic inflammation, treatment with TNF- $\alpha$  inhibitors would result in an overall reduction of heart failure risk; however, it is also possible that these agents increase heart failure risk in persons with rheumatoid arthritis, as they have been suggested to do in the general population.<sup>193</sup> Listing and colleagues, addressing this question,<sup>198</sup> found that TNF- $\alpha$  inhibitor treatment that effectively reduces the inflammatory activity of rheumatoid arthritis is more likely to be beneficial than harmful with regard to the risk of heart failure, especially if patients receive no concomitant therapy with glucocorticoids or cyclooxygenase-2 (COX-2) inhibitors. Furthermore, their data suggested that TNF- $\alpha$  inhibition does not increase the risk of worsening of prevalent heart failure.<sup>198</sup> Unfortunately, although this study offered some useful insights, the results fell short of providing clinically useful guidance and left many questions unanswered.<sup>199</sup> Thus, although TNF- $\alpha$  inhibitors represent a major advance in the treatment of rheumatic disease, their effects on heart failure in rheumatoid arthritis are unknown.

### BOX 41-1 Drugs Associated with Left Ventricular Systolic Dysfunction or Worsening Heart Failure

#### Drugs Causing Left Ventricular Systolic Dysfunction

##### Cytotoxic agents

- Anthracycline
- Trastuzumab

##### Antipsychotics

- Clozapine
- Atypical antipsychotic agents

##### Carbamazepine

##### Tricyclic antidepressants

##### Chloroquine

##### Hydroxychloroquine

##### Interferon- $\alpha$

##### Interleukin-2

##### TNF- $\alpha$ antagonists

#### Drugs Exacerbating Heart Failure

##### NSAIDs

##### COX-2 inhibitors

##### Corticosteroids

##### Thiazolidinediones

##### Calcium channel antagonists

- Non-dihydropyridine agents

##### $\beta$ -Adrenoreceptor antagonists

#### Unproven Associations

##### Doxazosin

##### $\beta_2$ -Adrenoreceptor agonists

COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs; TNF- $\alpha$ , tumor necrosis factor  $\alpha$ .

From Murphy CA, Dargie HJ. Drug-induced cardiovascular disorders. *Drug Saf* 2007;30:783-804.

### Drug-induced Heart Failure

Although heart failure is caused predominantly by cardiovascular conditions such as hypertension, coronary heart disease, and valvular heart disease, it can also be an adverse reaction induced by drug therapy (Box 41-1). Many therapeutic and recreational agents can exert important cardiotoxic effects that lead to left ventricular systolic dysfunction or overt heart failure. Two drug groups are of particular concern: cytotoxic drugs and nonsteroidal anti-inflammatory drugs (NSAIDs). Some drugs may predispose to heart failure by causing hypertension and other cardiovascular risk factors (Box 41-2). In addition, some drugs have the propensity to adversely affect hemodynamic mechanisms in patients with an already existing heart condition. Drugs may cause heart failure by various mechanisms, including direct myocyte injury, alteration of biochemical processes, or stimulation of allergic reactions. The outcome can vary in severity from benign to fatal. Because numerous drugs in various drug classes may precipitate or worsen heart failure, a detailed history of drug exposure in patients with signs or symptoms of heart failure is mandatory.

#### Cytotoxic Drugs (see Chapter 58)

The introduction of doxorubicin in the mid-1900s improved cancer therapy immeasurably. However, it soon became apparent that doxorubicin was associated with significant cardiotoxicity, and this has proved a consistent problem with all subsequent anthracycline preparations. Although rapid-onset left ventricular systolic dysfunction has been reported to follow anthracycline administration,<sup>200</sup> these drugs are

### BOX 41-2 Drugs Associated with Cardiovascular Risk Factors

Drug	Effect
Corticosteroids	Hypertension, dyslipidemia, diabetes mellitus)
Ciclosporin and tacrolimus	Hypertension, dyslipidemia
NSAIDs and COX-2 inhibitors	Hypertension (minimal)
Erythropoietin	Hypertension
Combined oral contraceptives	Hypertension
Venlafaxine	Hypertension
HAART	Hypertension, dyslipidemia

COX-2, cyclooxygenase-2; HAART, highly active antiretroviral therapy; NSAIDs, nonsteroidal anti-inflammatory drugs. (Modified from Murphy CA, Dargie HJ. Drug-induced cardiovascular disorders. *Drug Saf* 2007;30:783-804.)

usually associated with the development of chronic cardiomyopathy many years after their use.

The mechanism of doxorubicin-induced cardiotoxicity involves increased oxidative and nitrosative stress,<sup>201-204</sup> matrix metalloproteinase activation,<sup>205</sup> and alteration of cardiac energetics,<sup>206</sup> which eventually lead to cell death by apoptosis or cell necrosis.<sup>207-209</sup> However, the exact mechanisms have not been fully established. Cardiotoxicity with doxorubicin is dose dependent. The risk is minimized by restricting the cumulative doxorubicin dosage to less than 400 mg/m<sup>2</sup>. Dosages exceeding 550 mg/m<sup>2</sup> have significantly increased rates of cardiomyopathy: the incidence of heart failure has been reported as 18% at dosages between 551 and 600 mg/m<sup>2</sup>, increasing further to 36% at higher doses.<sup>210,211</sup> The expression of COX-2 limits doxorubicin-induced injury in rat cardiomyocytes; this observation may suggest that concomitant use of NSAIDs could constitute a risk for the development of cardiac injury during anthracycline therapy.<sup>212</sup>

Largely because of the antineoplastic efficacy of anthracyclines, cardiotoxicity has not led to withdrawal of these agents from general use. Instead, attempts have been made to identify methods of reducing the cardiac risk. Optimal therapeutic approaches for cardioprotection with the use of anthracyclines remain undefined.<sup>213</sup> Minimizing anthracycline dosage is practiced, as is its co-administration with other cytotoxic drugs tailored to specific tumors.<sup>214</sup> A slower rate of drug infusion seems to result in reduced cardiotoxicity,<sup>215</sup> but the antitumor effect may be compromised. Concomitant administration of antioxidant agents such as dexrazoxane, coenzyme Q10 (ubidecarenone),<sup>216</sup> probucol,<sup>207</sup> and statins may be cardioprotective.<sup>214</sup> Results of one study suggested that CB<sub>1</sub> cannabinoid receptor antagonists may represent a new cardioprotective strategy against doxorubicin-induced cardiotoxicity.<sup>217</sup>

All patients exposed to anthracyclines should be considered at risk of cardiomyopathy, but older age, prior irradiation, concomitant administration of other chemotherapeutic agents, and underlying heart disease heighten this risk.<sup>213,218,219</sup> Cardiac biomarkers, such as troponins and natriuretic peptides, may facilitate risk stratification, but their role is not yet defined.<sup>211</sup> Although some reports of cardiomyopathy regression exist,<sup>220</sup> anthracycline-induced cardiomyopathy should be considered as an irreversible process. There is specific evidence of symptomatic benefit with  $\beta$ -blockers,<sup>221,222</sup> but management is similar to that for any cause of left ventricular systolic dysfunction.

### Trastuzumab (see Chapter 58)

The human epidermal growth factor receptor 2 (HER-2) is a transmembrane tyrosine kinase receptor involved in growth regulation. HER-2 is overexpressed in approximately 20% of breast cancers, and its presence is associated with a poor prognosis. Trastuzumab is a humanized monoclonal antibody that targets the HER-2 receptor and has proven to be very effective in treating these tumors. Unfortunately, there is an independent risk of cardiomyopathy in association with trastuzumab.<sup>223,224</sup> The incidence of heart failure was shown to be 2.6% when trastuzumab was used as first-line monotherapy, rising to 8.5% in second- or third-line monotherapy, which included previous treatment with anthracyclines in a majority of patients.<sup>224</sup> In the protocol in which patients were randomly assigned to receive either trastuzumab or placebo in combination with paclitaxel or an anthracycline, the incidences of heart failure were 4.2% with paclitaxel alone, 8.8% with paclitaxel and trastuzumab, 9.6% with anthracycline alone, and 28.0% with anthracycline and trastuzumab.<sup>224</sup>

The mechanism underlying trastuzumab-induced cardiotoxicity is unknown but has been suggested to represent an exacerbation of anthracycline-induced cardiac effects.<sup>224</sup> Despite cardiotoxic effects, the beneficial therapeutic ratio for trastuzumab in treating HER-2-positive breast cancer is considered a strong rationale for the continuing use of HER-2 antibodies with other treatment modalities in breast cancer.<sup>225</sup> Encouragingly, there is evidence that trastuzumab-induced cardiomyopathy, unlike that induced by anthracyclines, may be reversible on drug cessation,<sup>226,227</sup> although this evidence remains unverified.

### Nonsteroidal Anti-inflammatory Drugs

Renal perfusion is reduced in heart failure, and prostaglandins become increasingly important in controlling renal plasma flow and fluid homeostasis. NSAIDs, however, reduce prostaglandin synthesis, thus decreasing glomerular filtration and resulting in salt and water retention.<sup>214,228</sup> NSAIDs act by inhibiting both COX-1 and COX-2. It was long thought that the analgesic aspect was generated by COX-2 inhibition and that the adverse gastrointestinal effects were mediated by COX-1. This led to the development of selective COX-2 inhibitors, such as celecoxib and valdecoxib. COX-2 inhibitors still have some of the adverse effects observed with NSAIDs: namely, the ability to increase blood pressure and to exacerbate heart failure through salt and water retention.<sup>214,228</sup> Gastrointestinal complications are less common with COX-2 inhibitors,<sup>229</sup> and these drugs were initially thought to be successful. However, soon after their release on the market, it became evident that some COX-2 inhibitors increase the risk of myocardial infarction and stroke.<sup>229-231</sup> A comparison of celecoxib and placebo in adenoma prevention did reveal higher rates of a composite endpoint of myocardial infarction, stroke, and heart failure in patients treated with celecoxib.<sup>232</sup>

Through a number of mechanisms, COX-2 inhibition may increase the risk of cardiovascular events. COX-2 inhibitors can increase systemic blood pressure slightly<sup>233</sup> but may accelerate atherosclerosis through effects on mitochondrial oxidative phosphorylation or monocyte chemotaxis.<sup>234</sup> There is probably also a prothrombotic effect of COX-2 inhibition.<sup>235</sup> Thromboxane is a prothrombotic prostanoid that depends on COX-1 for its production, whereas the production of prostacyclin (epoprostenol), an antithrombotic agent, depends on COX-2. Preferential COX-2 inhibition leads to reduced levels of prostacyclin, with a lesser effect on thromboxane, thereby potentially leading to a prothrombotic state.

Thus, it appears that both NSAIDs and COX-2 inhibitors are associated with a higher risk of cardiovascular events, including heart failure, myocardial infarction, and stroke. Although some COX-2 inhibitors have been withdrawn from

the market, NSAIDs have been available for many years, both by prescription and over the counter. A large number of patients depend on these analgesics to control pain; in the absence of alternative effective treatments, the removal of these drugs from circulation is not a feasible option. In clinical practice, physicians must be aware of the adverse effects of all the medicines they prescribe and, in investigating ill health, must always consider drugs as a cause, particularly when no alternative cause is apparent. On the other hand, a drug with a strong association with a particular cardiovascular adverse effect could be entirely blameless, and alternative causes should not be discounted.

### Thiazolidinediones

The thiazolidinediones rosiglitazone and pioglitazone are oral hypoglycemic agents that have been shown to improve glycemic control and may act to slow the progression of  $\beta$  cell failure.<sup>236</sup> Although improved glycemic control has been linked to better clinical outcomes in diabetes<sup>74,237,238</sup> and thiazolidinediones have been suggested to have potential cardiovascular benefits,<sup>239-242</sup> concerns have arisen with regard to the adverse cardiac effects of these drugs. Use of thiazolidinediones is associated with weight gain and edema,<sup>243</sup> and there is evidence that both rosiglitazone and pioglitazone increase the risk of congestive heart failure.<sup>239,241,244-246</sup> In a population-based study of older patients with diabetes, thiazolidinedione treatment was associated with an increased risk of congestive heart failure, acute myocardial infarction, and mortality in comparison with other combinations of oral hypoglycemic agent treatments.<sup>82</sup> A box warning for congestive heart failure was added for these agents, recommending against the use of thiazolidinediones in persons with preexisting congestive heart failure.<sup>247</sup> Two meta-analyses have also suggested that rosiglitazone may be associated with an increased risk of acute myocardial infarction and death.<sup>245,248</sup>

### Cardiotoxic Effects of Recreational Agents (see Also Chapter 24)

Many recreational agents can exert important cardiotoxic effects predisposing to heart failure. These include tobacco, as well as alcohol, cocaine, amphetamines, and other illicit drugs.<sup>250</sup> Patients should be strongly advised about the cardiovascular hazards of recreational agents.<sup>117</sup> Several epidemiological studies have revealed no correlation between the amount of alcohol ingested and the subsequent development of heart failure; nevertheless, it is strongly believed that any patient with a history of alcohol abuse or with current substantial routine alcohol consumption and new-onset heart failure without other obvious cause should be counseled to become abstinent.<sup>117</sup> Many heart failure programs limit alcoholic beverage consumption to no more than one alcoholic beverage serving daily for all patients with left ventricular dysfunction, regardless of cause.<sup>251,252</sup>

## FUTURE DIRECTIONS

Thus far, research aimed at preventing heart failure in individuals at high risk has been modest in comparison with the extensive efforts at discovering new treatments for patients after heart failure has developed. Because preventive efforts are likely to be applicable to much larger numbers of individuals, such efforts could lead to greater population-level benefits. It is therefore important that strategies of prevention of heart failure be developed that apply to the large number of at-risk individuals. Such a strategy would complement the current approaches that are aimed at intensive management of patients with manifest heart failure. The current knowledge of both prevention and treatment of hypertension, obesity, and atherosclerotic vascular disease has the potential to greatly reduce the incidence and mortality from heart failure.

Future endeavors to reduce heart failure burden must include the prevention of risk factors themselves, not just management of existing risk factors or established disease.

## Pharmacogenomics and Pharmacogenetics in Heart Failure

Dennis M. McNamara and Arthur M. Feldman

Medical therapy for systolic heart failure has evolved significantly since the nineteen eighties. Large randomized and placebo-controlled clinical trials have identified families of pharmacological agents and devices that can improve survival and decrease the frequency of hospitalizations for heart failure among patients in whom systolic dysfunction is diagnosed. As each new study has met the strict requirements of peer review and the new agents have been added to the pharmacopeia, the clinical management of patients has become complex because new drugs have been added to the standard regimen, rather than replacing

and could increase the risk of heart failure, whereas in other cases, the genetic variant was associated with attenuated signaling. These genetic variants include deletions or insertions; the inclusion or exclusion of the coding region of a gene; single-nucleotide polymorphisms that alter the nucleotide sequence within a single nucleotide triplet, which may result in the transcription of a protein with a different amino acid sequence; or mutations that alter a larger segment of the coding region of the gene, resulting in a dysfunctional protein. Variants such as deletions, insertions, single-nucleotide polymorphisms, and larger mutations can also occur in either the 5' regulatory region of the gene or in the region that encodes the 3' untranslated tail. In the former region, the genetic variant can alter the ability of regulatory proteins to bind to the promoter region of the gene, thereby either increasing or decreasing transcription. In contrast, mutations in the 3' untranslated region can alter RNA stability. Thus, a wide array of genotypic abnormalities can influence the amount, the structure, or the function of cardiac proteins that are important in the pathophysiological processes of heart failure.

The analysis of genetic variants in DNA samples was once labor intensive, time consuming, and expensive. However, the burgeoning in genomic technology, particularly silicon chip technology, has enabled scientists to simultaneously identify a large number of genetic variants in a single sample or multiple samples of DNA. This analysis can be performed rapidly, can be automated, and is now relatively inexpensive. However, it requires an a priori knowledge of the nucleotide sequence and gene of interest. In addition, because of the complexity and redundancy of critical pathways, it is unlikely that any single locus will determine therapeutic response, and the key to genomic targeting may be in polygenic analysis involving several loci for any given clinical or therapeutic paradigm.

More recently, investigators have begun to pursue genome-wide association studies (GWASs). This powerful technology enables investigators to identify characteristic markers that can help predict outcomes or response to drugs in a large population; however, these studies do not enable the

older agents. For an African American patient with ischemic cardiomyopathy and class III heart failure, heart failure guidelines recommend treatment with an angiotensin-converting enzyme (ACE) inhibitor, a  $\beta$ -blocker, an aldosterone receptor antagonist, isosorbide dinitrate, hydralazine, aspirin, and a statin. All seven of these therapies are recommended because they have improved survival in similar cohorts with systolic heart failure.

A common finding in all clinical trials has been that each new agent developed for the treatment of heart failure improves outcomes in some but not all patients with heart failure. Attempts to identify which patients will respond to a specific drug or device (or which patients might have an adverse response to a drug or device) initially focused evaluating whether subgroup analysis of predefined phenotypic identifiers—for example, age, gender, ejection fraction, or cause of heart failure—could enable this prediction. These efforts proved fruitless. However, early subgroup analysis of large randomized and multinational studies suggested that an individual's genotype could be used to predict drug response. For example, several studies demonstrated marked differences in drug response among patients from various continents, and another study suggested that patients who self-identified as African American might have had a different response to drug therapy than did patients who self-identified as being non-African American. Thus, investigators began to assess whether an individual's genotype could be used to predict drug response; this evolving area of investigation is referred to as "pharmacogenetics" or "pharmacogenomics." By identifying the genomic factors that are predictive of drug efficacy, this new field of science provides the opportunity to "personalize" care for an individual patient, lower the risk of an adverse response to an unnecessary agent, and decrease overall health care costs.

Studies of pharmacogenomics initially focused on genetic variants in single genes that encoded for drug targets, including receptors, enzymes, and signaling pathways that regulated the action of specific agents that were known to alter the pathobiological processes of heart failure. For example, variants were identified in the ACE gene (see Chapter 9). Mutation of the ACE gene resulted in the transcription of a protein with enhanced enzyme activity, which caused elevations in the levels of angiotensin II, a neurohormone known to contribute to the maladaptive remodeling that characterizes the progression of heart failure. Similarly, variants were also identified in the  $\beta$ -adrenergic receptors, a family of receptors that link the neurohormonal ligands epinephrine and norepinephrine with downstream activation of the neurohormone signaling cascade (see Chapter 10). These variants resulted in the transcription of an adrenergic receptor whose physiological characteristics differed from those of receptors that were transcribed from the wild-type gene. In some cases, the genetic variant increased ligand-receptor coupling

investigator to identify the specific genes that participate in the individual's response to a drug or device. However, these two types of identification are not mutually exclusive, and when used together, they will help increase the understanding of the role of genetics in predicting how drugs work in individual patients.

This chapter reviews the major genomic polymorphisms affecting the pathogenesis of heart failure and therapeutics, and it explores how advances in GWASs may accelerate the advance toward the current goal of “personalized” genomic therapy for the treatment of heart failure.

## RENIN-ANGIOTENSIN-ALDOSTERONE PATHWAY: THERAPEUTICS AND GENOMICS

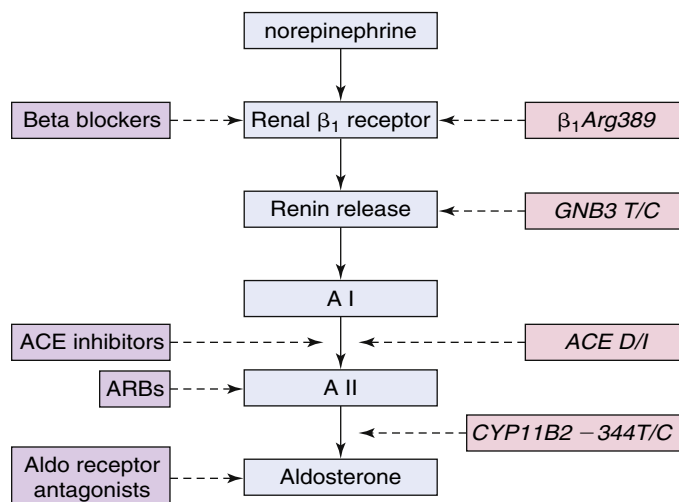

The majority of medical therapies for heart failure that improve survival inhibit the renin-angiotensin-aldosterone systemic (RAAS) pathway (Figure 42-1) (see Chapter 45). Myocardial injury and diminished cardiac function result in sympathetic activation and in the release of the protease renin, which initiates the pathway.  $\beta$ -Blockers, ACE inhibitors, angiotensin receptor antagonists, and aldosterone receptor antagonists all inhibit steps in the RAAS pathway. Functional genomic polymorphisms appear to influence therapy targeted at the RAAS pathway, including  $\beta_1$ -receptor variant 389 Gly/Arg, the ACE allelic deletion/insertion (D/I) polymorphism, the aldosterone synthase promoter polymorphism, and the G protein  $\beta_3$  subunit (GNB3) 894T haplotype (Table 42-1). A review of the functional nature of these polymorphisms, their effect on the pathogenesis of heart failure, and their effects on therapy demonstrates the potential utility of pharmacogenetic analysis.

## THE ANGIOTENSIN-CONVERTING ENZYME DELETION/INSERTION POLYMORPHISM

The ACE deletion/insertion (D/I) biallelic polymorphism of intron 16<sup>1,2</sup> is the polymorphism most extensively studied in cardiovascular disease, and its potential implications for the progression of heart failure have long been recognized.<sup>3</sup> The D allele has been linked to increased activity of ACE, and higher levels of the peptide mediator angiotensin II in multiple clinical situations, including hypertension and post-myocardial infarction status.<sup>4-7</sup> In view of the importance of ACE in the pathogenesis of heart failure, it was predicted that the ACE D allele would be associated with accelerated disease progression and would act as a disease modifier. Indeed, this has been demonstrated in multiple investigations of heart failure.<sup>3,8,9</sup>

### Pharmacogenetics of the ACE D Allele: $\beta$ -Blockers and Angiotensin-Converting Enzyme Inhibitors

The adverse influence of the ACE D allele on survival with heart failure is predicted from the increase in the activity of ACE, which is associated with the deletion. As a result, therapies that directly target and limit angiotensin activation would potentially have more effect in subjects with the ACE D allele. Indeed, the effect of both  $\beta$ -blockers<sup>10</sup> and ACE inhibitors<sup>11</sup> is greatest in patients with heart failure who have the homozygous ACE DD genotype. This was demonstrated in the Genetic Risk Assessment of Cardiac Events (GRACE) study, a prospective investigation of pharmacogenetics and clinical outcomes in systolic heart failure, conducted at the University of Pittsburgh. The effect of the ACE D allele on survival was evident exclusively in subjects not treated with  $\beta$ -blockers<sup>10,11</sup> (Figure 42-2). This pharmacogenetic

**FIGURE 42-1** Renin-angiotensin-aldosterone systemic (RAAS) pathway and site of action of drug therapies and functional polymorphisms. Major pharmacological therapies that improve survival in heart failure (in white boxes:  $\beta$ -blockers, angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], and aldosterone [Aldo] receptor antagonists) all act on RAAS. Major genetic polymorphisms (in gray boxes:  $\beta_1$ -receptor Arg389 variant, G protein  $\beta_3$  subunit [GNB3] T haplotype linked to low plasma renin), ACE D/I [deletion/insertion], and aldosterone synthase [CYP11B2] promoter) influence outcomes and the effects of therapy. A I, angiotensin I; A II, angiotensin II.

interaction of  $\beta$ -blockers and the ACE D allele is mediated through the  $\beta_1$ -receptor<sup>12</sup> and probably reflects the suppression of renin release by  $\beta$ -receptor antagonists.

Although the effect of the ACE D allele was most evident for subjects not taking  $\beta$ -blockers, it could still be eliminated in this subset by treatment with high-dose ACE inhibitors<sup>11</sup> (Figure 42-3). The genetic risk of accelerated progression of heart failure conferred by inheritance of the ACE D allele can therefore be effectively eliminated by pharmacotherapies designed to limit the effects of ACE activity: ACE inhibitors and  $\beta$ -receptor antagonists. The potential for “pharmacogenetic targeting” with this single locus is apparent when the effects of these two therapies is investigated within ACE genotype subsets. The effect of therapy consisting of both ACE inhibitor and  $\beta$ -blocker is predicted according to ACE genotype; the effects are strongest in patients with the ACE DD genotype, intermediate in patients with the heterozygous ACE DI genotype, and minimal in patients with the homozygous ACE II genotype (Figure 42-4).

The adverse influence of the ACE D allele on progression of heart failure and on survival has been consistently demonstrated. In an examination of more than 3000 subjects with hypertension, investigators found poorer survival rates among subjects with the ACE DD genotype.<sup>13</sup> Results of investigation of subjects after myocardial infarction suggested that the D allele is also associated with increased left ventricular remodeling.<sup>14</sup> The mechanism remains linked to angiotensin activation, inasmuch as in subjects with advanced heart failure, the D allele is associated with high serum levels of ACE, angiotensin II, and aldosterone.<sup>15</sup> Not surprisingly, the ACE D/I genotype also appears to be predictive of the time course of blood pressure response to ACE inhibitors but not other to antihypertensives.<sup>16</sup>

Genetic variability in the ACE pathway is not limited to the ACE D/I polymorphisms, and additional RAAS polymorphisms also influence blood pressure response to ACE inhibitors. In a study of more than 1400 hypertensive patients, the effects of ACE inhibitor therapy on blood pressure were linked to polygenetic variation in both the angiotensinogen and angiotensin II receptor genes.<sup>17</sup> In a second study of 450 patients with heart failure, haplotypes of the angiotensinogen gene were associated with poorer outcomes.<sup>18</sup>

**TABLE 42-1 Genetic Polymorphisms and Heart Failure Therapeutics**

Signaling Pathway	Gene (References)	Polymorphism	Functional Significance	Potential Therapeutic Influence
Renin-angiotensin-aldosterone systemic (RAAS) pathway	ACE <sup>8-12</sup>	D/I	ACE D: higher ACE activity and A II levels	ACE inhibitors β-blockers
	Aldosterone synthase (CYP11B2) <sup>49-51</sup>	Promoter-344 T/C	-344 C: increased transcriptional activity and aldosterone production	ACE inhibitors Aldosterone receptor antagonists/I/H
β-Adrenergic receptors	β <sub>1</sub> AR <sup>23-26</sup> β <sub>1</sub> AR <sup>32,33</sup> β <sub>2</sub> AR <sup>34,35</sup>	Arg389Gly Gly49Ser Gly16Arg, Gln27Gly	Arg: increased adrenergic signal Gly: enhanced downregulation Receptor downregulation	β-Blockers ACE inhibitors β-Blockers β-Blockers
α-Adrenergic signaling	α <sub>2c</sub> Receptor <sup>36,37,39-41</sup>	α <sub>2c</sub> Deletion	Deletion: decreased uptake of norepinephrine	β-Blockers
	G protein β <sub>3</sub> subunit (GNB3) <sup>62,63</sup>	C825T	825T: increased α-adrenergic signaling, lower plasma renin	ACE inhibitors/I/H
Nitric oxide	Endothelial nitric oxide synthase (NOS3) <sup>60,61</sup>	Asp298Glu	Asp: associated with lower NOS3 activity	ACE inhibitors/I/H

ACE, angiotensin-converting enzyme; β<sub>1</sub>AR, β<sub>1</sub>-adrenergic receptor; β<sub>2</sub>AR, β<sub>2</sub>-adrenergic receptor; D/I, deletion/insertion; I/H, isosorbide dinitrate and hydralazine; NOS3, endothelial nitric oxide synthase.

## β-Receptor Polymorphisms and β-Receptor Antagonists

The therapeutic efficacy of β-blockers in heart failure reflects not only the inhibition of renin release but also the direct effect of the receptor antagonist on myocardial β<sub>1</sub>- and β<sub>2</sub>-receptors (see Chapter 10). Two β<sub>1</sub>- and three β<sub>2</sub>-receptor polymorphisms influence receptor function or downregulation in vitro. The pharmacogenetic interactions of these polymorphisms with β-receptor agonists and antagonists have been investigated in subjects with asthma and hypertension. The β<sub>1</sub>-receptor variants have been explored most extensively in subjects with heart failure.<sup>19-22</sup> The Gly389Arg polymorphism is located in the intracellular region of the receptor. The Arg389 allele is more responsive to agonist stimulation and is the dominant allele. In the genetic substudy of the Beta-Blocker Evaluation of Survival Trial (BEST) of bucindolol in heart failure, subjects with the Arg389Arg genotype (approximately half the study group) had a much greater benefit from β-blockade than did subjects heterozygous or homozygous for the Gly389 allele, which was less responsive to the agonist.<sup>23</sup> In BEST, treatment with bucindolol was much less effective in African American patients, and it has been hypothesized that this may reflect lower frequency of the Arg389 allele among African Americans.<sup>24</sup>

The finding that subjects homozygous for the more active β<sub>1</sub>-receptor variant receive more benefit from the β antagonist bucindolol conforms to an attractive hypothesis; however, attempts to replicate this finding with metoprolol and carvedilol have not been successful.<sup>25</sup> For subjects randomly assigned to receive either metoprolol succinate or placebo in the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF), a genetic substudy demonstrated no effect of the Arg389 allele on either heart failure survival or the effect of therapy.<sup>26</sup> These results may reflect differences in the receptor sensitivities of the two agents, as well as the partial agonist properties of bucindolol. In addition, of relevance is that in contrast to BEST, the MERIT-HF genetic substudy was completed in a more homogeneous European cohort. In a large prospective cohort of more than 2000 subjects, the effect of the Gly389 allele on β-blocker therapy was modified by the coinheritance of the Gln41Gln genotype of G protein receptor kinase (GRK5), a downstream mediator of adrenergic signaling.<sup>27</sup>

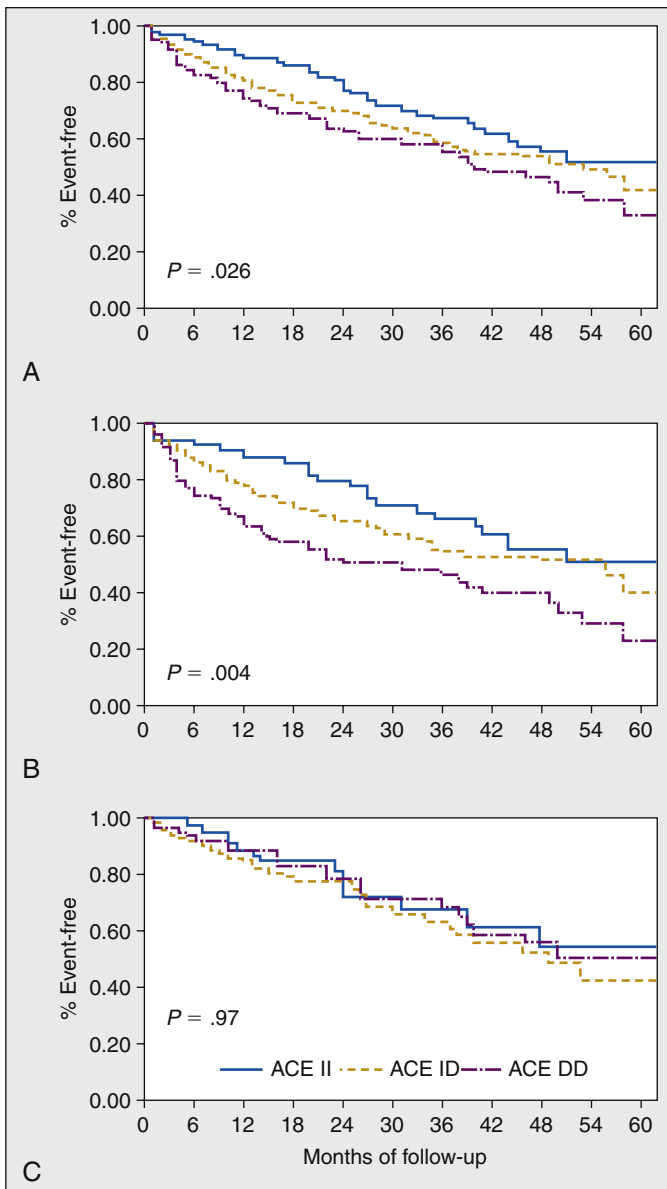

Further evidence for the influence of β-receptor genotype on β-blocker therapy was obtained in studies of left ventricular remodeling. A study of carvedilol therapy in nonischemic

cardiomyopathy demonstrated a marked increase in left ventricular ejection fraction (LVEF) in subjects with improvements of 19 ejection fraction (EF) units among subjects with Arg389Arg, 9 EF units among subjects with Gly389Gly, and 6 EF units among subjects with Gly389Gly. These results were consistent with the observed survival effect in the BEST trial.<sup>28</sup> Meta-analysis of three additional studies demonstrated improvements in LVEF, which were 5 EF units greater in subjects with Arg389Arg than in subjects with Gly389Arg or Gly389Gly.<sup>29</sup>

Although the Arg389Gly polymorphism is the most extensively studied, clinical investigations suggest that the Ser49Gly polymorphism also influences outcomes in heart failure.<sup>30</sup> This polymorphism is a variant that alters protein function secondary to a change in the amino acid sequence of the extracellular region. Receptors with the less common allele, Gly49, have an increased rate of receptor downregulation in vitro in response to agonist stimulation,<sup>31</sup> and the Gly49 receptor is linked more with an enhanced response to β-blocker therapy.<sup>32</sup> According to investigations in hypertension, haplotype analysis, which incorporates data from both polymorphisms, best predicts the effect of β-blockade treatment.<sup>33</sup> Common polymorphisms also exist in the extracellular region of the β<sub>2</sub>-adrenergic receptors (Gly16Arg and Gln27Gly) and also influence receptor downregulation in vitro. One report suggested that the subjects with heart failure who are homozygous for the Arg16Gln27 haplotype have an increased risk of death or transplantation.<sup>34</sup> A separate study of left ventricular remodeling revealed no influence of the β<sub>2</sub>-receptor polymorphisms on left ventricular size and ejection fraction.<sup>35</sup> In contrast to the findings with β<sub>1</sub>-receptor polymorphisms, those with β<sub>2</sub>-receptor polymorphisms appear less consistent in subjects with heart failure, and there is less evidence of their influence on the effectiveness of β-blockade.

## α<sub>2c</sub>-Adrenergic Receptor Deletion

It is increasingly recognized that most if not all pharmacogenetic influences on specific therapies (e.g., β-blockers in heart failure) are polygenic and involve multiple loci. Variations in α-adrenergic receptors are important genomic modifiers and appear to influence the effect of the β-receptor variants. The α<sub>2c</sub> receptor has a common deletion allele, in which four amino acids are missing,<sup>36</sup> which limits the reuptake of catecholamines by the presynaptic cell<sup>37,38</sup> and magnifies the

**FIGURE 42-2** Transplant-free survival according to angiotensin-converting enzyme (ACE) deletion/insertion (D/I) genotype (DD, DI, and II), from the Genetic Risk Assessment of Cardiac Events (GRACE) study, University of Pittsburgh.<sup>11</sup> **A**, Data for the overall cohort, in which the ACE D allele was associated with poorer event-free survival ( $n = 479$ ,  $P = .026$ ). **B**, Data for the subset of patients who received no  $\beta$ -blocker therapy ( $n = 277$ ,  $P = .004$ ). **C**, Data for the subset of patients treated with  $\beta$ -blocker therapy ( $n = 202$ ,  $P = .97$ ). (From McNamara DM, Holubkov R, Postava L, et al. Pharmacogenetic interactions between ACE inhibitor therapy and the angiotensin-converting enzyme deletion polymorphism in patients with congestive heart failure. *J Am Coll Cardiol* 2004;44:2019-2026.)

effect of agonist stimulation of the Arg389 receptor. The coinherance of Arg389 and  $\alpha_{2c}$  increases the risk of heart failure in African Americans.<sup>39</sup> This synergistic interaction is not limited to African Americans with heart failure, and a larger analysis of clinical outcomes in heart failure determined that coinherance of  $\beta_1$ -receptor and  $\alpha_{2c}$ -receptor variants increased the risk of death or the need for transplantation.<sup>40</sup> As these two loci interact for heart failure risk, they also act synergistically in determining the effect of  $\beta$ -blocker therapy. In a study of the effect of metoprolol on LVEF, coinherance of the  $\alpha_{2c}$  deletion and Arg389Arg genotype was predictive of the greatest therapeutic effect of  $\beta$ -blockade.<sup>41</sup> Similar analysis from BEST<sup>42</sup> suggested that predictive models of  $\beta$ -blocker response need to incorporate both loci.

**FIGURE 42-3** Pharmacogenetic interaction of the angiotensin-converting enzyme (ACE) deletion (D) allele and ACE inhibitor dosage in a cohort of the Genetic Risk Assessment of Cardiac Events (GRACE) study. **A**, Transplant-free survival of subjects with systolic heart failure who were treated with low-dose ACE inhibitors and no  $\beta$ -blockers ( $n = 130$ ). The ACE D allele was associated with markedly poor outcome ( $P = .005$ ). **B**, Transplant-free survival of subjects treated with high-dose ACE inhibitors and no  $\beta$ -blockers ( $n = 117$ ). The effect of the ACE D allele was diminished ( $P = .47$ ). (From McNamara DM, Holubkov R, Postava L, et al. Pharmacogenetic interactions between ACE inhibitor therapy and the angiotensin-converting enzyme deletion polymorphism in patients with congestive heart failure. *J Am Coll Cardiol* 2004;44:2019-2026.)

**FIGURE 42-4** Relative risk of event (death or transplantation) according to  $\beta$ -blocker use in the Genetic Risk Assessment of Cardiac Events (GRACE) study: Data from the overall cohort and comparison of angiotensin-converting enzyme (ACE) deletion/insertion (D/I) genotypes (DD, DI, and II). (Adapted from McNamara DM, Holubkov R, Postava L, et al. Pharmacogenetic interactions between ACE inhibitor therapy and the angiotensin-converting enzyme deletion polymorphism in patients with congestive heart failure. *J Am Coll Cardiol* 2004;44:2019-2026, Table 4.)

### Aldosterone Synthase

Aldosterone receptor antagonists improve survival in advanced heart failure<sup>43</sup> and after myocardial infarction,<sup>44</sup> and aldosterone activation is the most recently recognized target of neurohormonal inhibition in heart failure. The promoter polymorphism (C-344T) of the aldosterone synthase gene

(CYP11B2) is located in a steroid-binding region and appears to affect gene transcription. It has been investigated extensively in cardiovascular disease. The -344C allele is linked to the risk of hypertension, higher aldosterone synthase activity,<sup>45</sup> and greater left ventricular maladaptive remodeling.<sup>46</sup> The effect of the -344C allele was evaluated in the genetic substudy of the African American Heart Failure Trial (AHeFT), in which researchers investigated the addition of a fixed-dose combination of isosorbide dinitrate and hydralazine (I/H) to standard background heart failure therapy.<sup>47</sup> This substudy, Genetic Risk Assessment of Heart Failure in African Americans (GRAHF), was initiated to evaluate the ability of genomic polymorphisms identified in mostly white cohorts to predict outcomes in African Americans with systolic heart failure and to determine the genomic basis for racial differences in therapeutic efficacy of I/H and ACE inhibitors. In GRAHF, the aldosterone synthase promoter polymorphism was evaluated, and the -344C allele was found to be associated with significantly poorer event-free survival during the course of follow up<sup>48</sup> (Figure 42-5). The adverse effect of the -344C allele in risk of events was evident for both death ( $P = .001$ ) and hospitalization for heart failure ( $P = .013$ ), inasmuch as the majority of events occurred in subjects with the -344CC genotype (Figure 42-6).

The -344C allele was also linked to left ventricular remodeling; however its effect was diminished by treatment with I/H. An association of the -344C allele with lower LVEF at 6 months was apparent in subjects randomly assigned to receive placebo but not evident in patients treated with I/H (Figure 42-7). The effect of I/H therapy on remodeling for the -344 CC genotype mirrored the effect of conventional therapy with ACE inhibitors and  $\beta$ -blockers in a separate cohort of African Americans with heart failure, in which improvements at 1 year in left ventricular systolic dimension were greater in subjects with the -344CC genotype.<sup>49</sup> Not all studies demonstrate greater efficacy of therapy; a randomized study of 500 hypertensive subjects demonstrated diminished effect of ACE inhibitors on blood pressure in subjects with the -344CC genotype.<sup>50</sup> Surprisingly, the results from the AHeFT trial suggest that treatment with the aldosterone receptor antagonist spironolactone did not diminish the adverse affect of the C allele on left ventricular remodeling.<sup>47</sup>

## RACE, GENOMICS, AND HEART FAILURE THERAPY

The efficacy of medical therapies such as ACE inhibitors and I/H differs between white and African American patients with heart failure. The first Veteran's Administration Cooperative Vasodilator-Heart Failure Trial (V-HeFT I) demonstrated that I/H improved survival in subjects with heart failure<sup>51</sup>; however, this benefit was evident in the African American patients and less evident in white patients.<sup>52</sup> In the second V-HeFT study (V-HeFT II), the ACE inhibitor enalapril yielded results superior to those of I/H<sup>53</sup>; however, the superiority of ACE inhibitors was primarily in the white subjects and was not evident among African American patients with heart failure.<sup>52</sup> The observation of increased effect of I/H in African American cohorts led to the study design of A-HeFT, and this landmark trial evaluated the efficacy of fixed-combination I/H specifically in self-designated African Americans.<sup>47</sup> The results of the trial confirmed benefits of I/H and for the first time led to the approval by the U.S. Food and Drug Administration of a heart failure therapy in a specific racial subset (see Chapter 49). Race is probably a poor surrogate for differences in genomic background,<sup>54</sup> and investigations have focused increasingly on genetic variants that may underlie racial differences in therapeutic efficacy.

Common polymorphisms in genes that control vascular tone have been investigated for their role in the development

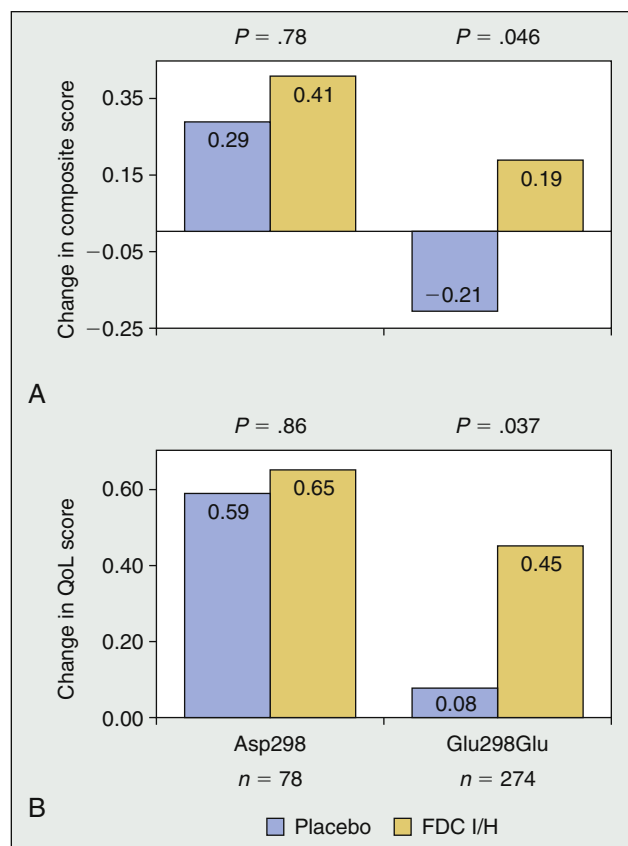

**FIGURE 42-5** Kaplan-Meier analysis from the African American Heart Failure Trial (AHeFT) of survival free from hospitalization for heart failure, demonstrating effect of aldosterone synthase (CYP11B2) promoter genotype (TT, TC, and CC). The -344C allele was linked to increased aldosterone levels and associated with poorer event-free survival ( $P = .018$ ). (From McNamara DM, Tam SW, Sabolinski ML, et al. Aldosterone synthase promoter polymorphism predicts outcome in African Americans with heart failure. *J Am Coll Cardiol* 2006;48:1277-1282).

**FIGURE 42-6** Percentage of subjects in the African American Heart Failure Trial (AHeFT) with events by the end of the study, according to aldosterone synthase (CYP11B2) promoter T-344C genotype. The -344C allele was associated with increased risk of death ( $P = .001$ ) and increased hospitalizations for heart failure (HF) ( $P = .013$ ). (From McNamara DM, Tam SW, Sabolinski ML, et al. Aldosterone synthase promoter polymorphism predicts outcome in African Americans with heart failure. *J Am Coll Cardiol* 2006;48:1277-1282).

**FIGURE 42-7** Left ventricular ejection fraction (LVEF) at 6 months in the African American Heart Failure Trial (AHeFT): Comparison of treatment group—placebo or fixed-dose combination of isosorbide dinitrate and hydralazine (I-H)—with the effect of aldosterone synthase promoter genotype. The -344C allele is associated with lower LVEF at 6 months for subjects receiving placebo ( $P = .05$ ) but not for those receiving I-H ( $P = .79$ ). (From McNamara DM, Tam SW, Sabolinski ML, et al. Endothelial nitric oxide synthase (NOS3) polymorphisms in African Americans with heart failure: results from the A-HeFT trial. *J Card Fail* 2009;15:191-198.)

**FIGURE 42-8** Interaction of nitric oxide synthase (NOS3) Glu298Asp polymorphisms and treatment with fixed-dose combination of isosorbide dinitrate and hydralazine (FDC I/H). **A**, Effect on composite score. Treatment was associated with improvement in the Glu298Glu homozygotes ( $n = 274$ ,  $P = .046$ ) but not in subjects with the Asp298 allele ( $n = 78$ ,  $P = .78$ ). **B**, Effect on change in quality of life (QoL). Significant improvement in QoL score at 6 months was demonstrated in subjects with the Glu298Glu allele ( $P = .037$ ) but not in those with the Asp298 allele. (From McNamara DM, Tam SW, Sabolinski ML, et al. Endothelial nitric oxide synthase (NOS3) polymorphisms in African Americans with heart failure: results from the A-HeFT trial. *J Card Fail* 2009;15:191-198.)

of essential hypertension. Hypertension is much more prevalent in African Americans, and significant racial differences in the prevalence of genomic variants are evident for endothelial nitric oxide synthase (NOS3; also known as eNOS), aldosterone synthase, and  $\alpha$  and  $\beta$ -adrenergic receptors. In addition to their role in hypertension, these genetic loci also play central roles in the pathogenesis of heart failure and in therapeutics.

The genetic substudy of AHeFT was designed to determine whether genetic alleles would be predictive of benefit from treatment with I/H. Because the prevalence of several polymorphisms of NOS3—the primary source of vascular nitric oxide production<sup>55</sup>—differs markedly between African American and white cohorts,<sup>56,57</sup> this locus emerged as a prime candidate for a genetic modifier of therapeutic efficacy. A polymorphism exists in exon 7 of NOS3, which results in the substitution of glutamic acid (Glu) for aspartic acid (Asp) at codon 298. The Asp298 variant is a reported risk factor for hypertension,<sup>58</sup> coronary disease,<sup>59</sup> and poor survival rates with heart failure.<sup>60</sup> The Glu298 variant is far more prevalent in African American cohorts. With regard to the primary endpoint in A-HeFT (a composite score of survival, hospitalization for heart failure, and quality of life), subjects in GRAHF who had the Glu298Glu genotype benefited significantly from therapy, whereas subjects with the Asp298 variant did not<sup>61</sup> (Figure 42-8). Further investigation is necessary to determine whether the NOS3 genotype can effectively target nitric oxide donor therapy.

There is a much higher prevalence of hypertensive cardiomyopathy (and a lower prevalence of coronary disease) among African American populations with heart failure than is evident in similar white cohorts. Adrenergic signaling is influenced by functional genetic variants, including the  $\alpha_{2c}$  deletion and the C825T polymorphism of GNB3. The C825T polymorphism is functionally silent; however, the T allele is linked to a splicing variant, which results in the loss of 41 amino acids. The truncated GNB3 inhibitory subunit increases  $\alpha$ -adrenergic signaling, is associated with a higher risk of hypertension, and is far more prevalent among African Americans than among white patients.<sup>62</sup> Increased  $\alpha$ -adrenergic tone may underlie the high prevalence of low-renin hypertension in African Americans.<sup>63</sup> In addition to differences in  $\alpha$ -adrenergic signaling, the prevalence of several genetic polymorphisms that influence heart failure therapeutics—including  $\beta_1$ -adrenergic receptor ( $\beta_1$ AR; Arg389),<sup>23</sup> NOS3,<sup>60</sup> and aldosterone synthase<sup>48</sup>—also differs between white and African American cohorts. Whether these genetic differences result in differences in the efficacy of ACE inhibitors or I/H remains to be determined.

## GENOME-WIDE ASSOCIATION STUDIES

Pharmacogenetic studies to date have focused predominantly on evaluating the interaction of a single gene locus with the efficacy of a given drug. In addition, most studies have been targeted at genes known to play critical roles in heart failure therapeutics: for example, ACE and the  $\beta_1$ -receptor. Advances in technology have made large-scale mapping of the human genome more efficient and affordable, and the realization that most human DNA is “inherited” in large blocks or haplotypes has led to the development of high-density genomic maps.<sup>64</sup> This has facilitated GWASs, in which the frequency of variants or markers across the entire genome is assessed in large cohorts with a disorder under investigation and compared with findings in a large control group. This technology has been applied to common complex polygenic diseases such as coronary artery disease,<sup>65</sup> hyperlipidemia,<sup>66</sup> and diabetes<sup>67</sup> and has elicited extensive new information about genes that contribute to these complex disorders. Although not yet applied to the pharmacogenomics of heart failure, GWASs have the potential to determine the genomic loci that will “drive” any predictive model of drug efficacy. Bioinformatics analysis, which incorporates multiple genomic drivers for any specific clinical paradigm (e.g., the effect of I/H in heart failure), will be used to convert genomic information into a useful clinical tool for efficiently targeting therapeutics.

## FUTURE DIRECTIONS

Genetic variation of key mediators of heart failure alters the effect of therapeutics that act on particular pathways. Patients who are genetically predisposed to greater renin-angiotensin activation by the presence of the ACE deletion allele obtain greater benefit from therapies ( $\beta$ -blockers and high-dose ACE inhibitors) designed to blunt this response. In addition, patients with the more active  $\beta_1$ -receptor 389Arg variant appear to obtain more clinical benefit when that receptor is blocked than do subjects with the less active 389Gly variant. Significant genetic differences in the nitric oxide pathway exist between white and African American patients with heart failure, and these differences may underlie the apparent enhanced response in African Americans to treatment with I/H. All these examples demonstrate the potential power of pharmacogenomics to target treatments and transform heart failure therapy.

Despite these findings in single gene studies since the 1990s, disagreement between pharmacogenetic analysis in clinical trials such as BEST and MERIT-HF and the lack of prospective validation studies have prevented pharmacogenomics from playing a role in clinical care by facilitating patient-specific therapy for heart failure. Replicating results of published studies has been difficult because some studies have been simply too small to attain statistical significance. The results of pharmacogenomic studies that assess the relevance of a single genetic variant may not be correlated with results that would be expected on the basis of the physiological and biochemical properties of the mutated protein because many responses are polygenic. Thus, pharmacogenetic evaluations must move beyond single-nucleotide polymorphism analysis if they are to become effective tools in clinical medicine.

As a result of the development of robust new technology and automation, the phase of pharmacogenomic investigation concerned with targeted single-gene loci will evolve toward polygenic analysis. This will allow multiple genomic drivers to be evaluated for each clinical phenotype and each therapeutic strategy. However, federal regulatory agencies must ensure that pharmacogenomic analysis is included in the routine evaluation of new pharmacological agents. With this new information, it is hoped that genomic analysis will soon become part of routine laboratory assessment and will allow clinicians to individualize pharmacotherapy and optimize outcomes for each patient with heart failure. This will decrease the cost of health care and, at the same time, allow patients to avoid the potential side effects of unnecessary drugs.

More than 1 million hospitalizations yearly are attributed directly to heart failure, and in approximately 2 million more, heart failure diagnosis complicates other admitting diagnoses such as pulmonary or renal disease.<sup>1</sup> Admissions related to heart failure can be divided about evenly between those for heart failure with low ejection fraction and those for heart failure with “preserved” ejection fraction<sup>2</sup> (Figure 43-1), which in turn is divided between those in which left ventricular ejection fraction (LVEF) is 40% to 55% and those in which LVEF exceeds 55%.<sup>3</sup> (Table 43-1). In contrast to trial populations, the average patient from the community who is admitted is 75 years old, with substantial comorbid conditions.

The most common cause of hospitalization for heart failure is exacerbation of chronic heart failure, which accounts for about 75% of admissions for heart failure with low ejection fraction and about 66% of those for heart failure with “preserved” ejection fraction.<sup>4</sup> New diagnoses of heart failure resulting from acute myocardial infarction or acute valvular regurgitation are treated predominantly by specific therapy for those cardiac conditions.

Acute heart failure occasionally results from

fulminant myocarditis (see Chapter 31), which necessitates rapid institution of life-saving therapies for cardiogenic shock; these therapies may include mechanical support, with good potential for ultimate recovery.<sup>5</sup> This chapter focuses on the management of the most common situation, subacute decompensation in patients with known chronic heart failure.<sup>4,6</sup> Information about the pathophysiology and treatment of decompensated heart failure with preserved ejection fraction is scarcer than information about decompensated heart failure with low ejection fraction, but this discussion indicates which considerations apply to all heart failure and which are restricted to heart failure with low ejection fraction.

## INITIAL CLINICAL ASSESSMENT

For patients hospitalized with decompensation and a history of chronic heart failure, the initial assessment should identify contributing factors that necessitate evaluation and focus on fluid status and perfusion, which will guide initial therapy.<sup>6</sup> Because chronic circulatory adaptations can mask decompensation, the first priority should be to assess the level of hemodynamic compromise; in initial triage in urgent care settings, the severity and urgency may be underestimated.<sup>7</sup> Hospitalization should trigger review of both the causes and potential exacerbating factors. For patients with known coronary artery disease, new-onset ischemia should always be considered (see Chapter 23). Other common exacerbating factors are tachyarrhythmias, thyroid disease, anemia, infections, chronic pulmonary disease, and, on occasion, pulmonary emboli<sup>8</sup> (Figure 43-2). Compliance can be undermined by inadequate support structure, poor understanding of the patient because of lack of education about heart failure, or limited literacy and numeracy skills.

## RECOGNIZING THE FOUR HEMODYNAMIC PROFILES

The central hemodynamic components of decompensated heart failure are the elevation of filling pressures and the reduction of cardiac output, which do not necessarily occur together, as shown in Figure 43-3.<sup>9</sup> Whether the left ventricular ejection fraction is low or “preserved,” the most common manifestation is generally profile B, “warm and wet,” with congestion and adequate perfusion. Clinical assessment of congestion is complicated by the frequent absence of rales and peripheral edema in patients with chronic heart failure.<sup>10</sup> Orthopnea in a patient with heart failure is considered an indication of elevated filling pressures until it is proved otherwise.<sup>7,10</sup> For some patients, gastrointestinal symptoms predominate, and needless diagnostic procedures may be performed when the degree of congestion is not appreciated. Jugular venous pressure provides the most visible and reliable index of elevated filling pressures on physical examination<sup>10</sup> (Table 43-2). Although only the right-sided filling pressures are directly assessed in this way, their elevation is nonetheless the best clinical sign of elevated left-sided pressures; they are concordant in about 75% of cases if defining thresholds of right atrial pressure exceed 10 mm Hg and pulmonary capillary wedge pressure exceeds 22 mm Hg.<sup>11</sup> Hepatomegaly, increased radiation of the pulmonary second sound, and serial increases in the intensity of a third heart sound can be informative. For experienced clinicians, the Valsalva maneuver can help identify elevated filling pressures, particularly when cardiac and pulmonary causes of dyspnea coexist.<sup>12</sup> The abdominojugular reflex is a sensitive measure but not very specific.<sup>13</sup> Elevated natriuretic peptide levels may be indicative of heart failure in a patient with unexplained dyspnea, but these levels are chronically elevated in most patients with a previous diagnosis of heart failure; therefore, the finding of a high level may not indicate the presence or severity of worsening congestion.<sup>14</sup> Other clues for elevated filling pressures can be present in echocardiographic findings of moderate or severe mitral or tricuspid regurgitation or pulmonary hypertension in the absence of other causes.<sup>11</sup> Echocardiography

**FIGURE 43-1** Estimation of typical proportions of patients accounting for hospitalizations for heart failure (HF) in the community. Approximately half of such hospitalizations are for heart failure with left ventricular ejection fraction (LVEF) exceeding 40%. Patients with acute pulmonary edema frequently have uncontrolled hypertension (HTN). Only a small fraction of patients present in cardiogenic shock. Clinical hypoperfusion at hospital admission may be present in up to 25% of patients with low ejection fraction in large tertiary centers, but this proportion is much smaller in community hospitals. SBP, systolic blood pressure. Data from large registries (Acute Decompensated Heart Failure Registry [ADHERE]<sup>1-3</sup>).

<b>TABLE 43-1 Typical Community Hospitalizations for Heart Failure According to LVEF</b>			
Characteristic	LVEF <0.40	LVEF 0.40 to 0.55	LVEF ≥0.55
Age	70	74	74
% Women	40	54	69
% African American	22	17	17
% With coronary artery disease	59	61	48
% With hypertension	69	76	78
Systolic blood pressure (average; mm Hg)	139	150	152
% Diabetes mellitus	40	48	44
% With atrial fibrillation	29	33	32
% With COPD	27	32	34
% With renal insufficiency	26	31	27

Data from publications describing the Acute Decompensated Heart Failure National Registry (ADHERE) database.<sup>2,3</sup>  
COPD, chronic obstructive pulmonary disease; LVEF, left ventricular ejection fraction.

with handheld devices may provide the most rapid assessment of volume status in the absence of skilled physical examination.<sup>15</sup> In the absence of frank pulmonary edema, arterial desaturation is rare in exacerbation of chronic heart failure, and on chest radiographs, acute changes often cannot be distinguished from chronic findings.

It is now known that in the majority of patients rehospitalized with heart failure, both right- and left-sided filling pressures have been increasing gradually for 2 weeks or longer before recognition of symptoms that led to a heart failure event, whether the ejection fraction is low or preserved.<sup>16</sup> These gradual increases are often not reflected

**FIGURE 43-2** Bar graph showing factors identified as leading to hospitalization in patients with previously known diagnosis of heart failure. The data reported in 48,612 patients from the OPTIMIZE-HF database are represented.<sup>8</sup> Two or more factors were identified in 19% of patients. ACS, acute coronary syndrome; Isch, ischemia; Nonadh, nonadherence; Tachy, tachycardia; Uncont HTN, uncontrolled hypertension.

#### TWO MINUTE ASSESSMENT OF HEMODYNAMIC PROFILE

		Congestion at rest?	
		NO	YES
Low perfusion at rest?	NO	<i>Warm &amp; dry</i> <b>A</b>	<i>Warm &amp; wet</i> <b>B</b>
	YES	<i>Cold &amp; dry</i> <b>L</b>	<i>Cold &amp; wet</i> <b>C</b>

Evidence for congestion

Orthopnea  
Elevated jugular venous pressure  
Rales (rarely)  
Hepatomegaly  
Ascites  
Edema (more common in older pts)  
Valsalva square wave

Evidence for low perfusion

Narrow auscultated pulse pressure  
Cool extremities  
May be sleepy, obtunded  
Suspect from ACEI/ARB hypotension  
Progressive oliguria

**FIGURE 43-3** Hemodynamic profiles of patients hospitalized for heart failure. Most patients can be classified as having one of these four profiles in a 2-minute bedside assessment, although in practice some patients may qualify for both profile B and profile C. This classification helps guide consideration of initial therapy and prognosis.<sup>9</sup> The clinical criteria for congestion (columns) concern dryness or wetness; the clinical evidence for perfusion (rows) concern coldness or warmth. For the “cold and dry” category, the label “L” is used instead of “D” to avoid the implication that heart failure invariably progresses. Many patients never develop a profile “L,” which can stand for “heart failure light” because it is without congestion. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

in changes in weight, which includes both wet and dry weight and is influenced by the balance of caloric intake and expenditure. However, an acute exacerbation of severe hypertension, particularly in populations with high prevalence of hypertensive heart disease, can cause truly acute pulmonary edema without evidence of elevated total body volume (see Figure 43-1).

**TABLE 43–2** Detection of Elevated Left-Sided Filling Pressures in Patients with Chronic Low-LVEF Heart Failure

Finding	Sensitivity for PCW	Specificity >22 mm Hg
<b>Right-Sided Findings</b>		
Estimated jugular venous pressure $\geq 12$	65%	64%
Edema $\geq$ grade 2+	41%	66%
Hepatojugular reflux	83%	27%
Hepatomegaly: enlargement $>4$ fingerbreadths	15%	93%
<b>Left-Sided Findings</b>		
Orthopnea	86%	25%
Rales $>$ “few at base”	15%	89%
Third heart sound	63%	32%
<b>Direct Right-Left Correlation</b>		
Directly measured right atrial pressure $\geq 10$ mm Hg	76%	83%
<b>Echocardiographic Assessment</b>		
Pulmonary artery systolic pressure $\geq 60$ mm Hg	47%	96%
Tricuspid regurgitation $\geq$ moderate	78%	70%
Mitral regurgitation $\geq$ moderate	78%	43%

PCW, Pulmonary capillary wedge pressure. Modified from Drazner MH, Hellkamp AS, Leier CV, et al. Value of clinician assessment of hemodynamics in advanced heart failure. The ESCAPE trial. *Circ Heart Fail* 2008;1:170-177; and Drazner MH, Hamilton MA, Fonarow G, et al. Relationship between right and left-sided filling pressures in 1000 patients with advanced heart failure. *J Heart Lung Transplant* 1999;18:1126-1132.

Patients with heart failure and low ejection fraction may also decompensate with profile C “cold and wet” but rarely with profile L “cold and dry” (see Figure 43-3). Cardiac output, although frequently reduced from normal, is often not reduced to critical levels and is rarely directly responsible for the resting symptoms that lead to admission, except in the unusual cases of true spiraling cardiogenic shock. Significant reduction of cardiac output, on the other hand, may be missed in a patient with chronic low cardiac output who appears oriented. Estimation of perfusion yields less reliable results than does assessment of filling pressures, even by the skilled examiner.<sup>10</sup> Temperature of the extremities, examination of the pulses, and auscultation to determine net pulse pressure must be assessed in the critical situation.<sup>7,10</sup> It is particularly important to auscultate blood pressure when atrial fibrillation or frequent premature beats generate misleadingly high systolic readings on automated measurement. Fluctuating mentation, often attributed to depression or sleep deprivation, may be a key sign of low cardiac output.

Severe compromise of resting cardiac output and perfusion do *not* usually occur in heart failure with truly preserved ejection fraction, in which decompensation is usually characteristic of profile B. However, hypoperfusion is occasionally present in patients with severe restrictive, infiltrative, or hypertrophic disease with a very small left ventricular cavity or severe mitral regurgitation.

## PRINCIPLES OF THERAPY GUIDED BY PROFILES

For most patients admitted with heart failure, symptoms and physical examination findings provide sufficient information to determine patients’ profiles for initial therapy.<sup>9,10</sup> For

patients who appear to be profile A (warm and dry), without clinical evidence of elevated filling pressures or hypoperfusion on clinical examination, the diagnosis of heart failure may not adequately explain the presenting symptoms, which could be caused by other conditions, such as pulmonary or hepatic disease, or by transient events, such as ischemia or arrhythmias. It is now well recognized that at least half of hospitalizations of patients with chronic heart failure are for diagnoses other than decompensated heart failure.<sup>17</sup>

## Focus on Congestion and Filling Pressures

For the patients who do have abnormal resting hemodynamic profiles, therapy is directed toward relief of congestion. Although heart failure was once considered primarily a condition of low cardiac output, therapies designed to stimulate contractility and cardiac output have to date been deleterious, leading to increased arrhythmias and ischemia and an apparent acceleration of progressive disease, often compared to “whipping a tired horse.” The focus for both congestion profiles B and C is on reduction of the elevated filling pressures responsible for most of the symptoms that led to hospitalization.<sup>18</sup> Many patients have normal stroke volume and cardiac output despite low ejection fraction. Although cardiac output frequently improves with better loading conditions, increase of cardiac output is not a *primary* target of acute therapy unless organ perfusion is critically compromised or when systemic or renal hypoperfusion limits direct reduction of filling pressures.

## What Is the Optimal Level of Filling Pressures?

In patients with heart failure caused by chronic dilated cardiomyopathy, filling pressures can often be lowered to levels of 15 to 16 mm Hg despite baseline levels over 30 mm Hg at admission.<sup>19-22</sup> (This contrasts with the requirement for higher filling pressures with acutely decreased compliance that has been described during new myocardial infarction,<sup>23</sup> as shown in Figure 43-4.) Most dilated hearts operate far beyond the level of filling at which stroke volume depends on increments in filling pressures. In fact, as high filling pressures are reduced, cardiac output usually increases (Figure 43-4).<sup>19,24</sup> This improvement in cardiac output could reflect multiple factors, including an actual increase in contractility from decreased myocardial oxygen consumption and improved gradient for myocardial perfusion, an improvement in ejection related to decreased systemic vascular resistance, and redistribution of mitral regurgitant volumes to supplement forward flow. Although all these may contribute, the most easily measured change is that of decreased mitral regurgitation caused by a reduction in the effective mitral regurgitant orifice, which in turn results from small reductions in left ventricular distention.<sup>20,21,25,26</sup> Both the landmark original study of nitroprusside<sup>27</sup> and more recent studies with tailored therapy have confirmed the central role of changes in mitral regurgitant flow.<sup>26</sup> The mitral regurgitant fraction during therapy may decrease from 0.50 to less than 0.20.<sup>20</sup> This appears to account for virtually all of the improvement in measured cardiac output (Figure 43-5). Similar considerations probably affect tricuspid regurgitation and right ventricular stroke volume.

Reduction of pulmonary capillary wedge pressures has long been observed, and more recently demonstrated, to reduce the symptoms of congestion that lead to most hospitalizations for heart failure. The immediate symptomatic improvement often occurs when filling pressures are still severely elevated. Therapy should not stop with initial relief, however. Many patients perceive relief from the most oppressive symptoms and do not appreciate that symptoms can be improved further. In addition to causing symptoms of heart failure, elevated filling pressures are associated with greater activation of the renin-angiotensin and sympathetic nervous

**FIGURE 43-4** Curves demonstrating relationship of filling pressures to stroke volume. In the acutely ischemic ventricle, compliance is decreased with little change in volume, and the curve is shifted to the right, as described by Russell and colleagues.<sup>103</sup> In the chronically dilated ventricle, the curve is actually reversed in such a way that reduction of filling pressures leads to higher stroke volume.<sup>19</sup>

**FIGURE 43-5** The change in distribution of stroke volume as ventricular loading conditions are improved, so that more of the total stroke volume is ejected forward and less flows backward into the left atrium.<sup>20</sup> The mitral effective regurgitant orifice (ERO) is significantly reduced after therapy.<sup>21</sup>

systems.<sup>28,29</sup> Even in the absence of symptoms, elevated filling pressures are important determinants of valvular regurgitation, abnormal ventricular filling patterns, pulmonary hypertension, and right ventricular dysfunction, all of which lead to worse outcomes. Whether near-normal filling pressures are measured directly (assessed from absence of signs and symptoms of congestion) or reflected by echocardiographic assessment, the ability to achieve them and maintain them over time<sup>30-34</sup> increases the likelihood of survival and lowers the likelihood of rehospitalization. It is not known to what extent current outcomes could be improved by more intensive reduction and prevention of recurrent congestion.

Current data do not allow definition of the filling pressure target for patients with heart failure and preserved ejection fraction. Like patients with heart failure and low ejection fraction, patients with heart failure and preserved ejection fraction retain fluid to a level substantially higher than optimal, although it is aggravated more commonly by intrinsic renal impairment.<sup>16</sup> The heterogeneity of myocardial disease and degrees of hypertrophy may dictate more heterogeneity in the optimal fluid levels for these patients, but it is unlikely that they will be more than a few millimeters higher than the target levels for the patients with low ejection fraction.

## Profile B: Wet and Warm

In most hospitalizations for heart failure, patients' conditions are designated as profile B ("warm and wet"),<sup>1,18</sup> for which the initial goal, beyond just the improvement of symptoms, is simply the reduction of estimated filling pressures ("get to dry") (Table 43-3). Elevated filling pressures can result from elevated intravascular volume, systemic vasoconstriction (venous or arterial or both), and the combination. Most patients presenting with profile B have at least some component of total body fluid overload that necessitates fluid removal, usually by diuretics. For profile B in which vasoconstriction dominates, as in settings of severe hypertension with incipient pulmonary edema, vasodilators are the first line of therapy (see "Specific Agents Used During Hospitalization" section), although adding a moderate bolus of intravenous diuretics may accelerate initial relief. Positive-pressure masks may also help avert the need for urgent intubation in patients with marked tachypnea and hypoxia. However, most cases of decompensated heart failure can be managed with a stepwise approach.

For the majority of profile B patients, diuretic therapy is the main intervention leading to stabilization in the acute situation. Furosemide, administered either in a bolus or by continuous infusion,<sup>35,36</sup> is generally effective in achieving diuresis, sometimes with the addition of oral metolazone or intravenous thiazides,<sup>37</sup> as described in Chapter 44.

### No Defined Role for Adjunctive Agents

Use of adjunctive therapies beyond diuretics has not been demonstrated to improve outcomes in hospitalized heart failure populations, dominated by the profile B patients. Multiple uncontrolled experiences confirm the worse early and late outcomes of patients who received approved intravenous inotropic infusions to facilitate diuresis.<sup>38</sup> The randomized study with milrinone<sup>39</sup> revealed increased arrhythmias and trends toward more ischemic events in hospital and more adverse events in the 60 days after discharge; this last effect was more evident in the patients with underlying coronary artery disease. The newer calcium-sensitizing agents, such as levosimendan, have produced no clinically significant benefit in either symptoms or outcomes.<sup>40</sup> Inotropic infusions may increase low levels of troponin leakage during hospitalization for heart failure, particularly in patients with underlying coronary artery disease.<sup>41</sup>

Nitroglycerin and nesiritide infusions may accelerate early symptomatic improvement but have not been proved to affect overall outcomes either positively or negatively during hospitalization or after discharge.<sup>42</sup> Both can cause hypotension, particularly when used in patients in whom circulating volume status has been overestimated. Current recommended doses of nesiritide have occasionally been implicated in the worsening of renal function, particularly in association with hypotension.<sup>43</sup> With increasing recognition of the multiple circulating forms of active and inactive natriuretic peptide fragments, a reengineered form may yet be identified that would have clinical utility for improving cardiorenal responses.<sup>44</sup>

Endothelin antagonists have not improved symptom relief or outcomes after discharge.<sup>45</sup> Therapy with vasopressin antagonists is effective in increasing serum sodium levels in the setting of hyponatremia, usually with some enhancement of diuresis. Relief of dyspnea is accelerated.<sup>46</sup> However, initial benefits for fluid balance are not sustained during long-term follow-up, in part because of increased thirst and water consumption.

### Nonresponders

In some patients who appear to have uncomplicated congestion, appropriate therapy does not relieve signs and symptoms of congestion as anticipated (Figure 43-6). Failure to

**TABLE 43-3 Hemodynamic Goals for Therapy of Advanced Heart Failure\***

Assessed Clinically	Measured Directly
Jugular venous pressure $\leq 8$ cm	
Absence of orthopnea	Pulmonary capillary wedge pressure $\leq 15$ mm Hg
No hepatomegaly or ascites	
No peripheral edema	Right atrial pressure $\leq 8$ mm Hg
Valsalva square wave absent	
Systolic blood pressure $\geq 80$ mm Hg	Systemic vascular resistance (average size), 1000-1200 dynes/sec/cm <sup>-5</sup> (higher for small patient, lower for obese patient)
Warm extremities	
SBP-DBP $\geq 25\%$ above normal	
SBP (proportional pulse pressure)	

\*Further adjustment of therapy is required for postural hypotension that lasts beyond the immediate postdose period and for progressive renal dysfunction. DBP, diastolic blood pressure; SBP, systolic blood pressure.

respond to empirical therapy is one of the reasonable indications to measure hemodynamics directly, in order to clarify the filling pressures, cardiac output, and vascular resistances and to allow more directed adjustment of therapies. No current evidence, however, suggests that more information will improve clinicians' ability to treat these patients, at least with the current therapies available.

#### Cardiorenal Syndrome

One reason for inadequate clinical response is the dreaded cardiorenal syndrome.<sup>47,48</sup> It occurs in approximately 25% of patients hospitalized with heart failure and is equally common among patients with low ejection fraction and patients with preserved ejection fraction, although intrinsic renal disease may play a larger role in older patients. Various definitions of the cardiorenal syndrome include renal dysfunction at the time of hospital admission, failure to respond to high-dose diuretics, worsening renal function during diuresis despite persistent fluid overload, and progressive uremia after establishment of apparently optimal volume status. Some patients have progressive elevation in blood urea nitrogen (BUN) levels with little change from baseline creatinine levels. The cardiorenal syndrome is associated with prolonged hospital stays and higher rates of mortality after discharge.

The term "prerenal" does not clarify either the mechanism or the solution. The syndrome was at one time assumed to reflect low cardiac output from excessively reduced filling pressures during diuresis. In fact, filling pressures usually still far exceed the optimal levels needed for maintenance of cardiac output as renal function deteriorates.<sup>47</sup> The cardiorenal dynamics become limiting most commonly in patients with severe right ventricular dysfunction and prolonged chronic volume overload. Increasing new information confirms a strong connection between renal dysfunction and chronically high right atrial pressures, possibly as a result of renal compromise from renal venous congestion and elevated intraperitoneal pressures.<sup>49</sup>

Of interest is that impaired renal function is about as likely to improve as to deteriorate during diuresis.<sup>50</sup> Patients with cardiorenal syndrome are often treated as if they have profile C, with either vasodilators or inotropic therapy. Inotropic therapy as used to facilitate diuresis is discussed in Chapter 44. If used, it should be in as low a dose as possible, such as 2  $\mu$ g/kg for dobutamine, to avoid adverse effects of inotropic

**FIGURE 43-6** Modification of the four basic hemodynamic profiles shown in Figure 43-2. In some cases, left-sided filling pressures become elevated as a result more of vasoconstriction than of volume overload, and vasodilation is the first line of therapy. The adequacy of perfusion can be difficult to ascertain or may fluctuate in some patients ("lukewarm"). A mismatch between right- and left-sided filling pressures occurs in 20% to 25% of patients, so that the jugular venous pressure is high when left-sided pressures are not, or vice versa.<sup>51</sup> About 25% of patients demonstrate the cardiorenal syndrome, in which renal function worsens during therapy despite excessive volume. EF, ejection fraction; HF, heart failure; JVP, jugular venous pressure. (From Campbell P, Drazner MH, Kato M, et al. Right-left mismatch in the ESCAPE population: discordance between right and left-sided filling pressures before and after therapy. *J Cardiac Fail* 2009;15(6 Suppl):S28.

therapy and to minimize the development of inotrope dependence. Weaning from the infusion is often accompanied by worsening of both fluid status and renal function. Potentially definitive trials have not yet shown any agent, including adenosine antagonists, to improve outcomes in this condition.

#### "Lukewarm"

The clinical assessment for hypoperfusion is less reliable than that for congestion.<sup>10</sup> Patients with unrecognized or borderline low cardiac output may not have adequate perfusion to support blood pressure and renal function; this situation is sometimes referred to as an intermediate "wet and lukewarm" profile, which may lead to treatment for profile C with either inotropic or vasodilator therapy, depending on systemic vascular resistance.

#### Right-Left Filling Pressure Mismatch

Some patients do not respond as expected to therapy guided by clinical estimation; they may have an atypical pattern of filling pressure elevation. Persistent symptoms, apparent cardiorenal syndrome, or hypoperfusion may occur during treatment that is based on jugular venous pressures that do not adequately reflect left-sided filling pressures. In most patients, right atrial pressure is greater or less than 10 mm Hg when pulmonary capillary wedge pressure is greater or less than 22 mm Hg. However, a right-left mismatch occurs in about 20% to 25% of patients with heart failure caused by chronic dilated cardiomyopathy and can lead to overdiuresis or underdiuresis.<sup>51</sup> Higher right-sided pressures can occur in patients with chronic cor pulmonale, with intrinsic pulmonary hypertension, or after direct right ventricular injury; higher left-sided pressures may occur in patients with long-standing left ventricular hypertrophy, aortic valve disease, or frequent ischemia. However, right-left mismatch is

usually not suspected clinically. Careful echocardiographic assessment may provide clues, but confirmation and quantitation of right-left mismatch often require direct hemodynamic measurement.

#### Very High or Very Low Systemic Vascular Resistance

Diuresis can lead to renal dysfunction without symptom relief when elevated filling pressures result from very high systemic vascular resistance (above 2000 dynes/sec/cm<sup>-5</sup>). This is easy to recognize and treat when the blood pressure is high in profile B patients (see Figure 43-6). In other patients, it can be suspected on the basis of a very narrow pulse pressure. However, when both blood pressure and cardiac output are low, severe vasoconstriction is difficult to confirm or treat without direct hemodynamic monitoring.

Some patients have persistent hypotension with any diuretic or vasodilating intervention despite apparently adequate cardiac output, as judged by reasonable pulse pressure and warm extremities. Such patients occasionally have marked intrinsic vasodilation unrelated to pharmacotherapy. Their systemic vascular resistances can be too low to support perfusion if the patients are given neurohormonal antagonists or other vasodilators. This may occur with intrinsic liver disease, in which circulating vasodilator substances have been implicated. Chronic liver disease with vasodilation should be suspected in patients in whom the degree of ascites is disproportionate to the other evidence of heart failure. Patients particularly at risk may be those with long-standing cirrhosis caused by alcohol or by other toxins or, in rare cases, cardiac cirrhosis after many years of right-sided heart failure from valvular disease, restrictive disease, or congenital heart disease.

#### Profile C: Wet and Cold

Fewer than 3% of patients present with true cardiogenic shock, in which systemic perfusion is inadequate to meet resting oxygen demand, organ function is jeopardized, and lactate is accumulating<sup>1,4</sup> (see Figure 43-1). These patients require rapid intervention and decisions as described in the “Escalating Support” section.

Most patients with profile C with recognized hypoperfusion and congestion are not in extremis, but they generally need to optimize perfusion before they can treat the congestion.<sup>18</sup> As discussed for profile B, reduction of filling pressures alone can lead to improved cardiac output.<sup>19</sup> However, it is sometimes not possible to initiate diuresis when baseline perfusion is severely impaired.

#### Choice of Vasoactive Agents: Vasodilator or Inotrope?

The initial choice of adjunctive agents for hypoperfusion depends on the assessment of systemic vascular resistance. When systemic vascular resistance is very high, the intravenous vasodilators can simultaneously increase cardiac output and decrease filling pressures<sup>52</sup> (Table 43-4). If effective, this strategy is clearly preferable, although cardiac output can be increased more directly by inotropic agents with some vasodilation effects, such as dobutamine and milrinone. The perception that inotropic agents are easy to use without the need for close monitoring and titration has led to exuberant use without good rationale. These agents increase the frequency of clinical ischemic events but more commonly may exacerbate subclinical myocardial injury, as reflected in low-level troponin release that may worsen long-term outcomes after discharge.<sup>39,41</sup>

Dosages of inotropic therapy should be as low as possible to minimize the deleterious effect of increased calcium loading and increased myocardial energy requirements and to minimize the risk of atrial fibrillation and ventricular tachyarrhythmias. Therapy should be continued until the desired goals of initial stabilization and volume reduction

**TABLE 43-4** Baseline and Final Hemodynamics Measured During Hospitalization for Heart Failure in Two Eras

Measurement	Baseline	On Oral Therapy
<b>Two-Center Experience, 1986–1997 (<i>n</i> = 754); Average LVEF = 0.22 ± 0.08<sup>11</sup></b>		
Right atrial pressure (mm Hg)	12 ± 7	10 ± 7
Pulmonary capillary wedge pressure	25 ± 9	17 ± 7
Cardiac index (L/min/m <sup>2</sup> )	2.1 ± 0.7	2.6 ± 0.6
Systemic vascular resistance (dynes/sec/cm <sup>-5</sup> )	1640 ± 620	1160 ± 300
<b>ESCAPE, 2000–2003 (<i>n</i> = 215); Average LVEF = 0.19 ± 0.07<sup>33</sup></b>		
Right atrial pressure (mm Hg)	14 ± 10	7 ± 4
Pulmonary capillary wedge pressure	25 ± 9	7 ± 4
Cardiac index (L/min/m <sup>2</sup> )	1.9 ± 0.6	2.4 ± 0.7
Systemic vascular resistance (dynes/sec/cm <sup>-5</sup> )	1500 ± 800	1100 ± 500

All changes significant in both eras. ESCAPE, Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness; LVEF, left ventricular ejection fraction.

are achieved, but weaning should begin quickly thereafter. Considerations regarding weaning of inotropic agents are discussed in the “Specific Agents Used During Hospitalization” section.

#### Profile L: Dry and Cold

Patients rarely present for hospitalization with true profile L (cold and dry)<sup>9</sup>; therefore, a patient with apparent profile L should be carefully evaluated for occult elevation of filling pressures indicative of profile C instead. In the unusual event that they have documented low filling pressures (pulmonary capillary wedge pressure <12 mm Hg, or right atrial pressure <5 mm Hg), a cautious trial of fluid repletion may be considered; oral replacement off diuretics is better tolerated than is intravenous fluid supplementation, which tends to leak into the lungs. Unless postural hypotension is present, this approach does not often improve clinical status and may lead to congestive symptoms. Patients with pulmonary capillary wedge pressures of approximately 16 mm Hg with normal right atrial pressures generally look surprisingly comfortable at rest even if the cardiac output is low. The goals of further therapy depend on the clinical situation, but options are limited. Intravenous inotropic therapy provides only temporary improvement and may be followed by clinical deterioration. Further vasodilation may increase resting cardiac output, but it frequently causes symptomatic hypotension, particularly upon standing. Cautious initiation of therapy with β-blocking agents may lead to later improvement in systolic function and cardiac output, particularly if resting heart rate is high. Titration of β-blocking agents should proceed slowly, with most titration steps occurring after discharge and with frequent reevaluation.

#### Use of Direct Hemodynamic Monitoring

**Cardiogenic Shock.** In patients who have initial severely symptomatic hypotension or rapid deterioration, hemodynamic monitoring is performed urgently to establish the diagnosis of cardiogenic shock, guide titration of high-dose pressor agents, and evaluate for emergency surgical intervention.

Description of these patients if evaluated for urgent mechanical circulatory support would be as for Interagency for Mechanically Assisted Circulatory Support (INTERMACS) profile 1 (precipitous deterioration despite rapidly escalating therapy, “crash and burn”) or profile 2 (failing on inotropes).<sup>53</sup> As discussed previously, the proportion of patients admitted with heart failure and cardiogenic shock is very small (see Figure 43-1).

**Defining Baseline Hemodynamic Status.** Direct hemodynamic monitoring with a pulmonary artery catheter is sometimes employed to guide diagnosis and management of heart failure during hospitalization (Box 43-1; see Table 43-4). For most patients, skilled clinical assessment should be adequate for placement in one of the four basic profiles for initiation of therapy. In the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE), clinical estimation was definitively compared with direct hemodynamic measurements<sup>33</sup>; the correlation was strong for filling pressures and only modest for cardiac output.<sup>10</sup> In patients in whom assessment yields limited or ambiguous findings, hemodynamic measurements may help increase certainty regarding, or actually define, the appropriate first targets of filling pressures and perfusion. Strategies of care may be informed by hemodynamic measurement in patients for whom symptom severity consistently exceeds clinical evidence of hemodynamic abnormalities, in which case exercise hemodynamic measurements may also be helpful. Hemodynamic measurement may clarify the contribution of heart failure to decompensation in the setting of other concomitant diagnoses, either cardiac (such as primary valve disease) or noncardiac (such as chronic pulmonary disease).

**Hemodynamic Monitoring While Tailoring Therapy.** One of the first routine uses of pulmonary artery catheterization in heart failure was to determine pulmonary pressures and reversibility of pulmonary hypertension during evaluation for cardiac transplantation in patients with advanced heart failure and low ejection fraction. When pulmonary vascular resistance was high in the setting of high left-sided filling pressures, the catheters were often left in place to ensure that pulmonary vascular resistance was sufficiently improved by reduction of left ventricular filling pressures with diuretics and vasodilators. Because severe vasoconstriction was commonly present before renin-angiotensin system inhibition became standard, vasodilation with nitroprusside or nitroglycerin was frequently necessary in combination and occasionally instead of diuretic therapy. Oral vasodilators were then substituted to maintain the lower filling pressures and vascular resistances as patients were weaned from the intravenous vasodilators.<sup>52,54,55</sup> After major improvement in symptoms and intermediate-term outcomes were noted, this strategy of tailored therapy to achieve near-normal filling pressures (see Table 43-3) could be applied to other patients admitted with advanced heart failure at specialized centers.<sup>56</sup>

The knowledge gained from physiology and therapeutic responses during hemodynamic monitoring has helped refine serial goals through clinical assessment (see Table 43-4). Therapy guided by clinical assessment was compared with therapy guided additionally with the use of a pulmonary artery catheter in ESCAPE (see Table 43-3) in patients with decompensation of chronic heart failure for whom there was clinical evidence regarding the need for invasive monitoring of therapy. Congestion, evidence of which was based on jugular venous pressure and edema, was alleviated similarly in both groups; in patients with the pulmonary artery catheter, renal function was better and mitral regurgitation was lower at the time of hospital discharge, perhaps in relation to the ability to assess left-sided filling more directly.<sup>26,50</sup> Symptomatic improvement was better at 1 month for the patients who underwent catheter-guided therapy, but there were no differences between the patient groups by 6 months, during which

### BOX 43-1 Possible Indications for Insertion of Pulmonary Artery Catheter During Hospitalization for Heart Failure

#### Life-threatening Circulatory Compromise

##### Uncertainty Regarding Baseline Hemodynamic Profile

- Symptom severity out of proportion to clinical examination, may need assessment during exercise
- Ambiguity regarding clinical assessment

##### Management of Decompensated Heart Failure with Unclear Contribution from Other Condition

###### Cardiac

- Active ischemia
- Primary valve disease

###### Noncardiac

- Severe pulmonary disease
- Renal failure
- Hepatic failure
- Sepsis or systemic inflammatory syndrome

Postoperative respiratory failure or refractory hypotension

##### Failure to Respond as Anticipated to Medical Therapy Guided by Empirical Assessment

##### Uncertainty regarding hemodynamics after therapy

- Suspected right-left mismatch
- Possible intrinsic pulmonary hypertension
- Possible unusually high or low systemic vascular resistance
- Refractory or recurrent symptoms of unclear origin
- Cardiorenal syndrome (hemodynamic measurement not often revealing)

##### Need for Detailed Hemodynamic Documentation

- Evaluation for cardiac transplantation or ventricular assist device
- Failure to wean from intravenous inotropic fusions

fluid retention recurred in both.<sup>33</sup> Pulmonary artery catheterization in these experienced centers was not associated with the adverse outcomes suggested from previous uncontrolled intensive care unit experiences,<sup>57</sup> in which use of pulmonary artery catheters was often triggered by clinical instability and sometimes led to more zealous use of fluid resuscitation and inotropic infusions.

**Later Use of Invasive Hemodynamic Monitoring.** In patients initially managed by clinical assessment, hemodynamic monitoring may be undertaken if patients fail to respond to or deteriorate during usual therapy. This may lead to detection of one of the modified profiles, such as right-left mismatch or unusual systemic vascular resistance. Hemodynamic monitoring is strongly recommended to help reevaluate optimization of filling pressures and systemic vascular resistance while oral agents are adjusted during weaning from inotropic infusions in patients who appear to be dependent on them. The value of hemodynamic information is less clear in patients who develop the cardiorenal syndrome during diuresis, in which the hemodynamic values obtained are usually those anticipated from clinical assessment.

Hemodynamic parameters related to filling pressures are robust prognostic parameters. High pulmonary capillary wedge pressure, right atrial pressure, and pulmonary artery systolic and mean pressures are all predictive of rehospitalization and mortality on a continuum, without a sharp threshold, and are more predictive when measured after therapy has been optimized, whereas indexes of cardiac output offer little prediction in patients with advanced heart failure.<sup>22,33</sup> However, invasive hemodynamic monitoring is not indicated purely to stratify risk in this population, for which there are many prognostic

parameters that can be measured noninvasively. Currently, the use of pulmonary artery catheterization to guide therapy is considered a reasonable strategy (level IIa recommendation) in experienced centers when the hemodynamic status is uncertain or when resting symptoms or circulatory compromise persist despite empirical therapy, but it is not recommended as routine practice.<sup>6</sup> Even in patients for whom redesigning therapy has been considered useful, repeated right-sided heart catheterization should not be necessary for long-term management.

## NONINVASIVE TECHNIQUES FOR MONITORING FILLING PRESSURES AND CARDIAC OUTPUT

Numerous parameters that are generally correlated with a hemodynamic parameter, usually with filling pressures, have been identified. Their utility should be considered separately in regard to diagnosis, to adjustment of therapy, and to prognosis. Some may help support a diagnosis of heart failure in a patient without previous known heart failure or in whom multiple conditions coexist. Assays of portions of the B-type natriuretic peptide (BNP) have consistently enhanced recognition of heart failure in multiple studies of patients presenting to emergency departments with dyspnea.<sup>14</sup> BNP levels generally decrease during effective therapy for heart failure, whereas increase in BNP levels over time is predictive of worse outcome. However, BNP levels as currently measured do not change rapidly enough to guide therapy in the hospital.<sup>58</sup> BNP levels over 1300 pg/mL at discharge are highly predictive of poor outcomes but do not have specific implications for current therapies other than to support<sup>59</sup> consideration of transplantation or mechanical circulatory support.

Several approaches to measuring thoracic impedance have been developed to track intrathoracic fluid accumulation, which is correlated generally with decreased electrical impedance, but none has been sufficiently reliable to guide diagnosis and therapy in individual patients.<sup>60</sup> Findings of impedance cardiography are correlated modestly with cardiac output, but they do not identify hemodynamic profile consistently, nor do they change directionally with measured cardiac output during therapy.<sup>60</sup> Echocardiographic estimates of central venous pressure elevation can be used when clinical evaluation of jugular venous pressure is not available,<sup>15</sup> but the clinical utility of echocardiographically estimated filling pressures has not been validated for serial evaluation of hospitalized patients. Further refinements of handheld echocardiographic measurements will probably offer potentially useful information, particularly when serial information is available for individual patients.

## SPECIFIC AGENTS USED DURING HOSPITALIZATION

Diuretics, intravenous vasodilators, and intravenous inotropic agents are the major medications used during acute management of decompensated heart failure when oral therapy has been inadequate to prevent hospitalization. The major principles of diuretic use are described in Chapter 44.

### Intravenous Vasodilators

After diuretics, intravenous vasodilators are the most useful medications for the acute management of heart failure (see Chapter 44). They reduce filling pressures and symptoms immediately. Cardiac output increases as vasodilation and diuresis occur, primarily as a result of decreased mitral regurgitation, as discussed previously. They do not usually increase heart rate or exacerbate arrhythmias unless titrated to excessive levels of vasodilation and severe hypotension.

### Nitroprusside

Nitroprusside was the first vasodilator shown to improve cardiac output in heart failure.<sup>27</sup> It has dramatic efficacy in therapy for severe hypertension, in which systemic vascular resistance is also severely elevated. Although useful for hypertensive crises, nitroprusside, when titrated carefully in heart failure, is rarely associated with serious hypotension. Its use in heart failure has traditionally been monitored invasively through pulmonary artery catheters.<sup>61</sup> Noninvasive blood pressure monitoring with an automated cuff usually obviates the need for an indwelling arterial catheter. The rapidity of onset and offset, with a half-life of approximately 2 minutes, facilitates early establishment of an individual patient's optimal vasodilation and efficient weaning onto an oral vasodilator regimen that is adjusted to equivalent hemodynamic effects. Nitroprusside is generally initiated at 10 µg/min and increased by 10 to 20 µg every 10 to 20 minutes as tolerated, with hemodynamic goals of reducing the pulmonary capillary wedge pressure to 16 mm Hg without lowering systolic blood pressure below 80 mm Hg.<sup>52,56</sup> The systemic vascular resistance is used to guide the relative emphasis on vasodilation versus diuresis. Once the systemic vascular resistance is near normal, further reduction of filling pressures is generally accomplished primarily by diuresis; conversely, once near-normal filling pressures have been established, further vasodilation may not be necessary. Individual response varies markedly: 50 to 100 µg/min is effective in some patients, whereas others require 300 to 400 µg/min to achieve adequate vasodilation. Doses are often measured in absolute doses rather than per kilogram but rarely exceed 4 µg/kg (Table 43-5).

The major limitation of nitroprusside in this setting is side effects from cyanide, predominantly gastrointestinal and central nervous system manifestations, often manifested by nausea and "feeling weird." Cyanide is most likely to accumulate in patients in whom hepatic perfusion is severely reduced as a result of low cardiac output and in whom hepatic function is decreased as a result of elevated right-sided pressures or previous underlying liver disease. Cyanide toxicity is most likely to develop in patients receiving more than 250 µg/min for more than 48 hours. Cyanide results are rarely available in time to be useful; suspected toxicity is treated by decreasing or discontinuing the nitroprusside infusion, and additional therapy is almost never required in this setting. Less important during short-term nitroprusside administration is the thiocyanate metabolite, which can accumulate over days during more chronic use, particularly when renal function is impaired. Although it is the most effective intravenous vasodilator available, decreasing familiarity with nitroprusside has unfortunately limited its use in heart failure to a few specialized centers.

### Nitroglycerin

Regardless of the route of administration, nitroglycerin is one of the safest and most versatile agents in acute therapy for decompensated heart failure. Nitroglycerin infusion is most commonly used for treatment of acute ischemic syndromes or heart failure in which acute ischemia is suspected. However, nitrates are very effective arterial vasodilators in the setting of vasoconstriction, although they are commonly considered as only venodilators.<sup>62-64</sup> Dose responses for both nitroglycerin and nitroprusside are markedly variable interindividually, but decreasing systemic vascular resistance requires higher doses of nitroglycerin than of nitroprusside. Dosing is generally begun at 20 µg/min of nitroglycerin, increased in 20-µg increments to the hemodynamic goals described previously. The most common side effect of intravenous or oral nitrates is headache, which, if mild, can be treated with analgesics and often resolves during continued therapy.<sup>42</sup> As with all

**TABLE 43-5** Common Intravenous Vasoactive Agents for Heart Failure

Agent	Initial Dose	Effective Dose Range
<b>Vasodilators</b>		
Nitroglycerin	20 µg/min	40-400 µg/min*
Nitroprusside	10 µg/min	30-350 µg/min* Usually <4 µg/kg/min
Nesiritide	With or without 1- to 2-µg/kg bolus	0.005-0.03 µg/kg/min
<b>Inotropic Agents†</b>		
Dobutamine	1-2 µg/kg/min	2-10 µg/kg/min for inotropy and vasodilation
<b>Dopamine</b>		
• for heart failure	1-2 µg/kg/min	2-4 µg/kg/min for vasodilation and inotropy
• for hypotension	4-5 µg/kg/min	5-15 µg/kg/min for inotropy and vasoconstriction
Milrinone	50- to 75-µg/kg bolus may be administered over 10 min	0.10-0.75 µg/kg/min for vasodilation and inotropy

\*Customarily titrated to effect, using absolute doses rather than per kg.  
†These inotropic agents also cause vasodilation. The more potent inotropic agents epinephrine and norepinephrine and the pressor agent vasopressin are rarely used for chronic decompensated heart failure but are discussed in the “Specific Agents Used During Hospitalization” section.

vasodilating agents, blood pressure often decreases, and it may decrease precipitously if initial filling pressures were actually low rather than elevated. A rare reaction is a prolonged episode of profound hypotension with bradycardia, usually when initial filling pressures are normal or low.

**Nesiritide**

Nesiritide is a recombinant form of BNP, which is an endogenous peptide secreted primarily from the left ventricle in response to wall stress. Like nitroprusside and nitroglycerin, nesiritide acts to increase cyclic guanosine monophosphate. It may be administered as a bolus before fixed dose infusion. Nesiritide lowers filling pressures and improves symptoms during therapy for decompensated heart failure.<sup>65</sup> As with nitroglycerin, blood pressure must be monitored closely during nesiritide therapy because hypotension can occur. Because nesiritide has a longer half-life (18 minutes), hypotension can last longer than with intravenous nitroglycerin, but it is usually well tolerated in the supine position. Inappropriate bradycardia occasionally accompanies hypotension. Headache is less common with nesiritide than nitroglycerin. Both agents have been shown to be effective for decreasing filling pressures and relieving symptoms in heart failure.<sup>42</sup>

Nesiritide has not been associated with major diuresis when used alone in clinical trials. It does appear to potentiate the effect of concomitant diuretics, so that the total diuretic dose required may be slightly lower; this effect may persist after the infusion is stopped. Controversy regarding potential deleterious effects of nesiritide has been extensive.<sup>43</sup> Although it was considered at one time to be renal sparing, in current dosing regimens it does not appear to improve renal function more than other vasodilators and may in fact worsen renal function in patients who develop hypotension. Nesiritide is sometimes used specifically to decrease pulmonary vascular resistance in patients with heart failure, particularly

after cardiac surgery. A large ongoing trial should help define its clinical role in heart failure–related decompensation. The intravenous vasodilator phentolamine is an α-adrenergic blocker, used in some early investigations of vasodilators<sup>54</sup> but no longer generally available for infusion. Intravenous enalaprilat is converted to enalapril, a long-acting vasodilator that is not appropriate for intravenous titration but is used occasionally in postoperative patients as a substitute for their usual oral angiotensin-converting enzyme (ACE) inhibitor until they can resume oral intake. Intravenous hydralazine has unpredictable dose-response effects and can cause serious sustained hypotension, even after previous doses have been well tolerated. Only the oral form is used for management of heart failure.

**Monitoring of Intravenous Vasodilators**

Increasing experience with nitroglycerin and nesiritide indicates that they can often be used to treat exacerbations of heart failure without invasive hemodynamic monitoring.<sup>42</sup> Blood pressure can generally be monitored through an automated blood pressure cuff with frequent readings, so that the discomfort and risk involved with an indwelling arterial catheter are not warranted. Transient episodes of hypotension are usually quite well tolerated when related to vasodilation rather than to ischemia or arrhythmias. The ability to use these agents without invasive monitoring facilitates their use on monitored stepdown units; thus, intensive care unit resources are not challenged. Patients with more critical hemodynamic compromise require an intensive care unit regardless of the choice of initial therapy. Limited capacity for invasive monitoring should not be a factor in determining whether vasodilator or inotropic infusions are employed.

**Weaning from Intravenous Vasodilator Agents**

Once patients are considered to have reached optimal circulatory status, they are weaned from intravenous agents as oral agents are adjusted. In some cases, only the volume status has changed. In other cases, oral vasodilators are adjusted to maintain the profiles achieved with the intravenous agents.<sup>54,56</sup> It is important to recognize that the current intravenous vasodilators cause both arterial and venous dilation. As patients are weaned from these agents, filling pressures frequently rise again as venous capacitance decreases, necessitating either further diuresis or effective substitution with sufficient venodilation by oral agents. The selection and adjustment of oral therapy is discussed in the “Designing the Oral Regimen” section. When the short-acting intravenous agents are monitored by means of pulmonary artery catheters, patients are weaned as oral dosages are increased, to maintain the optimal hemodynamics achieved. When oral agents are adjusted according to clinical assessment, the jugular venous pressure, supine blood pressure, and upright blood pressure guide dosing (see Table 43-2). The timing of oral vasodilator dose increases requires more monitoring during weaning from nesiritide because of its longer half-life.

**Intravenous Inotropic Agents**

**Considerations for Use and Weaning**

The perception that intravenous inotropic agents are easy to use has led to their frequent initiation at the time of hospitalization for heart failure in the absence of any specific indications for inotropic support. The concept of hospitalization for an “inotropic holiday” with infusions for 24 to 72 hours was once popular. However, these agents are associated with more tachyarrhythmias and ischemic events than are placebo or vasodilator infusions.<sup>39</sup> In addition, the presence of inotropic infusions may complicate the redesigning of a regimen of an oral diuretic and vasodilator for discharge; the efficacy of diuretics and tolerability of ACE inhibitor doses may be

overestimated when the effect of the inotropic stimulation lingers. This may prolong hospitalization or increase the likelihood of early rehospitalization. The use of current inotropic agents, therefore, would be most appropriate when they provide necessary benefits not offered by initial therapies (see also Chapter 44).

Inotropic therapy might be considered as the “until” therapy, with a predefined endpoint<sup>66</sup>. It may be used *until* the underlying hemodynamic profile and cause of severe hypotension are elucidated. It may be used *until* diuresis is effective in patients with conditions refractory to escalating diuretic therapy. It may be used *until* kidney, lung, or liver function has improved to establish eligibility for cardiac transplantation or for operative intervention. It may be used *until* recovery from a superimposed insult such as pneumonia, pulmonary embolus, myocardial infarction, or surgery. Most of the experience with prolonged infusions has been derived from patients waiting *until* an appropriate heart can be found for cardiac transplantation.

Many patients considered dependent on intravenous inotropic therapy can nonetheless be stabilized with oral therapy tailored to filling pressures and systemic vascular resistance.<sup>52,67</sup> This may necessitate temporary or permanent discontinuation of  $\beta$ -adrenergic antagonists and ACE inhibitors, because of their negative inotropic effects in severely compromised patients. The use of nitrates and the addition of hydralazine may be particularly effective in restoring compensation with oral vasodilators after prolonged inotropic infusion.<sup>67</sup>

There is a growing population of patients, however, for whom multiple adjustments of oral therapy have become inadequate to maintain freedom from congestion with adequate renal function. Many of these patients are those in whom right ventricular failure has become prominent and the cardiorenal syndrome is manifest. Continuous intravenous inotropic infusions have been recognized as palliative care *until* death for a population of these patients (see Chapter 61). This therapy has been associated with frequent complications from indwelling catheters and with sepsis.<sup>68</sup> Escalating doses are usually required, and survival expectancy is less than 50% during the next 3 to 6 months. In rare cases, however, patients have remained stable on moderate doses and have occasionally been weaned completely from inotropic support later. For most patients, the last chapter of their life with heart failure is smoother and more comfortable if they are not tethered to a continuous infusion at home.

### Specific Inotropic Agents

**Dobutamine.** The most commonly used inotropic agent during hospitalization for heart failure is dobutamine, an agent that stimulates  $\beta$ -adrenergic receptors with little effect on  $\alpha$ -adrenergic receptors, so that contractility is increased with peripheral and pulmonary vasodilation. Dobutamine was introduced as an alternative to dopamine, one that produced less tachycardia, but it does not affect dopaminergic receptors. Early uncontrolled studies demonstrated increased cardiac output with decreased filling pressures. Myocardial stores of adenosine triphosphate were shown to be improved after a brief period of dobutamine therapy, and sometimes symptomatic benefit persisted.<sup>69</sup> Much of this benefit has been attributed to the potentiation of diuresis when fewer options were available for enhancement of diuretic therapy.

Heart rate is consistently increased during dobutamine therapy, particularly in patients with atrial fibrillation. Atrial and ventricular tachyarrhythmias and symptoms of ischemia are increased during dobutamine therapy for decompensated heart failure. A comparison of dobutamine with nesiritide revealed increased premature ventricular contractions, episodes of nonsustained ventricular tachycardia, and signs that fulfilled criteria for the diagnosis of proarrhythmia.<sup>70</sup>

When dobutamine therapy is considered warranted despite these risks, the lowest dosage possible should be used for the desired effect. Enhancement of diuresis and improvement of renal function can be observed at doses of 1 to 2  $\mu\text{g}/\text{kg}/\text{min}$ . Treatment for more severe hypoperfusion usually necessitates higher doses. Patients receiving chronic maintenance infusions generally exhibit tachyphylaxis and require increasing dosages over time. There may be little benefit from increasing the dosage above 10  $\mu\text{g}/\text{kg}/\text{min}$ , however, and other therapy should be added or substituted as the dosage approaches 15  $\mu\text{g}/\text{kg}/\text{min}$ . An exception may be in patients with hypotension during chronic therapy with  $\beta$ -adrenergic antagonists. Dobutamine is often adequate for improving cardiac output in this setting, but dosages higher than usual may be required.<sup>71</sup>

On occasion, patients taking dobutamine for prolonged periods of many weeks may develop an eosinophilic hypersensitivity that is usually manifested in an elevated circulating eosinophil count and sometime in urine eosinophil levels as well. This can take the form of a skin rash, but of greater importance, eosinophilic myocarditis has been found in the explanted hearts of about 15% of patients receiving chronic infusions before cardiac transplantation.

**Dopamine.** Dopamine stimulates  $\beta$ -receptors,  $\alpha$ -receptors, and dopaminergic receptors that cause vasodilation in the renal and peripheral vasculature. At dosages of 3  $\mu\text{g}/\text{kg}/\text{min}$  or less, dopamine is predominantly vasodilatory. The dopaminergic receptors are overwhelmed by  $\alpha$ -adrenergic stimulation when dopamine doses reach 5  $\mu\text{g}/\text{kg}/\text{min}$ , or when other vasoconstricting pressors are given. Dopamine also causes release of norepinephrine from nerve terminals, which itself stimulates  $\alpha$ - and  $\beta$ -receptors and raises circulating norepinephrine levels.

Because of the effect on dopaminergic receptors in animal models, the concept of “renal-dose dopamine” at 1 to 3  $\mu\text{g}/\text{kg}/\text{min}$  has been popular. For patients with renal dysfunction and normal circulation, it is controversial whether this therapy enhances renal function specifically. In patients with heart failure, any dosage of dopamine can have systemic hemodynamic effects from enhanced cardiac output and decreased systemic vascular resistance. The benefit of low-dosage dopamine to enhance diuresis and renal function is clinically similar to that of dobutamine at the same dosages. Similarly, tachyarrhythmias and ischemic episodes can also be observed even with low dosages.

Dopamine is a good choice for therapy in rapidly changing situations in which modest inotropy and vasodilation may be adequate but further pressor support may be required, inasmuch as this can be achieved by dose escalation. When blood pressure support is the initial need, dopamine should be started at a dosage of at least 4  $\mu\text{g}/\text{kg}/\text{min}$ . Similarly, when patients are weaned from the use of dopamine as a pressor agent, it may be necessary to discontinue it once a dosage of 3  $\mu\text{g}/\text{kg}/\text{min}$  is reached, because gradual weaning through lower doses may in fact cause vasodilation and hypotension. There is little evidence to support the addition of dopamine to dobutamine for enhanced renal function for patients with heart failure, and it would be expected to increase the risk of arrhythmias and ischemia.

**Milrinone.** Amrinone, milrinone, and the phosphodiesterase inhibitors lead to increased levels of cyclic adenosine monophosphate by inhibiting its breakdown, rather than by increasing its production through stimulation of  $\beta$ -receptors. These agents then may act synergistically with  $\beta$ -adrenergic agents to achieve further increase in cardiac output than does either agent alone. They may also be more effective than  $\beta$ -adrenergic receptor stimulation to increase cardiac output when excess  $\beta$ -blocking agents have been given. Phosphodiesterase inhibition increases contractility and causes marked vasodilation. The degree to which cardiac output increases and systemic vascular resistance decreases is markedly

variable, so that some patients exhibit predominant vasodilation. There is thus a significant incidence of hypotension with milrinone, unlike dobutamine, which rarely causes hypotension except in unappreciated vasodilatory states such as sepsis. In a trial of patients hospitalized with heart failure and an average baseline blood pressure of 120 mm Hg, 10% of the patients developed clinically significant hypotension, which was a higher percentage than among those who received placebo.<sup>39</sup> When hypotension is considered the indication for use of an intravenous inotropic agent rather than an intravenous vasodilator, milrinone is rarely an appropriate choice.

Milrinone has been associated with slightly less elevation in heart rate than have dobutamine and dopamine.<sup>72</sup> Like the other intravenous inotropic agents, however, milrinone increases the frequency of atrial and ventricular tachyarrhythmias and ischemic events. A trial of 48-hour infusion of milrinone during heart failure hospitalization caused significantly more adverse events than did placebo; these events included atrial and ventricular tachyarrhythmias, cardiac arrest, and myocardial infarction.<sup>39</sup>

The use of milrinone for short-term stabilization is complicated by its prolonged half-life. Unlike the pharmacological half-lives of dopamine and dobutamine, which are in minutes, the elimination half-life of milrinone is about 2.5 hours, and the physiological half-life is closer to 6 hours. Although bolus therapy was originally recommended, milrinone is frequently used without a bolus to avoid rapid initial effects, at doses as low as 0.01 µg/kg/min. The drug is then titrated to the desired hemodynamic effect, in increments of the lowest doses possible, up to a maximum of 0.75 µg/kg/min. Because the drug is excreted renally, dosage adjustment is recommended. In the setting of decreased renal function, which occurs commonly in heart failure, effects accumulate and persist over a longer period of time. When milrinone is discontinued after several days, the physiological half-life often seems to exceed 12 or even 18 hours. As a result, clinicians frequently consider patients to have tolerated weaning from this agent, but then the patients deteriorate after transfer out of the intensive care unit or discharge home. It is thus even more important for this inotrope that the infusion be discontinued with further observation of fluid balance and perfusion for at least 48 hours before hospital discharge.

Because milrinone has been studied in trials in an oral form, more is known about the long-term effects of this agent than about the other intravenous inotropic drugs in current use. During chronic use, rates of mortality from heart failure and of sudden death were increased in comparison to placebo, without significant improvement in symptoms.<sup>73</sup> Hemodynamics deteriorated during chronic use but worsened further when the drug was withheld; this observation raised speculation that the phosphodiesterase inhibitors might accelerate hemodynamic decline.

Patients awaiting cardiac transplantation may be supported with extended infusions of milrinone either alone or in combination with dobutamine when dobutamine no longer provides sufficient stabilization of organ function preoperatively.<sup>74</sup> Patients requiring two inotropic infusions are, however, increasingly being offered mechanical support devices as bridges to transplantation. Some centers previously provided intermittent outpatient inotropic infusions, but this practice has no basis of evidence and is not approved.

**Epinephrine and Norepinephrine.** Epinephrine and norepinephrine are full β-receptor agonists, in contrast to dopamine and dobutamine. Significant additional inotropic and blood pressure support can be provided by these agents for short-term life-saving intervention over a span of minutes to hours before definitive therapy. Although norepinephrine is commonly confused with phenylephrine (Neo-Synephrine), both norepinephrine and epinephrine stimulate type 1 β-adrenergic receptors and α-adrenergic receptors, increasing contractility, heart rate, and peripheral vascular resistance,

while promoting cardiac arrhythmias and ischemia. (Phenylephrine is a pure vasoconstricting agent.) Kidney failure, hepatic failure, and gangrene can result from use of these agents, which should not be administered except in true emergency situations. Epinephrine has more affinity for type 2 β-receptors, which are vasodilatory, than does norepinephrine and thus is slightly less likely to cause tissue necrosis from intense vasoconstriction, although both are profound vasoconstrictors appropriate for therapy of vasodilatory shock. There is ample anecdotal evidence leading to the term “letho-fed” for norepinephrine.

When fatal hypotension is imminent, epinephrine or norepinephrine are used at a starting dose of 1 µg/min, not usually expressed as per-kilogram dosing. Before this point, injection of 0.25 mg of epinephrine from the code cart may provide several minutes of stabilization during which to make more definitive plans for circulatory support or the orchestration of the end of life. To maintain survival for brief periods of minutes until definitive therapy, boluses of calcium can be helpful, particularly in the presence of conditions that may acutely lower serum calcium, such as transfusion, dialysis or cardiopulmonary bypass. Contractility increases rapidly with increased circulating calcium concentration.<sup>75</sup> This therapy is highly arrhythmogenic and may exacerbate ongoing myocardial necrosis; therefore, it should not be maintained.

**Vasopressin.** Vasopressin is used increasingly to potentiate the effects of catecholamines in patients who remain severely hypotensive, with systolic blood pressures of 60 to 70 mm Hg, despite high-dose pressor support. This experience is derived from early postoperative management after heart transplantation or insertion of mechanical support devices.<sup>76,77</sup> Some patients who have been most compromised preoperatively develop profound vasoplegia, with low systemic vascular resistance states of the systemic inflammatory response syndrome. Vasopressin has been used for periods of hours to days, in doses of 0.05 to over 0.1 U/min. At these doses, patients already receiving norepinephrine frequently have further 30-mm Hg increases in systolic blood pressure.<sup>76,77</sup> Although vasopressin is considered an antidiuretic hormone, its use in critical settings is sometimes associated with profound water diuresis that reverses after discontinuation of the drug. As a potent vasoconstricting hormone itself, vasopressin can contribute to ischemic injury and necrosis of organs and limbs during use of other vasoconstricting agents.

## REEVALUATION

Serial evaluation and adjustments in therapy usually lead to resolution of the acute decompensation that led to the hospitalization for heart failure. In affected patients, the focus shifts gradually toward redesign of the outpatient regimen for stabilization. In addition to redirecting pharmacological and pacing device therapies, the hospitalization provides a valuable opportunity to review and revise the individual prognosis for long-term quality and length of survival.

## Escalating Support

A small minority of patients present with rapidly deteriorating circulatory status and life-threatening hypoperfusion, from which survival may be possible only with rapid, aggressive intervention. It is critical that clinicians recognize the need for an accelerated tempo of assessment and decision in these situations. The goal in these cases is to stabilize the patient to a point at which decisions can be made regarding definitive surgical therapy such as mechanical support, or until spontaneous recovery can occur, as in young adults with fulminant myocarditis.<sup>5</sup>

The situation of the patient who requires rapidly escalating support is described as the “crash and burn” level in the evolving classification of patients considered for mechanical circulatory support.<sup>53</sup> Evidence of this situation usually includes more than one of the following: systolic blood pressure remaining below 75 mm Hg, cardiac index persistently below 1.5 to 1.8 L/min/m<sup>2</sup>, systemic acidosis progressing to acidemia with positive lactate levels, “shock liver” with transaminase levels rising to the thousands of units per liter, obtundation, and anuria.

Dopamine is the most common first-line drug administered in this situation, but if the situation does not improve within minutes, escalation would include more intense inotropic support with epinephrine at escalating doses. Vasopressin is frequently added as well, as discussed previously in the “Specific Inotropic Agents” section. For the patient with otherwise robust health, consultation regarding surgical options should be obtained immediately. The role of the intra-aortic balloon pump for intermediate stabilization has been established for cardiogenic shock caused by acute myocardial infarction; the pump is usually inserted while other therapies are under way in the cardiac catheterization suite. When it can be performed expeditiously, balloon pump insertion seems reasonable for other cases of cardiogenic shock with underlying coronary artery disease.<sup>78</sup> For cardiogenic shock of other causes, its role is less clear, and plans for insertion should not detract from progress to more definitive intervention. Some experts advocate its use for stabilization of medical therapy and anesthesia regardless of cause, whereas others believe that it offers little benefit for patients without epicardial coronary artery disease and, moreover, increases the risk of vascular and infectious complications.

Poor survival rates with high incidences of multiorgan failure and infection are increasingly recognized among patients who undergo implantation of durable ventricular assist devices for unstable conditions. Most of these patients now are considered instead for temporary assist devices, as a “bridge” to a decision about an implantable device or, in some cases, to recovery from fulminant myocarditis. The “bridge-to-bridge” strategy also provides crucial opportunities to better assess the medical candidacy of patients for aggressive interventions, the psychosocial factors critical for a good outcome, and the patient’s preferences regarding extreme intervention in comparison with focus on comfort and acceptance of the imminent end of life. The use of circulatory assist devices in heart failure is discussed in Chapter 47.

Cardiac transplantation and mechanical circulatory support either as a bridge to transplantation or permanent “destination” therapy are not often appropriate (see Chapters 54 and 55). Most patients hospitalized with heart failure are elderly, with an average age of approximately 75 years, and have multiple comorbid conditions that preclude good outcomes with surgical intervention.<sup>1,79</sup> In these patients, the support that should be escalated is the humane support shown by compassionate medical staff and supportive consult services to the patient and family. Despite the negative connotation of heart “failure,” many patients and families need counseling to recognize its poor prognosis and the limited options for life-saving therapies. Whether days or weeks of life are anticipated, the challenge is to work with them to define and reach meaningful goals for the time remaining.

## PLANNING FOR HOSPITAL DISCHARGE

The majority of patients hospitalized with heart failure have not reached the end of their lives; instead, they can be stabilized to return to a reasonable level of function on an oral regimen designed to maintain stability. In unselected series,

however, 30% to 50% of patients discharged with a diagnosis of heart failure are rehospitalized within the next 3 to 6 months.<sup>1</sup> Failure to meet criteria for discharge contributes to this rate of rehospitalization.<sup>80</sup> There is continual pressure to reduce the lengths of stay, particularly when patients exceed the generally acknowledged “break-even point” for reimbursement of 5 days. However, admissions for less than 3 days usually represent patients who did not need admission but could have been managed at home with daily contact and repeated blood tests for electrolytes and renal function. Regardless of the length of stay, premature discharges do not save money, inasmuch as the last day of the first hospitalization consumes fewer resources than does the first day of rehospitalization, and readmissions within 30 days may not be reimbursed.

Criteria for discharge include stable fluid status, blood pressure, and renal function on the oral regimen planned for home for at least 24 hours (Table 43-6). Patients should be free of dyspnea or symptomatic hypotension while at rest, washing, and walking on the ward. Patients who have received intravenous inotropic agents should be observed for at least 48 hours after weaning in case of masking inadequacy or intolerability of the discharge regimen.

## Designing the Oral Regimen

Consideration of the components of the discharge regimen should influence therapy as soon as the patient has responded to the initial interventions. For the patients who have been hospitalized before, the question “How will this time be different?” should also be asked.

As discussed in the chapter on diuretic therapy (see Chapter 44), lower diuretic doses are necessary to maintain fluid balance than to achieve net fluid loss. As intravenous diuretics are discontinued, titration of oral diuretics should trigger discontinuation of a “sliding scale” of potassium replacement

**TABLE 43-6 Discharge Criteria for Hospitalization with Heart Failure**

Clinical status goals
<ul style="list-style-type: none"> <li>• Achievement of dry weight</li> <li>• Definition of blood pressure range</li> <li>• Walking without dyspnea or dizziness</li> </ul>
Stability goals
<ul style="list-style-type: none"> <li>• 24 hours without changes in oral regimen for heart failure</li> <li>• ≥48 hours off intravenous inotropic agents, if used</li> <li>• Even fluid balance on oral diuretics</li> <li>• Renal function stable or improving</li> </ul>
Discharge regimen
<ul style="list-style-type: none"> <li>• Estimated diuretic dose, with plan for first escalation if needed</li> <li>• ACE inhibitor/ARB or documented contraindication</li> <li>• β-Blocker discharge dose, plans for outpatient initiation, or documented contraindication</li> <li>• Anticoagulation for atrial fibrillation unless contraindicated</li> </ul>
Patient/family education
<ul style="list-style-type: none"> <li>• Sodium restriction</li> <li>• Fluid limitation if indicated</li> <li>• Medication schedule</li> <li>• Medication effects</li> <li>• Exercise prescription</li> </ul>
Monitoring of symptoms and weights
Instructions regarding when and whom to call
Scheduled call to patient within 3 days
Clinic appointment within 10 days and information handed off to monitoring physician

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker.

in favor of regularly scheduled dosing. If spironolactone is to be added to the home regimen, it should be started several days before discharge, and extreme caution should be taken to avoid hyperkalemia, because the drug's potential to worsen renal function and raise potassium levels may not be evident for several days.<sup>81</sup>

ACE inhibitors do not usually relieve the acute symptoms of heart failure and may actually compromise effective diuresis.<sup>82</sup> Their benefit in reducing remodeling, ischemic events, atrial fibrillation, and heart failure events is experienced over the longer term (see Chapter 45). Patients previously stable with long-acting ACE inhibitors should continue those doses in the hospital as tolerated. When ACE inhibitors are poorly tolerated—systolic blood pressures are frequently below 80 mm Hg or symptomatic hypotension is present—captopril is frequently preferred to the longer-acting ACE inhibitors.<sup>83</sup> Depending on the referral population, up to 30% of patients with advanced heart failure may not be able to tolerate ACE inhibitors because of hypotension or severe renal dysfunction.<sup>84</sup> In these patients, the usual regimen is hydralazine, 25 to 150 mg three to four times daily, and oral isosorbide dinitrate, 10 to 80 mg three times daily. Although ACE inhibitors were shown to be superior in patients with class II heart failure, the Veterans Administration Cooperative Vasodilator–Heart Failure Trial II (V-HeFT II) demonstrated equivalent rates of survival with enalapril and with hydralazine and nitrates in class III and class IV heart failure.<sup>85</sup> Most experience has been with the short-acting nitrate, although longer-acting oral nitrates have also been used. When hydralazine is not tolerated, vasodilation can also be achieved with high doses of oral nitrates alone. There is currently no accepted regimen for patients who cannot tolerate ACE inhibitors, hydralazine, or nitrates.

Addition of the hydralazine-nitrate combination to the ACE inhibitor/angiotensin receptor blocker (ARB) regimens should be considered when class III or IV symptoms persist in African American patients, for whom substantial improvement in both function and survival was demonstrated in the African American Heart Failure Trial (A-HeFT) (See Chapter 49).<sup>86</sup> Addition of these agents, particularly nitrates, to ACE inhibitor/ARB regimens in other patient populations may often result in clinical improvement<sup>64</sup> but has not been studied definitively.

$\beta$ -Adrenergic blocking agents should be continued in previously tolerated doses for patients admitted with fluid retention but without evidence of hypoperfusion (profile B). If recently started or increased, these agents should be stopped or decreased until fluid retention is effectively treated.  $\beta$ -Adrenergic blocking agents should in general be decreased or stopped in patients in whom hypoperfusion is evident, particularly if therapy with intravenous inotropic agents is considered.

Initiation of  $\beta$ -adrenergic blocking agents is not recommended during hospitalization for heart failure decompensation when hypoperfusion<sup>6</sup> has been prominent or intravenous inotropic therapy has been used. However, the majority of patients admitted in profile B can undergo cautious initiation of  $\beta$ -blocker therapy in hospital once fluid status has been stabilized, if blood pressures has not been low.<sup>87</sup>  $\beta$ -Blocker therapy initially causes elevation of filling pressures and reduction of cardiac output; therefore, patients should have sufficient hemodynamic margin to tolerate this challenge.

Lack of confidence in outpatient compliance with follow-up is not a good reason to initiate these agents prematurely before discharge in patients with tenuous compensation, because close surveillance will continue to be necessary. During the titration of oral medications before discharge, liberal parameters to withhold doses for low blood pressures should be avoided. Often a regimen is assumed to be well tolerated

but in fact has not been given. The effects of rebound vasoconstriction and neurohormonal stimulation during erratic medication dosing may complicate transition to the same regimen at home.

Implantable devices for defibrillation are indicated only in patients who have reasonable expectation of survival with good functional status for more than 1 year (see Chapter 47).<sup>88</sup> Among large community populations, the rate of mortality within 1 year of hospitalization for heart failure is 20% to 35% after the first such hospitalization and more than 40% after rehospitalization.<sup>89</sup> In patients who are repeatedly hospitalized for heart failure and chronic renal dysfunction, defibrillators are not predicted to prolong survival.<sup>17</sup> Furthermore, implantation of cardioverter-defibrillators for primary prevention of sudden death is contraindicated in patients with class IV symptoms of heart failure except in ambulatory patients with high likelihood of benefit from resynchronization therapy.<sup>88</sup> At the time of hospitalization for heart failure, symptoms are by definition class IV, occurring at rest or with minimal exertion. Thus, until clinical stability with class III or better functional status has been demonstrated after hospital discharge, implantable cardioverter-defibrillators should usually not be considered for primary prevention of sudden death. Cardiac resynchronization therapy is indicated in selected patients with severe symptoms who are nonetheless ambulatory with their stable oral medical regimen. Good clinical responses are most likely in patients with baseline QRS duration higher than 150 msec; they have rarely occurred in patients who have recently required intravenous inotropic therapy.<sup>90</sup> Depending on the overall likelihood of clinical response and the patients' preferences regarding mode of death and inappropriate shocks, cardiac resynchronization devices without defibrillation capability may often be appropriate.<sup>91</sup>

## Patient Education before Discharge

Patient education should take place during the entire hospitalization, with specific focus on salt and fluid intake, medication schedules, and the concept of a flexible diuretic regimen.<sup>92-94</sup> Participation in the ritual of daily measurements of weight and of intake and output makes real the concepts of fluid balance. Although hospitalization is considered a true “teachable moment,” too often the discharge information is rapidly delivered as the patients are packing their belongings. In addition to information about what they should not do, patients need positive information on the activities they can pursue, reinforcing that they should “Keep dry, keep active, and keep goals.” Patients need to understand specifically which changes necessitate a call to their care team and which necessitate a call to 911.

## Charting the Course

For some patients with heart failure, the hospital is the only place where their course with heart failure is reviewed and discussed. It may be difficult to assess the patient's short-term prognosis at the time of admission, when patients often appear frailer than at discharge. However, as the clinical status responds or fails to respond, particularly after multiple hospitalizations, general prognosis becomes more evident at the time of discharge, both to physicians and to the nursing staff.<sup>95</sup>

Almost 60% of patients discharged from hospitalizations for heart failure are readmitted within the next 6 months. Of those readmissions, the proportion for heart failure is about half after the first admission, and it increases thereafter.<sup>96</sup> Risk factors for readmission are similar to those for hospitalization for heart failure in general. The BUN level, BNP level, and systolic blood pressures have been strong

predictors of in-hospital mortality and also contribute to risk of heart failure–related events after discharge.<sup>79,97</sup> The ESCAPE risk score was designed specifically from information at discharge to determine risk for death or readmission within 6 months, and it includes high (>500 pg/mL) and higher (>1300 pg/mL) BNP levels, high (>40 mg/dL) and higher (>90 mg/dL) BUN levels, diuretic dose (>240 mg of furosemide or >120 mg of torsemide), low serum sodium level (<130 mEq/L), inability to tolerate  $\beta$ -blocker therapy, short 6-minute walk distance (<300 feet), need for cardiopulmonary resuscitation or intubation during hospitalization, and age older than 70.<sup>98</sup>

The 1-month reevaluation after hospital discharge is an opportunity for further refinement of prognosis and plans.<sup>32,34</sup> Patients with persistent or recurrent evidence of congestion at 1 month are likely to have declining functional capacity and quality of life and are at more than twice the risk for death or readmission than are those who remain free of congestion.<sup>32</sup> Evaluation for transplantation or mechanical circulatory support may be indicated for a small minority of these patients at highest risk. For most patients, however, an estimated survival time of less than 1 year should prompt a review of the overall goals of therapy. There is wide variation between patients in their preference for quality of life versus length of life, even in advanced disease,<sup>99</sup> and these may change between admission and the outpatient setting. This transition to focus on quality of life should occur gradually, before presentation of a specific resuscitation menu, although the concept of allowing natural death may be introduced in preference to a list of “Do Not” procedures. Many patients wish adequate time in order to address concerns at home such as financial planning or family reconciliation. Many patients worry about how death is likely to occur and whether it will be painful.<sup>100</sup> Discussions facilitated by palliative care teams can provide comfort and reassurance regarding relief of terminal symptoms, as well as the availability of extended bereavement counseling for family members.

The discharge plan requires that the patient have a follow-up appointment, usually within the first 7 to 14 days. Although this requirement presumably transfers responsibility to the outside physician, the handoff can leave patients stranded early after discharge. Follow-up contact should be scheduled to occur during the first few days that the patient is at home, often from a specialized nurse. For this protocol to be effective, detailed discharge information must transfer smoothly to the outpatient care team.

## CONTINUUM OF CARE THROUGH THE COMMUNITY: FUTURE DIRECTIONS

Both quality of life and survival with heart failure have improved dramatically since 1980, as has appreciation of the heavy burden of this disease. The medical advances reflect understanding of the role of neurohormonal stimulation and antagonism, the physiology and evaluation of congestion leading to decompensation, and the indications for devices to avert sudden death and enhance synchrony. Most therapies investigated for acute decompensation have been unsuccessful attempts to encompass the broad population of hospitalized patients. Clinicians remain optimistic that more specific neurohormonal or metabolic profiling will identify a subset of patients who would benefit from specific antagonists or metabolic manipulation. Therapy tailored to individual targets seems more promising than the blind application of all approved therapies until cumulative intolerance. However, the majority of new therapies is more likely to achieve long-term effects when initiated electively during clinical stability than during decompensation.

There are several areas of hospitalization and rehospitalization in which management may improve in the near future. New approaches to improving renal perfusion may enable more definitive therapy to maintain both renal function and fluid balance in hospital and after discharge, in view of the fact that the cardiorenal syndrome is a relentless driver of heart failure events. However, the most profound intervention to affect every aspect of patient success with heart failure has been the assembly of dedicated teams to educate and connect with patients, an approach that evolved from cardiac transplantation programs and clinical research programs with subsidized personnel support.<sup>101</sup> The providers include not only physicians and specialized nurses but also dietitians, pharmacists, social workers, and community services. Such effective management is, however, available to fewer than 5% of patients with heart failure.<sup>102</sup>

The unsupportable price of heart failure hospitalizations can clearly be reduced with better technology to monitor physiological parameters at home and link the patient to providers who share the same electronic records. With steadfast advocacy, the health care system will mature to support clinical reimbursement and focused training for the health professionals, both of which are necessary to bridge the gaps in disease management of heart failure. An additional obligation of specialists in the field is to refine triage in such a way that high-technology solutions can still be offered to patients who will derive the most benefit. Specialists must also find the courage to guide other patients through a natural conclusion of their disease. As patients and medical institutions recognize their shared responsibility for managing heart failure, it will increasingly “take a village” to sustain patients beyond hospitalization to enjoy meaningful lives in their communities.

## Conclusion, 657

Volume overload is one of the most common and important problems facing patients with heart failure. Fluid retention is probably the most frequent manifestation of heart failure. In addition, acute exacerbations in patients with chronic heart failure are often precipitated by volume overload. Even patients with stable chronic heart failure often have symptoms related to fluid status. Although treatment of the fluid overload may not resolve (and could potentially worsen) the underlying problem, it invariably improves the patient's symptoms substantially.

Many factors (such as diet and medication compliance) influence fluid status

Whereas, in most patients effective diuresis is straightforward, in conditions refractory to standard therapy, fluid management may be complicated and potentially deleterious. Diuresis may lead to electrolyte abnormalities and consequent arrhythmias. Intravascular depletion can cause hypotension, especially in patients receiving angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor antagonists. Neurohormonal activation can also be precipitated by diuretics. Perhaps most important, however, is the renal dysfunction that may be caused by diuretic therapy.

Diuresis is more difficult to achieve when renal function worsens. Increasing diuretic doses may lead to an elevated serum creatinine level with little additional urinary volume, especially in very ill patients (see Chapter 43). Moreover, deteriorating kidney function portends a particularly poor prognosis. Even a slight increase in serum creatinine level is predictive of an increased risk of mortality.<sup>1</sup> Fortunately, new medications and interventions are being developed which may improve the ability to safely and effectively control the fluid status of patients with heart failure.

The various diuretics, sites of action, dosages, and pharmacokinetics are listed in Table 44-1. These data are widely available. This chapter provides the basics of standard therapy and discusses experimental and innovative approaches for patients with refractory heart failure.

## TYPES OF DIURETICS

### Loop Diuretics

Loop diuretics are generally considered first-line diuretic therapy. They are effective and well tolerated. Although high levels achieved with rapid intravenous administration may cause ototoxicity, this complication is rare and can be prevented by slower administration.<sup>2</sup>

Of concern have been the possible direct and indirect effects of furosemide on myocardium. High doses of diuretics have consistently been associated with worse outcome.<sup>3</sup> It is unknown, however, whether this is because affected individuals are the most ill, or whether the doses have adverse consequences.

In view of the importance of effective diuresis on symptoms, the most common problem is probably underdosing with these drugs. As glomerular filtration decreases, higher doses must be used. This is because loop diuretics are secreted in the proximal tubule and act from the luminal side of the loop of Henle. Thus, doses of furosemide greater than 200 mg may need to be given.

Equivalent high doses of bumetanide and torsemide can be substituted, although there appear to be minimal diuretic differences among the various loop diuretics.<sup>8,9</sup> Despite the common assumption that bowel edema decreases absorption of oral loop diuretics, marked diuresis alters the pharmacokinetics of both furosemide and torsemide in only a small percentage of patients. In these patients, bowel edema delays absorption, rather than decreases it.<sup>9</sup> Thus, even in most edematous patients, adequate dosages of oral diuretics should be successful natriuretics. Although absorption of furosemide appears to be more variable than that of other loop diuretics, furosemide is both inexpensive and effective in most patients.

Of course, changes in a patient's status necessitate changes in the diuretic dosage needed. Improved cardiac function causes increased drug delivery to the nephron, which results in the need to reduce the diuretic dose.<sup>10</sup> Diuresis may also alter the heart's geometry and improve cardiac function. Just as the abnormal valvular and papillary muscle geometry caused by ventricular enlargement can lead to mitral regurgitation,<sup>11</sup> diuresis might reduce left ventricular volume, decrease mitral regurgitation, and improve cardiac performance.<sup>12</sup>

### Loop Diuretics and Hypertonic Saline

Coadministration of hypertonic saline with loop diuretics has been suggested to result in more effective diuresis.<sup>13</sup> The theory is that increased intravascular volume helps reduce tissue edema, improve renal blood flow, and decrease neurohormonal activation. However, most observers believe that increased salt intake leads to decompensation and should be avoided. At present, this remains a highly speculative treatment that should be tried only under investigational circumstances.

### Other Diuretics

The thiazide diuretics are not as potent as the loop diuretics and therefore are rarely used alone in patients with heart failure. They are ineffective when the glomerular filtration rate

**TABLE 44–1 Comparison of Conventional Diuretic Medications, Listed According to Site of Action**

	FE <sub>Na</sub> <sup>+</sup> (Maximum, %)	Dosage (mg/day)	Onset of Action		Action Duration		Peak Oral Effect (Hours)	Comments
Diuretic			Oral (Hours)	IV (Minutes)	Oral (Hours)	IV (Hours)		
Ascending Loop of Henle								
Furosemide	20-25	40-400	1	5	6	2-3	1-3	
Bumetanide	20-25	1-5	0.5	5	6	2-3	1-3	
Torsemide	20-25	10-200	1	10	6-8	6-8	1-3	
Ethacrynic acid	20-25	50-100	0.5	5	6-8	3	2	High ototoxicity risk, but (unlike other loop diuretics) can use in sulfa-allergic pts
Early Distal Tubule								
Metolazone	5-8	2.5-20	1	—	12-24	—	2-4	Greatest potential for potassium loss; also slight actions in proximal tubule
Chlorthalidone	5-10	25-200	2	—	24-48	—	6	Ineffective when GFR <30
Hydrochlorothiazide	5-8	25-100	2	—	12	—	4	Ineffective when GFR <30
Chlorothiazide	5-8	500-1000	1	15-30	8	—	4	Ineffective when GFR <30
Late Distal Tubule								
Spironolactone	2	50-400	48-72	—	48-72	—	1-2 days	Efficacy dependent upon aldosterone presence
Triamterene	2	75-300	2	—	12-16	—	6-8	
Amiloride	2	5-10	2	—	24	—	6-16	
Proximal Tubule								
Acetazolamide	4	250-375	1	30-60	8	3-4	2-4	Efficacy limited by metabolic acidosis it causes

FE<sub>Na</sub><sup>+</sup> (Max, %), maximal natriuretic effect (maximum fractional excretion of filtered sodium); GFR, glomerular filtration rate; IV, intravenously.

(GFR) is below approximately 30 mL/min, a common occurrence in patients with heart failure. Furthermore, thiazides cause a greater decrease in potassium than do loop diuretics for the same quantity of diuresis.<sup>14</sup>

Spironolactone is also not a potent diuretic. It works at the distal end of the distal convoluted tubule and cortical collecting duct, where it acts as a competitive inhibitor at the aldosterone receptor. Spironolactone blocks distal sodium resorption. Spironolactone and other potassium-sparing agents are weak diuretics because the distal delivery of sodium is decreased in the normal state. They are therefore rarely effective as a single agent in patients who need diuresis.

Spironolactone at low doses is commonly used not because of its diuretic effects but because its benefit is presumed to be the result of direct cardiac actions.<sup>15</sup> Aldosterone inhibition is important (at least in patients with severe heart failure) because of its role in myocardial remodeling and vascular fibrosis,<sup>16,17</sup> vascular damage,<sup>18</sup> baroreceptor dysfunction,<sup>19</sup> and prevention of myocardial norepinephrine uptake.

There are data to suggest that torsemide, but not furosemide, may block the renin-angiotensin-aldosterone system. This could then result in less cardiac fibrosis and myocardial remodeling.<sup>4</sup> In one animal study, torsemide suppressed left

ventricular fibrosis, myocardial protein levels of transforming growth factor- $\beta_1$ , collagen III, and aldosterone synthase and improved survival rate to the control level, but furosemide did not.<sup>5</sup> There is also a suggestion that the activities of torsemide on the sympathetic system might be different from those of furosemide.<sup>6</sup> In a nonrandomized clinical study, outcomes with torsemide were better.<sup>7</sup> The conclusions from these studies must be tempered with some concerns, however. The animal studies do not mimic clinical use, and the human study was only an observational analysis. Even if there are differences among agents, perhaps the concomitant use of ACE inhibitors and  $\beta$ -blockers prevents furosemide toxicity. Because of the common use of the very inexpensive furosemide, it is clear that until definitive proof is present, diuresis with furosemide will be necessary and will continue.

## COMBINATION OF DIURETICS

In patients with more advanced heart failure, distal tubule reabsorption may limit the efficacy of loop diuretics. In such patients, the combination of agents may be potent enough to enable diuresis. In particular, the combination of metolazone

and loop diuretics has been shown to be very effective.<sup>20</sup> Because of the pharmacokinetics of metolazone, however, an effect should not be expected immediately. This combination may result in potent potassium wasting, and the clinician needs to monitor potassium levels carefully and address any resulting hypokalemia.

In addition to its beneficial effects with regard to mortality (which is believed not to be secondary to potassium sparing), spironolactone may be used to maintain serum potassium concentrations. When used in combination with other diuretics, it may potentiate the effects of the loop diuretic while helping control potassium loss. Dosages for diuretic and potassium-sparing effects are higher (50 to 100 mg/day) than those shown to be beneficial in the Randomized Aldactone Evaluation Study (RALES) (25 mg/day; see Chapter 45).<sup>15</sup>

## EXTENT OF DIURESIS

The extent to which a patient should undergo diuresis is not known. Often treatment is directed toward improving acute symptoms; the physician may permit continued fluid overload. However, it is not enough to prevent pulmonary edema. Symptoms improve when the fluid status is optimized. Nonetheless, clinical evaluations are difficult, and the extent to which the patient needs diuresis may not be clear. Although it may be obvious that someone with peripheral edema and ascites has fluid overload, the extent of fluid in the abdomen may be difficult to determine, and intravascular pressures may be markedly elevated with no obvious extra fluid.

Some physicians believe that all patients with severe heart failure should be treated with hemodynamic monitoring. They believe that a pulmonary capillary wedge pressure of 15 to 20 mm Hg should be achieved with a combination of diuresis and vasodilatation. However, this theory has not been supported by the results of the randomized Evaluation Study of Congestive heart failure and Pulmonary artery catheterization Effectiveness (ESCAPE), which showed that addition of a pulmonary artery catheter to careful clinical assessment did not affect rates of overall mortality and hospitalization (Figure 44-1; see also Chapter 43).<sup>21</sup> Other investigations of continuous monitoring with implanted devices have yielded results that supported the prognostic importance of elevated filling pressures, but these results did not also show that monitoring could lead to a better outcome.<sup>22a</sup> The Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure (COMPASS-HF) trial was a randomized controlled study of an implantable continuous hemodynamic monitor (the Chronicle) that was placed in the right ventricular outflow tract in patients with advanced heart failure. The primary efficacy endpoint of COMPASS-HF, which was reduction in the rate of heart failure–related events (hospitalizations and emergency or urgent care visits necessitating intravenous therapy), was not met insofar as the group with the implantable hemodynamic device had a nonsignificant ( $P = .33$ ) 21% lower rate of all heart failure–related events than did the control group.<sup>22a</sup> Several other additional implantable hemodynamic monitors are under investigation: the Heart-POD, a stand-alone pressure monitor that is placed in the left atrium through a transseptal approach; the CardioMEMS Heart Sensor, a wireless system that is implanted in the pulmonary artery; and the RemonCHF System, an acoustic wave technology device that measures absolute pressures in the pulmonary artery (reviewed by Tallaj and colleagues<sup>22b</sup>). Each of these devices is currently being tested in patients with heart failure. Although patients with obvious fluid overload feel better if peripheral edema can be eliminated, the ideal method for achieving this has not been established clearly. Moreover, worsening renal function or adverse events are limiting factors in some patients.

**FIGURE 44-1** Hemodynamic monitoring by means of a pulmonary arterial catheter has not been shown to improve outcomes in patients admitted with heart failure. This illustration shows the cumulative proportion of patients contributing each possible numerical outcome for the number of days neither dead nor hospitalized during the 180 possible days of follow-up. The far left side of the curve represents early deaths; patients were considered to have survived 180 days if they lived for 6 months without rehospitalization. The curves for the two groups are virtually identical. PAC, pulmonary artery catheter. (From Binanay C, Califf RM, Hasselblad V, et al. Evaluation study of congestive heart failure and pulmonary artery catheterization effectiveness: the ESCAPE trial. *JAMA* 2005;294:1625-1633.) Copyright © (2011) American Medical Association. All rights reserved.

Study data have raised hope that measurement of B-type natriuretic peptide (BNP) or N-terminal pro-B-type natriuretic peptide (NT-proBNP) may be helpful in assessing fluid status (see also Chapter 37). It is suggested that a normal value (or the best value for an individual patient) enables each patient's fluid status to be adjusted optimally. As with hemodynamic monitoring, the promise of better outcomes has not been definitively proven. Better outcomes have occurred in randomized studies evaluating the impact of following NT-proBNP or BNP. Interestingly, however, doses of beta blockade and ACE inhibition are increased in these studies, suggesting that it is not the natriuretic peptide, but attention to getting patients on proven doses of medication, that is important.<sup>23,24</sup> Although natriuretic peptides are clearly prognostic (as discussed elsewhere), the difficulty in using them to treat individual patients may be partly related to the multiple factors other than filling pressures that can influence concentrations.<sup>25,26</sup>

## RISKS WITH DIURESIS

The most obvious risks with diuresis are hypokalemia and consequent ventricular arrhythmias. Rapid diuresis and the change in potassium that often occurs with hospitalization appear to increase the risk of potentially life-threatening arrhythmias.<sup>27</sup> Less worrisome, but often very bothersome to the patient, are muscle aches, which may occur with hypokalemia.

The risk of potassium depletion is common because when a diuretic increases sodium delivery to the distal renal tubule, potassium is excreted as the sodium is reabsorbed. Neurohormonal activation may further contribute to the hypokalemic effects of diuretics. To further complicate the issue, however, are factors that might lead to potassium retention.

Because most patients with heart failure receive potassium-sparing ACE inhibitors and frequently receive spironolactone, it is difficult to predict how an individual's electrolyte concentration will respond to a diuretic. Renal function, neurohormonal activation, and individual variability all affect

electrolyte concentrations. Indeed, hyperkalemia could occur if potassium is prescribed for a patient receiving potassium-sparing agents in addition to diuretics.

The frequent prescription of potassium to patients receiving loop diuretics or the instruction to eat potassium-rich foods may lead to serious problems.<sup>28</sup> Even salt substitutes (which frequently contain potassium) may cause hyperkalemia in a patient receiving potassium-sparing agents. For these reasons, electrolytes need to be monitored carefully in all patients with heart failure.

Patients with heart failure often waste magnesium and have magnesium depletion.<sup>29</sup> The need for and efficacy of magnesium replacement, however, are less certain than those of potassium. Serum concentrations of magnesium do not adequately reflect tissue stores, and oral replacement is rarely effective. Although low magnesium concentrations are predictive of a worse outcome,<sup>30</sup> it is not known whether this is directly secondary to magnesium depletion or reflective of other abnormalities. At present, few data indicate the necessity of chronic oral magnesium replacement.

Diuretics also cause other metabolic abnormalities. Bicarbonate reabsorption (with consequent metabolic alkalosis) and decreased serum uric acid excretion (with consequent gout and possibly change in free radical concentration) may lead to clinically important abnormalities. Hyponatremia often occurs in patients with severe heart failure. It is usually secondary to total body fluid overload, not to sodium depletion,<sup>31</sup> and it reflects stimulation of the vasopressin and renin-angiotensin systems.<sup>32</sup> Although chronic hyponatremia is prognostic,<sup>33</sup> there is no conclusive evidence that it is dangerous and needs to be treated.

Diuretics clearly lead to neurohormonal activation, which can have deleterious consequences. For example, plasma renin activity and plasma concentrations of angiotensin II increase in patients with heart failure after diuretic therapy.<sup>34,35</sup> Patients with normal concentrations of catecholamines, aldosterone, or plasma renin activity demonstrate increases in these concentrations after diuresis.<sup>36</sup> Of interest, however, is that patients with elevated baseline concentrations may have decreased neurohormonal concentrations after initial diuretic treatment (and improvement in symptoms), but concentrations increase as dry weight is approached and less sodium is delivered to the renal tubule.<sup>37</sup>

As discussed previously, there are suggestions that furosemide (and perhaps other loop diuretics) might be directly harmful. In addition to the prognostic importance of diuretic dose (which might merely reflect the severity of disease), one animal study demonstrated worse outcomes with furosemide in a pacing model of heart failure. Not only did furosemide lead to activation of the renin-angiotensin-aldosterone axis but also animals with heart failure that received active drug demonstrated more cardiac dilation and worsening survival rates (Figure 44-2).<sup>38</sup>

Although the beneficial effects of neurohormonal antagonism suggest that activation by diuretics may be deleterious, adequate diuresis is mandated because it provides symptom relief. Adverse consequences of diuresis, whether secondary to neurohormonal activation or to electrolyte depletion, must be dealt with directly after adequate diuresis. However, the many possible ways that diuretics might cause worse outcomes also suggest that clinicians should always consider stopping diuretics when possible.

## DIURETIC RESISTANCE AND MANAGEMENT

One of the inherent limitations of diuretics is that they achieve water loss by means of excretion of solute at the expense of glomerular filtration, with activation of neurohormonal systems that ultimately limit the effectiveness of diuretics. In

**FIGURE 44-2** Furosemide may lead to neurohormonal activation, which raises questions about its long-term outcome. In animals, furosemide, for the treatment of fluid overload in a pacing model of heart failure, led to cardiac dilation and increased rates of mortality. EDDI, end-diastolic diameter index; FS, fractional shortening. (From McCurley JM, Hanlon SU, Wei SK, et al. Furosemide and the progression of left ventricular dysfunction in experimental heart failure. *J Am Coll Cardiol* 2004;44:1301-1307.)

normal subjects, the magnitude of natriuresis after a given dose of diuretic declines over time, which is known as the “braking phenomenon” (Figure 44-3).

The magnitude of the natriuretic effect of potent loop diuretics may also be decreased in patients with heart failure, particularly as heart failure progresses. Although the bioavailability of these diuretics is generally not lower in heart failure, the potential delay in their rate of absorption may result in peak drug levels within the tubular lumen in the ascending loop of Henle that are insufficient to induce maximal natriuresis. The use of intravenous formulations or higher doses may obviate this problem.

Even with intravenous dosing, a rightward shift of the dose-response curve is observed between the diuretic concentration in the tubular lumen and its natriuretic effect in heart failure (Figure 44-4). Moreover, the maximal effect is lower in heart failure. This rightward shift has been referred to as “diuretic resistance” and it probably has several causes, in addition to the braking phenomenon described previously. First, most loop diuretics, with the exception of torsemide, are short-acting drugs. Accordingly, after a period of natriuresis, the diuretic concentration in plasma and tubular fluid declines below the diuretic threshold. In this situation, renal sodium reabsorption is no longer inhibited, and a period of antinatriuresis or postdiuretic sodium chloride (NaCl) retention ensues. If dietary NaCl intake is moderate to excessive, postdiuretic NaCl retention may overcome the initial natriuresis in patients with excessive activation of the adrenergic nervous system and the renin-angiotensin system. This observation forms the rationale for administering short-acting diuretics several times per day or by constant infusion to obtain consistent daily salt and water loss. Second, renal responsiveness to endogenous natriuretic peptides is lost as heart failure advances. Third, diuretics increase solute delivery to distal segments of the nephron, which causes epithelial cells to undergo both hypertrophy and hyperplasia.

## REFRACTORY CONDITIONS

In patients whose conditions are refractory to oral diuretics, intravenous loop diuretics may be effective. By achieving higher serum concentrations, such patients may achieve

**FIGURE 44-3** Effects of diuretics on urinary sodium (Na) excretion and extracellular fluid volume. **Main graph:** Effects of a loop diuretic on urinary sodium excretion ( $U_{Na}V$ ). Bars represent 6-hour periods before (in sodium balance) and after doses of loop diuretic (D). The dotted line indicates dietary sodium intake. The solid red portion of the open bars indicates the amount by which sodium excretion exceeds intake during natriuresis. The pink shaded area indicates the amount of positive sodium balance after the diuretic effect has worn off. Net sodium balance during 24 hours is the difference between the pink shaded area (postdiuretic sodium chloride [NaCl] retention) and the bars (diuretic-induced natriuresis). Chronic adaptation is indicated by progressively smaller peak natriuretic effects (the “braking phenomenon”) and is mirrored by a return to neutral balance. **Inset:** Effect of a diuretic on body weight. Note that steady state is reached within 6 to 8 days despite continued diuretic administration. (From Mann DL. Management of heart failure with a reduced ejection fraction. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald’s heart disease*, Philadelphia, 2008, Elsevier, Figure 25-12.)

**FIGURE 44-4** Dose-response curves for loop diuretics. **A**, Fractional sodium (Na) excretion ( $FE_{Na}$ ) as a function of loop diuretic concentration. In comparison with normal patients, patients with chronic renal failure (CRF) manifest a rightward shift in the curve, as a result of impaired diuretic secretion. The maximal response is preserved when expressed as  $FE_{Na}$  but not when expressed as absolute sodium excretion. Patients with heart failure (HF) demonstrate a rightward and downward shift, even when the response is expressed as  $FE_{Na}$ , and thus are relatively diuretic resistant. **B**, Comparison of the response to intravenous and oral doses of loop diuretics in normal subjects and in patients with heart failure. Diuretic bioavailability is shown for normal and patients with heart failure. The natriuretic threshold necessary to produce a diuresis is shown for normal subjects (dotted line) and for patients with heart failure (solid line). In a normal individual, an oral dose may be as effective as an intravenous dose because the diuretic bioavailabilities (area under the curve) that are above the natriuretic threshold for intravenous and oral diuretics are approximately equal. However, if the natriuretic threshold increases in a patient with heart failure, then the oral dose may not produce a high enough serum level to elicit significant natriuresis. CHF, congestive heart failure. (From Mann DL. Management of heart failure with a reduced ejection fraction. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald’s heart disease*, Philadelphia, 2008, Elsevier, Figure 25-13.)

adequate diuresis. Some physicians use intravenous drips of loop diuretics,<sup>39</sup> although high doses of the agents may be just as effective.<sup>40</sup> The optimal dose and means of administration of loop diuretics have recently been evaluated in the Diuretic Optimal Strategy Evaluation in Acute Heart Failure (DOSE) trial ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT00577135) Identifier: NCT00577135), sponsored by the National Heart, Lung, and Blood Institute.<sup>40a</sup> Initial results from the DOSE study have demonstrated that Q12 hour

bolus dosing and continuous infusion appear to be equivalent in terms of symptom relief, changes in renal function, and measures of congestion. Although high dose therapy ( $2.5 \times$  oral dose given IV) was not superior to low dose ( $1 \times$  the oral dose given IV) based on the primary efficacy endpoint of global symptom relief over 72 hours, high dose was associated with improvements in dyspnea resolution of signs and symptoms of congestion, net fluid loss, and greater decrease in NTproBNP.

These potentially beneficial findings were balanced against a modest worsening of renal function in the high dose arm, although these differences in renal function were transient and did not persist until discharge or day 60.<sup>40a</sup> When diuretics, alone or in combination, are not adequate, however, there are numerous other techniques that may be tried.

First, clinicians should investigate possible reversible causes. Prostatic or other mechanical obstruction may be overlooked in a patient with severe heart failure. Nephrotoxic agents should also be eliminated. In this regard, it is important to query the patient about the concurrent use of drugs that adversely affect renal function. In particular, the adverse potential of nonsteroidal anti-inflammatory drugs (NSAIDs) is underappreciated. Renal function in patients with heart failure may be dependent on renal prostaglandins. Even in normal individuals, the combination of diuretics and aspirin may lead to decreases in the GFR.<sup>41</sup> In patients with severe heart failure, even a single dose of indomethacin may markedly lower the GFR.<sup>42</sup> The insulin-sensitizing thiazolidinediones have also been linked to increased fluid retention in patients with heart failure, although the clinical significance of this finding is not known. It has been suggested that thiazolidinediones activate proliferator-activated  $\gamma$ -receptor expression in the renal collecting duct, which enhances expression of cell-surface epithelial sodium channels. Moreover, studies in healthy men have shown that pioglitazone stimulates plasma renin activity that may contribute to increased sodium retention. It is not clear, however, whether the fluid retained in these patients is intravascular.

### Inotropic Agents (see Chapter 43)

Because the underlying cause of inadequate diuresis is often insufficient renal perfusion secondary (either directly or indirectly) to low cardiac output, inotropic support is often used to effect diuresis in a patient with refractory heart failure. Indeed, inotropes have been shown to improve renal blood flow, but not necessarily more than ACE inhibitors.<sup>43</sup> Of interest is that in one small study, milrinone increased diuresis only in patients with a serum creatinine concentration of less than 2 mg/dL<sup>44</sup>; this suggests that improved renal blood flow does not lead to further diuresis in some patients or that renal blood flow does not increase in certain patients.

The Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME) study showed that acute inotropic support does not necessarily improve outcomes in patients admitted to a hospital for heart failure (Figure 44-5).<sup>45</sup> This was true even for the patients with BUN concentrations in the highest quartile. Similarly, milrinone did not decrease the number of patients

with 25% or more worsening of renal function.<sup>46</sup> Nevertheless, increased cardiac output is generally assumed to improve diuresis in a patient with severe heart failure; anecdotal evidence supports the use of dobutamine and milrinone in patients with inadequate diuresis secondary to heart failure.

### Dopaminergic Agents

Dopamine (at low doses, such as 2 to 5  $\mu$ g/kg/min) and other dopaminergic agents have frequently been used to increase renal blood flow, renal function, and diuresis. Because dopamine-1 receptor blockade leads to increased renal plasma flow, it conceptually makes sense that such agents will work. In one study of 120 patients with heart failure, low-dose dopamine increased creatinine clearance from  $35.6 \pm 11.6$  mL/min to  $48.8 \pm 12.3$  mL/min.<sup>47</sup> An inotropic effect could lead to an improved GFR.<sup>48</sup> However, many researchers have questioned the clinical utility of dopamine,<sup>49</sup> and a meta-analysis of low doses of dopamine given to reduce the incidence and severity of renal failure in critically ill patients revealed no improvement in rates of death or renal failure.<sup>50</sup>

Other dopaminergic agents have also been less beneficial than once assumed. A study of the dopaminergic agent ibopamine revealed increased mortality.<sup>51</sup> No effect on renal function was reported in that study. In another study, renal function improved slightly in 10 patients with mild to moderate heart failure.<sup>52</sup> Fenoldopam, a dopaminergic agent available to treat hypertensive crisis, has demonstrated only minor renal effects. Renal function was reported in one study<sup>53</sup> to improve in comparison with nitroprusside in patients with hypertensive emergency; however, in another study, GFR did not improve, even though renal blood flow increased.<sup>54</sup>

### Ultrafiltration and Dialysis

Ultrafiltration and other forms of dialysis may be useful for patients with refractory heart failure, and they have been advocated by some experts for even more widespread use. In contrast to conventional hemodialysis, ultrafiltration removes water, sodium, and non-protein-bound small and medium-sized molecular solutes. One system makes it possible to perform this with peripheral catheters.

Studies have clearly demonstrated the feasibility of removing fluid with ultrafiltration (although adequate peripheral intravenous access may be difficult to achieve). The largest randomized study to date (UltrafiltrationN versus IV Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure [UNLOAD]) demonstrated that it was possible to remove large amounts of fluid safely.<sup>55</sup> However, there remains the question of whether ultrafiltration is safer than usual diuretics or leads to a better outcome.

**FIGURE 44-5** The inotropic agent milrinone did not improve outcomes in Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-HF). Adverse events were increased in patients receiving milrinone. Afib, atrial fibrillation; MI, myocardial infarction. (From Cuffe MS, Califf RM, Adams KF Jr, Short-term intravenous milrinone for acute exacerbation of chronic heart failure: a randomized controlled trial. *JAMA*. 2002;287:1541-1547.) Copyright © (2011) American Medical Association. All rights reserved.

Results of small preliminary studies suggested that ultrafiltration might lead to less neurohormonal activation. In one study of 16 patients, plasma renin activity, and norepinephrine and aldosterone concentrations fell with ultrafiltration but not with furosemide. In addition, the weight loss persisted in the patients who received ultrafiltration.<sup>56</sup> If ultrafiltration could lead to less renal dysfunction and more weight loss, it certainly would be useful for the sickest patients. However, subsequent studies have not proved that a benefit exists.

In a review of the clinical use of ultrafiltration at one center, renal dysfunction was common.<sup>57</sup> Furthermore, a randomized crossover study yielded no differences between subjects who received furosemide and those who received ultrafiltration.<sup>58</sup> Even in UNLOAD, the incidence of worsening creatinine concentration appeared higher in the patients who received ultrafiltration.<sup>54</sup> It is true that the long-term outcome with ultrafiltration in UNLOAD was better, with fewer repeat hospitalizations, than that with diuretics. However, patients also lost more fluid with ultrafiltration, which raises the concern that more effective conventional diuresis would have yielded the same results.

At present, it is reasonable to consider ultrafiltration for patients with fluid overload who have difficulty achieving diuresis with conventional medications. More evidence of benefit must be collected to support the broader use advocated by some experts. In addition, the use of dialysis can be appropriate in patients who cannot maintain both euvolemia and renal function.

## Natriuretic Peptides (see Chapter 18)

The renal actions of the natriuretic peptides have been extensively discussed and are being investigated. Both BNP and atrial natriuretic peptide (ANP) are hemodynamically active. They cause vasodilation and lower ventricular filling pressures; nesiritide (recombinant human BNP) was approved in the United States for treatment of heart failure on the basis of its hemodynamic effects.<sup>59</sup> After widespread use, however, concerns about adverse effects were raised, and most physicians believe that more information is needed.

In the acute situation, ANP and BNP are effective natriuretic and diuretic agents.<sup>60</sup> Whether these agents have similar effects in more chronic situations, however, remains uncertain.<sup>61</sup> Studies suggest that tolerance to these agents can develop, perhaps as a result of changes in the receptor density or form. In a crossover study of patients with worsening renal function and heart failure, nesiritide had no natriuretic, diuretic, or renal effects.<sup>62</sup> There are anecdotal reports of effective diuresis; however, the publication of analyses that demonstrate more renal dysfunction and worse survival among patients receiving nesiritide<sup>63,64</sup> mandates that these drugs be used only as indicated by the U.S. Food and Drug Administration (FDA). Because there are no renal indications for the drug, it is rarely useful in clinical practice.

Other natriuretic peptides are being developed.<sup>65</sup> Differences in hemodynamic effects (such as vasodilation) or renal actions might make some of these agents safer or more effective than nesiritide.

## Adenosine Antagonists

Plasma adenosine concentrations are elevated in patients with heart failure.<sup>66</sup> In these patients, adenosine may decrease glomerular filtration, an action that could be secondary to dilation of postglomerular vessels<sup>67</sup> or vasoconstrictive effects before the glomerulus.<sup>68</sup> Perhaps the most important actions of adenosine in the kidney, however, are its effects on tubuloglomerular feedback. An acute increase in sodium concentration in the proximal tubule feeds back to decrease GFR via the macula densa; this relationship is known as “tubuloglomerular

**FIGURE 44-6** Adenosine antagonists are being investigated as diuretics that improve renal function. In one study, the adenosine  $A_1$  antagonist BG9719 in combination with furosemide increased urine output while preserving the glomerular filtration rate (GFR). (From Gottlieb SS, Abraham W, Butler J, et al. The prognostic importance of different definitions of worsening renal function in congestive heart failure. *J Card Fail* 2002;8:136-141.)

feedback.”<sup>69</sup> Adenosine constricts the afferent arteriole via the adenosine-1 ( $A_1$ )-receptor, leading to decreased glomerular filtration and less diuresis.

Selective  $A_1$ -receptor blockade has been shown to increase urine volume and sodium excretion.<sup>70</sup> Some studies also suggest that  $A_1$ -receptor blockade increases GFR.<sup>71</sup> In an early clinical study, the adenosine  $A_1$  antagonist BG9719 caused a dose-dependent increase in urine output. Although furosemide alone caused a large diuresis, the addition of BG9719 to furosemide not only caused a further increase but also prevented the decline in creatinine clearance associated with furosemide (Figure 44-6). Recent studies of another  $A_1$  receptor, rolofylline (KW-3902), supports their beneficial renal actions. In a crossover study, rolofylline improved GFR.<sup>72</sup> In another study, clinical utility was seen.<sup>73</sup> However, in the pivotal Placebo-controlled Randomized study of the selective  $A_1$  adenosine receptor antagonist KW-3902 for patients hospitalized with acute HF and volume Overload to assess Treatment Effect on Congestion and renal function Trial (PROTECT), rolofylline did not improve symptoms of acute heart failure in comparison with placebo. Moreover, treatment with rolofylline, 30 mg, did not reduce the risk of death or rehospitalization for cardiovascular or renal reasons, which was the secondary endpoint of the trial. The chief worry with these agents is that adenosine  $A_1$ -receptor blockade could cause seizures.

## Vasopressin Antagonists

The importance of vasopressin as the cause of hyponatremia and fluid retention in patients with heart failure has been debated. It appears to work through aquaporin, a vasopressin-regulated water channel in collecting duct cells, which is excreted partly into urine<sup>74</sup> and whose levels are correlated with arginine vasopressin concentrations. Urinary aquaporin increases in the setting of a hypertonic load. Although elevated concentrations of vasopressin have been observed in patients with congestive heart failure, the reported concentrations have not been very high.<sup>75</sup> Nevertheless, in hyponatremic patients, any elevation must be considered inappropriate, and an antagonist could theoretically be an effective aquaretic.

Vasopressin antagonists have been given to patients with hyponatremia, many of whom have heart failure. These agents clearly can reverse hyponatremia<sup>76</sup> and, at least in the acute situation, cause aquaresis. For example, a single dose of conivaptan caused a dose-related increase in aquaresis that

was associated with improved hemodynamic parameters.<sup>77</sup> Results of more prolonged studies, however, suggest that both increased water intake and decreased responsiveness to the vasopressin antagonist might limit the chronic effects of these drugs. For example, the selective vasopressin-2 ( $V_2$ ) antagonist OPC-31260 caused only short-term effects in an animal model.<sup>78</sup> Another selective  $V_2$  antagonist, SR121463, produced less urine excretion after 1 day, although the amount was more than with placebo.<sup>79</sup> In these normally hydrated rats, moreover, water intake increased to compensate for increased urine output. In human studies, the decrease in weight occurs early, but this decrease appears to slow down with time.<sup>80</sup>

Nevertheless, it is hoped, on the basis of animal studies,<sup>81</sup> that antidiuretic hormone (ADH) antagonists can cause diuresis without the neurohormonal activation of loop diuretics. If so, long-term outcome could conceivably be improved. This possibility was tested with tolvaptan in the Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study With Tolvaptan (EVEREST), which was a study of combined acute and chronic situations. Although tolvaptan decreased body weight and improved patient symptomatology in the acute situation,<sup>82</sup> there was no improvement in the composite endpoint of mortality or hospitalizations (hazard ratio, 1.04; 95% confidence interval, 0.95 to 1.14;  $P = .55$ ) in patients who received the active drug.<sup>83</sup> Tolvaptan is currently approved by the FDA for the treatment of hyponatremia, but it is not approved for the treatment of heart failure.

## CONCLUSION

Most cases of congestive heart failure can be managed very successfully with standard diuretic medications. Adequate dosages and multiple medications, if necessary, may mitigate symptoms of heart failure. However, diuresis is limited in some patients because of worsening renal function, which is a poor prognostic sign. For such patients, innovative approaches may be necessary. Fortunately, multiple drugs are being developed to address this issue. It is hoped that these drugs might enable diuresis while preventing renal dysfunction.

Activation of the renin-angiotensin-aldosterone system (RAAS) plays a key role in the pathophysiological progression of heart failure (see Chapter 9). Increased secretion of renin by the juxtaglomerular apparatus, in the setting of decreased renal perfusion, serves to protect glomerular perfusion pressure, through angiotensin II–induced efferent arteriolar constriction. However, most of the actions of angiotensin II, predominantly mediated through the angiotensin II type 1 (AT<sub>1</sub>) receptor, serve to aggravate the hemodynamic status of patients with heart failure, accentuate symptoms, accelerate the progression of cardiac and vascular disease, and increase morbidity and mortality. The actions of angiotensin II that contribute to progression of heart failure, symptoms, and adverse outcomes include

- Vasoconstriction
- Sodium retention
- Myocyte hypertrophy
- Myocardial and vascular fibroproliferation
- Myocyte apoptosis
- Generation of oxygen free radicals
- Endothelial dysfunction
- Endothelin generation
- Sympathetic activation
- Diminished thrombolysis

The RAAS may be inhibited at many levels: renin inhibition, inhibition of the conversion of angiotensin I to angiotensin II, antagonism of one or more angiotensin II receptors, and blockade of the primary target of aldosterone, the mineralocorticoid receptor.

Angiotensin-converting enzyme (ACE) inhibitors were the first agents clinically available for inhibiting the RAAS<sup>1</sup> and continue to be the most widely used in clinical practice. They act by inhibiting one of several proteases responsible for cleaving angiotensin I, a decapeptide, to form angiotensin II, an octapeptide (Figure 45-1). However, alternative enzymatic pathways have become recognized as playing a major role

in angiotensin II production in humans.<sup>2</sup> For example, in the failing human heart, angiotensin II formation is only partially inhibited by an ACE inhibitor but almost completely blocked by an inhibitor of chymase, another protease that catalyzes the formation of angiotensin II from angiotensin I.<sup>3</sup> Accordingly, ACE inhibitor therapy achieves only partial inhibition of angiotensin II production.<sup>4,5</sup>

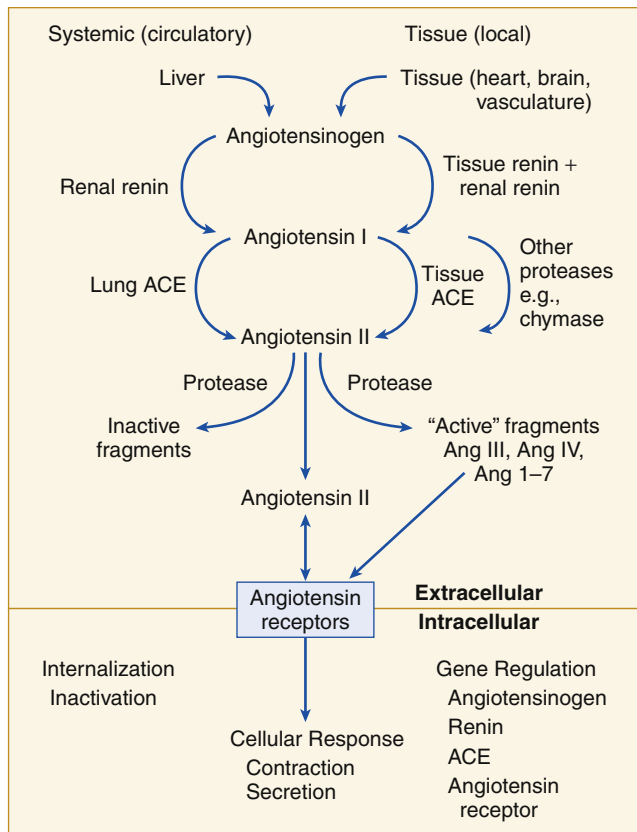

ACE not only cleaves angiotensin I to form angiotensin II but also is the principal protease that degrades bradykinin; thus, ACE inhibition leads to

increased levels of bradykinin within the circulation and at the tissue level.<sup>6-8</sup> The hemodynamic effects of ACE inhibitors may be mediated, in part, through increases in regional bradykinin levels. Bradykinin stimulates endothelial release of nitric oxide and vasodilator prostaglandins,<sup>9,10</sup> contributing to the vasodilator effects of ACE inhibitors. In some animal models of myocardial injury or pressure overload, the beneficial effects of ACE inhibitors mitigating cardiomyocyte hypertrophy and fibroblast hyperplasia within the myocardium are blocked by a bradykinin antagonist.<sup>11-13</sup> Thus, reduction of bradykinin metabolism, resulting in potentiation of local bradykinin levels, probably contributes to the therapeutic benefit of ACE inhibitors.<sup>7</sup>

To the extent that ACE inhibitors reduce production of angiotensin II, effects attributable to angiotensin II are diminished regardless of which receptor mediates the particular effect. In contrast, effects of angiotensin II receptor antagonists limit the responses specifically mediated by that receptor. Because the majority of clinically relevant effects of angiotensin II appear to be mediated through the AT<sub>1</sub> receptor, AT<sub>1</sub> receptor antagonists mirror the actions anticipated through blockade of angiotensin II production. However, loss of feedback inhibition results in increased angiotensin II levels after administration of an AT<sub>1</sub> receptor antagonist, which leads to overstimulation of alternative angiotensin II receptors. The unopposed activation of non-AT<sub>1</sub> receptors may mediate some of the clinically relevant effects attributable to AT<sub>1</sub> receptor blockade. For instance, stimulation of the AT<sub>2</sub> receptor may be responsible for the antiproliferative and antifibrotic effects of AT<sub>1</sub> antagonists<sup>14</sup> within the cardiovascular system. Unopposed activation of the AT<sub>2</sub> receptor may, however, also promote apoptosis.<sup>15</sup>

Although the hemodynamic and clinical effects of ACE inhibitors are notably similar to those of angiotensin receptor blockers (ARBs), these two classes of agents should not be considered identical in their actions, inasmuch as they possess both overlapping and distinct effects. As discussed later, clinical evidence for the benefit of ACE inhibitors exceeds that for ARBs, a finding that is

**FIGURE 45-1** The systemic and tissue components of the renin-angiotensin-aldosterone system. Several tissues, including those of the myocardium, vasculature, kidney, and brain, have the capacity to generate angiotensin II independently of the circulating renin-angiotensin-aldosterone system. Angiotensin II produced at the tissue level may play an important role in the pathophysiological progression of heart failure. ACE, angiotensin-converting enzyme; Ang III and Ang IV, angiotensin III and angiotensin IV; Ang 1-7, angiotensin (1-7). (Modified from Timmermans PB, Wong PC, Chiu AT, et al: Angiotensin II receptors and angiotensin II receptor antagonists. *Pharmacol Rev* 1993;45:205.)

strongly influenced by the earlier development of ACE inhibitors and the current ethical dilemma of designing trials in their absence. Results of clinical trials, both early and more recent, have helped determine whether and under what circumstances these agents can be used interchangeably or in combination.

Some of the effects of RAAS activation are mediated through aldosterone, the secretion of which is partially under the control of angiotensin II stimulation of the AT<sub>1</sub> receptor.<sup>16</sup> However, increases in aldosterone persist in the circulation (endocrine effects) and at tissue levels (autocrine and paracrine effects) in the presence of angiotensin II inhibition.<sup>4,17</sup> Furthermore, the mineralocorticoid receptor can be activated by other factors, independent of aldosterone. For example, glucocorticoids bind to and activate the mineralocorticoid receptor in the presence of an increased oxidative state.<sup>18</sup> Aside from its effect on renal sodium-potassium exchange, the mineralocorticoid receptor mediates a wide array of effects across the cardiovascular system. There is substantial experimental evidence that mineralocorticoid receptor activation contributes to several adverse myocardial effects, such as increased myocardial fibrosis, inflammation, myocyte hypertrophy, and apoptosis.<sup>18-26</sup> Clinical observations that mineralocorticoid receptor blockade reduces vascular events such as acute coronary syndromes<sup>27</sup> have generated interest in exploring the biological processes of vascular mineralocorticoid receptor action. Jaffe and associates<sup>28,29</sup> reported that mineralocorticoid receptors are expressed in blood vessels and regulate gene transcription in vascular smooth

muscle cells. Using a gene-chip microarray approach, they observed an increase in the expression of collagen subtypes and of factors known to promote vascular calcification and inflammation. They also reported the intriguing finding that angiotensin II promoted mineralocorticoid receptor-specific effects in the absence of aldosterone.<sup>29</sup> Thus, indirect mineralocorticoid receptor activation probably contributes importantly to RAAS-induced pathological effects throughout the cardiovascular and renal systems.

## HEMODYNAMIC EFFECTS OF INHIBITING THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM

The acute hemodynamic effects of ACE inhibitors and ARBs are influenced by vasodilation. In the early investigations of ACE inhibitors, captopril, enalapril, and lisinopril all produced dose-dependent decreases in right atrial pressure, pulmonary capillary wedge pressure, and systemic vascular resistance, with a resultant increase in cardiac index.<sup>30-32</sup> In studies in which follow-up hemodynamic measurements were obtained, these hemodynamic benefits of ACE inhibitor therapy were shown to be sustained.<sup>30,32</sup> In addition, inhibition of neurohormonal activation over time is evident from decreases in heart rates and plasma catecholamine levels at rest and with exercise.<sup>33,34</sup> Similarly, ARBs such as losartan and irbesartan produce dose-dependent decreases in right atrial pressure, pulmonary capillary wedge pressure, and systemic vascular resistance in association with increased cardiac index, which are sustained over time in the absence of tachyphylaxis.<sup>35-37</sup> These hemodynamic effects of ARBs occur without increases in heart rate or neurohormonal activation. Beneficial hemodynamic and clinical effects of irbesartan were reported by Havranek and colleagues<sup>36</sup> in patients already taking ACE inhibitors. Likewise, the administration of valsartan (160 mg) to patients with heart failure who were already taking ACE inhibitors produced acute and sustained hemodynamic benefits, accompanied by a reduction in aldosterone levels and by a trend for reduction in plasma norepinephrine levels.<sup>38</sup>

In summary, these data indicate that ACE inhibitors and ARBs produce similar hemodynamic benefits in patients with heart failure and left ventricular (LV) systolic dysfunction. The addition of ARBs to ACE inhibitor therapy also produces significant and sustained hemodynamic benefits, which is consistent with results of clinical studies demonstrating that angiotensin II levels remain elevated in patients receiving ACE inhibitor therapy.<sup>4,5</sup>

## EFFECTS OF RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM INHIBITION ON VENTRICULAR REMODELING

### Experimental Observations

“LV remodeling” refers to alterations in ventricular mass, chamber size, and shape that result from myocardial injury or from pressure or volume overload (see Chapter 15). At the cellular level, myocardial pathological changes accompany LV remodeling and involve myocyte hypertrophy and fibroblast hyperplasia, in addition to an increase in collagen deposition within the interstitium. When these processes occur in the noninfarcted myocardium, they contribute to progressive LV remodeling and LV dysfunction. A substantial amount of experimental and clinical data support the pivotal role of the RAAS in contributing to these cellular processes.

Angiotensin II is formed locally within the myocardium and is known to be an important stimulus to these cellular events.

**FIGURE 45-2** Left ventricular pressure-volume relationships (mean  $\pm$  standard error of the mean) of untreated and captopril-treated rats with large myocardial infarctions 3 months after coronary ligation. Shaded area represents the volumes  $\pm$  2 standard deviations in controls that did not have infarction. Vertical arrows indicate operating volumes of treated and untreated rats with horizontal arrow denoting shift between the two groups.  $P < .05$  for differences in operating volume index between untreated and treated animals with horizontal arrow denoting the shift between the untreated (right) and treated (left) groups. (From Pfeffer JM, Pfeffer MA, Braunwald E. Influence of chronic captopril therapy on the infarcted left ventricle of the rat. *Circ Res* 1985;57:84-95.)

Sadoshima and associates<sup>39,40</sup> demonstrated the localization of angiotensin II within myocyte granules 30 minutes after mechanical stretch and that the increase in myocyte protein synthesis in response to mechanical stretch is largely blocked by an  $AT_1$  receptor antagonist. Angiotensin II also stimulates collagen production and proliferation of cardiac fibroblasts.<sup>40</sup> These pivotal experimental data support the premise that the RAAS plays a central role in the pathophysiological processes of ventricular remodeling and progression of heart failure.

Results of numerous studies have confirmed that ACE inhibitors mitigate progressive LV remodeling in the failing heart. Pfeffer and colleagues<sup>41</sup> developed a rat model of myocardial infarction to study ventricular remodeling in an experimental setting and found that captopril therapy not only improved survival after myocardial infarction but also significantly reduced the extent of LV chamber enlargement.<sup>42,43</sup> Figure 45-2 displays passive pressure-volume relationships obtained immediately post mortem in rats after myocardial infarction. Hearts from untreated animals with infarction demonstrated significant increases in LV chamber size for a given pressure, manifest by a marked rightward shift of the pressure-volume relation. In contrast, captopril treatment reduced the extent of LV dilation, which resulted in a leftward shift of the pressure-volume relation.

Using a rat model of myocardial infarction, Taylor and associates examined the effects of ACE inhibition and  $AT_1$  receptor blockade on nonmyocyte proliferation and collagen deposition within the noninfarct zone.<sup>44</sup> Figure 45-3 depicts a noninfarcted section of rat heart stained immunohistochemically for proliferating cell nuclear antigen, a marker of proliferation or DNA repair, or both. Interstitial cell (mostly fibroblast) proliferation is evident within the noninfarct zone from the heart of a placebo-treated rat 2 weeks after myocardial infarction. In this study, ACE inhibition reduced nonmyocyte proliferation to levels comparable with those in animals that did not have infarction (Figure 45-4). The  $AT_1$  receptor antagonist losartan reduced nonmyocyte proliferation to a lesser degree than did the ACE inhibitor. These somewhat disparate effects of ACE inhibition versus  $AT_1$  receptor blockade may result from ACE inhibitor-mediated increase in local bradykinin levels, shown in some studies to be important in

**FIGURE 45-3** Microscopic image ( $\times 100$ ) of noninfarcted myocardium stained by immunohistochemical methods for proliferating cell nuclear antigen. Nuclei that stained positively (arrows) are black. This section was obtained from the left ventricle of a placebo-treated animal with an infarct size of 41% of left ventricular myocardium. Scale bar, 50  $\mu$ m. (From Taylor K, Patten RD, Smith JJ, et al. Divergent effects of angiotensin converting enzyme inhibition and angiotensin II receptor antagonism on myocardial cellular proliferation and collagen deposition after myocardial infarction in rats. *J Cardiovasc Pharmacol* 1998;31:654-660.)

**FIGURE 45-4** Cellular proliferation within the noninfarct zone is evident from the number of cells per unit area (square millimeters) that stained positively for proliferating cell nuclear antigen (PCNA) (mean  $\pm$  standard error of the mean). Placebo-treated animals with infarction displayed significantly greater PCNA labeling than did animals without infarction ("No MI"). Enalapril decreased proliferative activity, whereas losartan had an intermediate effect. Combination therapy ("Emal/Los") also tended to limit proliferation. \* $P < .04$  between placebo and "No MI" conditions; † $P < .01$  between enalapril and placebo conditions; ‡ $P < .03$  between enalapril and losartan conditions; § $P = .08$  between combination therapy and placebo conditions. (From Taylor K, Patten RD, Smith JJ, et al. Divergent effects of angiotensin converting enzyme inhibition and angiotensin II receptor antagonism on myocardial cellular proliferation and collagen deposition after myocardial infarction in rats. *J Cardiovasc Pharmacol* 1998;31:654-660.)

the growth-inhibitory effects of ACE inhibitors. It is interesting that the combination of ACE inhibitor and  $AT_1$  receptor antagonist resulted in slightly greater effect (although not statistically different) in limiting collagen deposition, which suggested that the actions of the two agents may be additive.

In support of this, Dahl salt-sensitive rats treated with the combination of the ACE inhibitor benazepril and the  $AT_1$  receptor antagonist valsartan exhibited improved survival, reduced heart failure markers, and less LV hypertrophy in comparison with rats treated with either agent alone.<sup>45</sup> In a sheep model of myocardial infarction, Mankad and

co-workers<sup>46</sup> examined end-diastolic and end-systolic volumes by using gated magnetic resonance imaging, comparing the effects of the ACE inhibitor ramipril alone or in combination with losartan. After 8 weeks of therapy, combined ACE inhibition and AT<sub>1</sub> blockade effected a greater reduction in end-diastolic and end-systolic volumes. These data constitute evidence that (1) the effects of combined AT<sub>1</sub> receptor blockade and ACE inhibition may be more effective in limiting progressive LV remodeling; and (2) activation of the RAAS plays a pivotal role in the pathophysiological processes of heart failure and progressive LV remodeling. Moreover, they underscore the importance of inhibiting the renin-angiotensin-aldosterone hormonal axis in the management of heart failure.

## Clinical Studies

In addition to a wealth of experimental evidence supporting the important role of the RAAS in the pathophysiological processes of ventricular remodeling, clinical evidence also supports this premise. Because of the large number of trials demonstrating consistent benefits of ACE inhibitors in rates of mortality and morbidity, these agents have become a mainstay of therapy for patients with LV systolic dysfunction. Sharpe and associates<sup>47</sup> demonstrated that captopril initiated within 48 hours after Q-wave myocardial infarction reduced the increase in LV end-diastolic volume after only 3 months of therapy. Similarly, in the multicenter Survival and Ventricular Enlargement (SAVE) trial, captopril improved survival among patients after myocardial infarction with reduced LV ejection fraction (LVEF) (<40%) and mitigated the degree of LV chamber dilation after the first year of therapy.<sup>48</sup> Konstam and associates demonstrated that ACE inhibitors prevent progressive LV remodeling in patients with LV systolic dysfunction with or without symptoms of heart failure.<sup>49,50</sup> Figure 45-5 displays mean pressure-volume loops obtained from the Studies of Left Ventricular Dysfunction (SOLVD) substudy. The placebo recipients exhibited LV dilation over the span of this study (1 year), whereas the enalapril recipients exhibited the opposite, which was consistent with a decrease in LV chamber size for a given LV pressure. This study demonstrated clinically that ACE inhibition prevents, and perhaps reverses, the extent of ventricular remodeling in patients with LV systolic dysfunction.

The precise effect of AT<sub>1</sub> receptor antagonists on ventricular remodeling is not as well studied. In the Evaluation of Losartan In The Elderly (ELITE) radionuclide substudy, researchers compared the effect of losartan, an AT<sub>1</sub> antagonist,

with that of the ACE inhibitor captopril on LV remodeling in elderly patients with heart failure and systolic dysfunction (ejection fraction <40%). After 48 weeks of therapy, captopril and losartan demonstrated statistically equivalent effects in reducing LV end-diastolic and end-systolic volumes, although there was a trend toward a greater beneficial effect of captopril in this study.<sup>51</sup> McKelvie and coworkers compared the effects of the AT<sub>1</sub> antagonist candesartan with those of the ACE inhibitor enalapril and the effects of their combination on LV remodeling as part of the Randomized Evaluation Strategies for Left Ventricular Dysfunction (RESOLVD) pilot study.<sup>52</sup> With combination therapy, they observed a significant reduction in LV end-systolic volume at 43 weeks in comparison with enalapril treatment alone; this finding suggested that combination of an ACE inhibitor and ARB in the clinical setting may have additive benefits. Whether these effects were secondary to beneficial changes in myocardial structure or were related purely to afterload reduction is unknown. Perhaps the largest study of whether combination therapy with an ACE inhibitor and ARB produces greater reduction in LV remodeling has been the Valsartan in Acute Myocardial Infarction Trial (VALIANT), in which investigators examined the effect of valsartan alone, captopril alone, and their combination in patients after an acute myocardial infarction complicated by heart failure, LV dysfunction, or both. Although the patient population in this trial differed from that in heart failure trials (after myocardial infarction, mean LVEF among the groups was 39%), the degree of LV remodeling (increase in LV end-diastolic volume and change in LVEF) was similar among all three groups of patients.<sup>53</sup> The results of this VALIANT substudy therefore do not support the view that combination therapy in patients with heart failure or LV dysfunction after myocardial infarction exerts a greater effect in limiting LV remodeling than either class of agent alone.

Findings related to effects of mineralocorticoid receptor inhibition on cardiac remodeling in heart failure have been mixed. Although some studies have suggested a benefit,<sup>54,55</sup> Udelson and colleagues found no effect of the selective mineralocorticoid receptor antagonist eplerenone, when added to an ACE inhibitor and  $\beta$ -blocker, during 9 months of randomized, controlled treatment in patients with New York Heart Association (NYHA) class II to class III heart failure and reduced LVEF.<sup>56</sup> It is possible that the reduction in mortality observed with mineralocorticoid receptor blockers in selected populations with heart failure (see "Aldosterone Receptor Blockers" section) is at least partly mediated by vascular effects, as opposed to myocardial effects.

**FIGURE 45-5** Mean left ventricular pressure-volume relationships at baseline and at 1 year in patients enrolled in the Studies of Left Ventricular Dysfunction (SOLVD) prevention trial who were randomly assigned to receive chronic treatment with placebo or enalapril. (From Konstam MA, Kronenberg MW, Rousseau MF, et al, for the SOLVD Investigators. Effects of the angiotensin converting enzyme inhibitor, enalapril, on the long-term progression of left ventricular dilatation in patients with asymptomatic systolic dysfunction. *Circulation* 1993;88:2277-2283.)

## EFFECTS OF INHIBITING THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM ON FUNCTIONAL CAPACITY AND SYMPTOMS

Reduced functional capacity in patients with heart failure caused by systolic dysfunction results from cardiac and non-cardiac factors. ACE inhibitors have variably been shown to improve exercise capacity in patients with heart failure and systolic dysfunction, presumably through their sustained hemodynamic benefits, as described previously. However, the improvement in exercise capacity noted with ACE inhibitors is often modest in clinical trials. These modest improvements may result, in part, from improved survival among patients with NYHA class IV heart failure. For example, in the Vasodilators in Heart Failure Treatment (V-HeFT) II trial, in which ACE-inhibition was compared with the combination of hydralazine and isosorbide dinitrate, subjects receiving the latter protocol had a more pronounced improvement in exercise capacity, judged by peak exercise oxygen consumption. However, the survival rate among patients treated with the ACE inhibitor was better than that among subjects taking hydralazine and isosorbide, which raised the question of whether more severe heart failure symptoms may have diluted any improvement in exercise capacity in the subjects treated with enalapril.<sup>57</sup>

### Angiotensin-Converting Enzyme Inhibitors

A number of studies have demonstrated that ACE inhibitors improve exercise time and ameliorate symptoms of heart failure. The benefits of ACE inhibitors in the management of heart failure symptoms have long been recognized. In the early 1980s, captopril treatment was shown to improve exercise time by 25% and to reduce heart failure symptoms and NYHA class in patients with severe heart failure treated with digoxin and diuretics.<sup>58</sup> Similar improvements in exercise capacity and heart failure symptoms were noted with the ACE inhibitors enalapril,<sup>30</sup> lisinopril,<sup>31</sup> and quinapril.<sup>59</sup> These clinical data demonstrate that ACE inhibitors favorably influence symptoms of heart failure and exercise capacity in patients with LV systolic dysfunction.

### Angiotensin Receptor Blockers

ARBs also improve exercise capacity and symptoms in patients with heart failure. Losartan has been shown to improve symptoms of heart failure after 12 weeks of therapy in patients with reduced LVEF (<45%).<sup>37</sup> In a comparative trial with the ACE inhibitor enalapril, losartan-treated

patients demonstrated similar exercise capacity and symptoms of heart failure after 12 weeks of treatment.<sup>60</sup> Vescovo and associates<sup>61</sup> evaluated exercise capacity in small groups of patients, one treated with enalapril and the other with losartan. Both groups demonstrated similar improvements in exercise capacity, as demonstrated by peak oxygen consumption. Interestingly, Vescovo and associates also compared the myosin profiles in skeletal muscle and demonstrated a myosin heavy chain shift toward slow, fatigue-resistant isoforms, which suggested that improvement in exercise capacity by these agents may be, in part, related to noncardiac factors.

Riegger and colleagues<sup>62</sup> studied the effects of various doses of the ARB candesartan (4, 8, and 16 mg) in patients with heart failure and LV systolic dysfunction. In this study, ACE inhibitors were withdrawn 2 weeks before the placebo run-in period. With all three doses of candesartan, patients demonstrated improved score of heart failure symptoms and improved exercise capacity in comparison with placebo-treated patients. Researchers in the RESOLVD pilot study compared candesartan alone, enalapril alone, and their combination over a 43-week period. Each agent resulted in similar improvements in exercise capacity and quality of life.<sup>52</sup> Thus, available studies suggest that ARBs produce improvements in exercise capacity and heart failure symptoms that are similar to those produced by ACE inhibitors, either historically or in a direct, individual manner.

## EFFECTS OF INHIBITING THE RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM ON MORBIDITY AND MORTALITY

### Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors were the first class of agents shown to significantly alter the natural history of heart failure, as demonstrated by a reduction in the frequency of death and of other morbid events. Most of these data have been accumulated from patients with reduced LVEF, and clinicians have therefore recognized the necessity for measuring ventricular systolic function and prescribing ACE inhibitors to patients with reduced ejection fraction (e.g., ≤35%) as standards of care for patients with heart failure. Table 45-1 lists the key trials demonstrating benefit of ACE inhibitors in this population.

In the first Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS), patients with class IV symptoms of heart failure were randomly assigned to receive enalapril or placebo. The study was stopped prematurely because of a marked reduction in mortality among the patients taking enalapril; this

**TABLE 45-1** Selected Clinical Trials of Angiotensin-Converting Enzyme Inhibitor in Heart Failure

Trial	Agent	Population	Findings
CONSENSUS I	Enalapril titrated to 20 mg bid vs. placebo	NYHA class IV	<ul style="list-style-type: none"> <li>31% Decrease in 1-year mortality rate</li> <li>50% Decrease in deaths from progressive heart failure</li> </ul>

CHF, congestive heart failure; CONSENSUS, Cooperative North Scandinavian Enalapril Survival Study; EF, ejection fraction; NYHA, New York Heart Association (classification); SOLVD, Studies of Left Ventricular Dysfunction; V-HeFT, Vasodilator in Heart Failure Trial.

made CONSENSUS the first study to display an effect of any pharmacological agent on mortality in heart failure.<sup>63</sup>

The SOLVD treatment<sup>64</sup> and prevention trials<sup>65</sup> were investigations of the effects of enalapril in patients with reduced LVEF ( $\leq 35\%$ ) with and without symptoms of heart failure, respectively. Most patients in the SOLVD treatment trial had NYHA class II or III symptoms. Among those randomly assigned to receive enalapril, mortality was reduced significantly (Figure 45-6), as was the combined endpoint of death or hospitalization for heart failure. The SOLVD prevention trial failed to reach significance with regard to its primary endpoint, manifesting only a trend of 8% reduction in mortality. However, there were significant reductions in the progression to clinically overt heart failure and in the combined endpoint of death or hospitalization for heart failure. For patients with heart failure and reduced LVEF, these landmark trials extended the indication for ACE inhibitor prescription across the entire spectrum of clinical symptoms.

Close to 80% of the total population of the SOLVD trials were thought by the investigator to have heart failure on the basis of ischemic heart disease. However, patients who had had myocardial infarction within the previous month were excluded. Findings of these studies were further substantiated by results of trials enrolling patients after myocardial infarction. For example, the SAVE trial<sup>66</sup> enrolled patients between 3 and 16 days after myocardial infarction who had ejection fractions of 40% or less; patients randomly assigned to receive the ACE inhibitor captopril demonstrated a significant reduction in mortality. Similar benefits were observed in the Acute Infarction Ramipril Efficacy (AIRE) trial,<sup>67</sup> in which patients with clinical evidence of heart failure (regardless of ejection fraction) in the setting of a recent acute myocardial infarction (within the previous 2 to 9 days) were randomly assigned to receive either ramipril or placebo. ACE inhibitor treatment in this study resulted in a 35% reduction in mortality after 1 year of follow-up.

#### Effect of Angiotensin-Converting Enzyme Inhibitors on Clinical Outcomes and Mechanisms Underlying These Effects

The original hypothesis behind investigation of ACE inhibitors in patients with heart failure was that these agents would reduce the progression of clinical heart failure through vasodilation. Studies with ACE inhibitors have certainly demonstrated reduction in fatal and morbid events linked to progressive heart

failure. Since the inception of these trials, the rationale for such clinical actions has expanded substantially, with a recognition that ACE inhibitors directly affect the cellular mechanisms responsible for progressive myocardial disease.

Clinical trials have consistently demonstrated a reduction in the number of hospitalizations for heart failure, typically analyzed in terms of time to first event with a combined endpoint of death or hospitalization for heart failure. The endpoint of hospitalizations for heart failure serves as a useful marker for both disease severity and activity and for the effect of a treatment on the overall cost of care for patients with heart failure.

Beyond an effect on clinical events linked to progressive heart failure, both the SOLVD and SAVE studies demonstrated significant reductions in the incidence of myocardial infarction. This effect contributed to the overall influence of ACE inhibitors on mortality. Furthermore, within the SOLVD population, enalapril caused a significant reduction in number of patients hospitalized for unstable angina. These findings provided, for the first time, evidence for an influence of ACE inhibitors on the pathogenesis of acute coronary syndromes, an influence probably mediated by effects on the arterial wall, on the balance between thrombosis and thrombolysis, or on both.

In the clinical trials of ACE inhibitors in patients with heart failure, the effect of these agents on sudden cardiac deaths has been less clear than the effect on deaths attributed to progressive heart failure or to fatal myocardial infarction.<sup>68</sup> Results of trials with ACE inhibitors in patients with recent myocardial infarction have been more supportive of a reduction by these agents in the incidence of sudden cardiac death. Such effects may be mediated not by direct electrophysiological consequences of inhibiting the RAAS but rather by an effect on myocardial hypertrophy, fibrosis, and remodeling. An additional influence may be mediated by downregulation of adrenergic neurotransmitter release.

Each of these clinical findings must be interpreted with caution, because differentiation of cause of death is, at best, a highly inexact science. The data from the Assessment of Treatment with Lisinopril and Survival (ATLAS) trial, in which high-dose and low-dose ACE inhibitor effects were compared, suggested considerable discrepancy between the clinically adjudicated cause of death and the findings at autopsy.<sup>69</sup> In a substantial proportion of patients in whom death was attributed to either progressive heart failure or sudden cardiac death and for whom autopsy findings were available, postmortem cardiac examination revealed evidence of a recent myocardial infarction (see Figure 45-6). Nevertheless, with a growing understanding of the breadth of actions of ACE inhibitors in impeding the progression of cardiovascular disease, it seems increasingly likely that these agents favorably affect survival in various ways.

#### Angiotensin Receptor Blockers

Investigation of the effect of ARBs on clinical outcomes in patients with heart failure has been hampered by the ethical imperative, arising from results of the aforementioned clinical trials, not to withhold ACE inhibitors from this population. Various groups have taken different approaches to this problem, such as the following:

- Investigation of the relative effects of an ACE inhibitor and an ARB
- Examination of the effect of an ARB when superimposed on “standard treatment,” including an ACE inhibitor
- Examination of populations in whom withholding an ACE inhibitor is considered ethically feasible, such as patients who cannot tolerate ACE inhibitors and those with preserved LV systolic function

Table 45-2 lists the key trials in which the effect of ARBs on clinical outcomes in patients with heart failure were examined.

**FIGURE 45-6** Mortality curves from the Studies of Left Ventricular Dysfunction (SOLVD) treatment trial, demonstrating a 16% reduction in mortality among patients with symptoms of heart failure who were treated with the angiotensin-converting enzyme (ACE) inhibitor enalapril. (From Effect of angiotensin converting enzyme inhibition with enalapril on survival in patients with reduced left ventricular ejection fraction and congestive heart failure: results of the treatment trial of the Studies of Left Ventricular Dysfunction (SOLVD); a randomized double blind trial. *N Engl J Med* 1991;325:293-302.)

### Second Evaluation of Losartan in the Elderly (ELITE-II)

The ELITE-II trial<sup>70</sup> tested the hypothesis that the ARB losartan (target dose, 50 mg/day) would reduce mortality in relation to the ACE inhibitor captopril (target dose, 50 mg three times daily), in elderly patients with heart failure and reduced LVEF. This hypothesis was based on findings within the first ELITE trial,<sup>71</sup> in which, with a primary hypothesis related to renal function, fewer deaths occurred in patients randomly assigned to receive losartan than in those randomly assigned to receive captopril. The results of ELITE-II failed to support the stated hypothesis; the numbers of deaths in the two treatment groups were similar. It is tempting to conclude from ELITE-II that the effect of an ARB on mortality is similar to that of an ACE inhibitor. However, this conclusion is not statistically valid, because the study was not powered for equivalence or noninferiority; that is, the number of patients studied (3152) yielded wide confidence intervals around the point estimate for the relative risk of death for patients randomly assigned to receive losartan in comparison with captopril. It has been speculated that a higher dose of losartan would have yielded more favorable results, although the basis for such speculation is weak.

Similarity of the clinical benefits of ACE inhibitors and ARBs is supported by findings with regard to other endpoints in the ELITE-II trial. Results in the two treatment groups were no different with regard to the combined endpoint of death or hospitalization for heart failure, dropping out for worsening heart failure, NYHA class (which improved in both treatment groups), and a health-related quality-of-life scale. These findings provide support for the contention that ARBs are effective agents in treating patients with heart failure and reduced ejection fraction.

One way in which the ARB losartan significantly improved on findings observed with the ACE inhibitor captopril was in terms of patient tolerance: 14.7% of patients randomly assigned to receive captopril discontinued treatment because of adverse effects, in contrast to only 9.7% of patients randomly assigned to receive losartan. The difference was a result of adverse effects attributable to bradykinin, particularly cough, which occurred in approximately 3% of patients randomly assigned to receive captopril, as opposed to fewer than 1% of those randomly assigned to receive losartan.

### Valsartan in Heart Failure Trial (Val-HeFT)

Investigators in the Val-HeFT study took an approach different from that of ELITE-II. They hypothesized that treatment with a high dose (160 mg twice daily) of the ARB valsartan would significantly reduce the incidence of adverse clinical outcomes when added to “standard treatment” in patients with heart failure and a dilated left ventricle. Patients were randomly assigned to receive either valsartan or placebo in addition to baseline medical treatment, which included an ACE inhibitor in 93% of patients and a  $\beta$ -blocker in 35%. There were two primary endpoints—all-cause mortality and the combination of death or major cardiovascular event—with the  $\alpha$  error split evenly between the two; that is, the results could be considered positive if valsartan performed better than did placebo with regard to either endpoint, with a probability value less than approximately .025.<sup>72</sup>

There was no difference between the valsartan and placebo recipients with regard to all-cause mortality. However, there was a significant 13% reduction in the combined primary endpoint, an effect driven solely by the reduction in hospitalizations for heart failure.<sup>72</sup> Additional significant benefits were observed within the valsartan recipients with regard to NYHA class, signs and symptoms of heart failure, and LVEF. The Val-HeFT trial, therefore, was the first study with an ARB to demonstrate a significant clinical finding, in terms of a primary endpoint directed at an important clinical outcome, in a population of patients with heart failure.

The findings of Val-HeFT were complicated by results across various patient subsets. Significant treatment  $\times$  subgroup interactions were observed with regard to baseline ACE inhibitor use and to baseline  $\beta$ -blocker use. The 7% of the population that were not receiving an ACE inhibitor at baseline, presumably because of intolerance, exhibited significantly greater benefit, with regard to the combination endpoint, than did the 93% of patients receiving an ACE inhibitor. This small group contributed importantly to the overall result and provides the best estimate to date of the effect that an ARB has on clinical outcomes in patients with heart failure. The point estimate for reduction in combined mortality and morbidity was 45% within this group.

Of concern was the significant treatment  $\times$  subgroup interaction for baseline  $\beta$ -blocker use, which similarly revealed significantly greater improvement in the combination endpoint

within patients who did not receive  $\beta$ -blockers. For patients receiving  $\beta$ -blockers, the point estimate favored placebo over valsartan. This finding is directionally the same as a nonsignificant trend observed in ELITE-II in which captopril was superior to losartan among the 25% of that study's population who received a  $\beta$ -blocker at baseline. Such results must be interpreted cautiously and could be linked to other unidentified features within the population that are correlated with  $\beta$ -blocker use or could result from an unidentified interaction between  $\beta$ -blockers and ARBs, particularly for patients also receiving an ACE inhibitor.

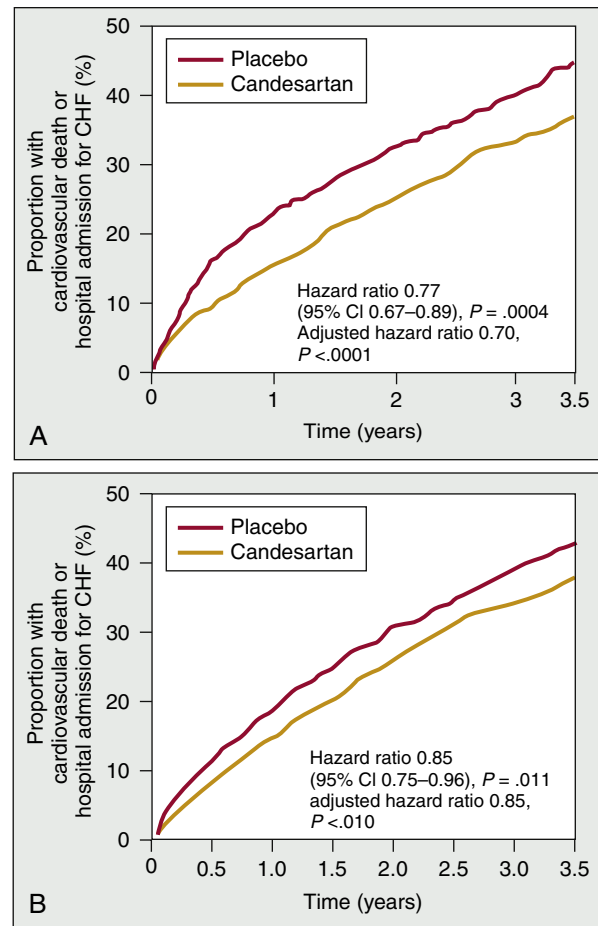

The Val-HeFT study provides greatest support for use of an ARB in a population that it was not intended to study: patients who did not receive an ACE inhibitor. Because this group was small, because it was not the study's intent, and because of the wealth of data supporting the use of ACE inhibitors, the Val-HeFT results do not alter the recommendation to consider ACE inhibitors first-line agents for all patients with heart failure and reduced ejection fraction. However, Val-HeFT certainly lends credence to the previously stated recommendation to prescribe an ARB for patients who cannot tolerate ACE inhibitors, specifically those intolerant because of cough or angioedema. It also suggests a role for adding an ARB to an ACE inhibitor, particularly for patients who continue to be symptomatic and who cannot tolerate a  $\beta$ -blocker.

#### Candesartan in Heart Failure Assessment in Reduction of Mortality (CHARM) Trial

The ChARM study<sup>73</sup> employed a novel design, dividing its population with heart failure into three groups:

- Those with reduced ejection fraction, who received an ACE inhibitor (CHARM-Added)<sup>74</sup>
- Those who could not tolerate ACE inhibitors (CHARM-Alternative)<sup>75</sup>
- Those with preserved ejection fraction (CHARM-Preserved)<sup>76</sup>

In each trial, patients were randomly assigned to receive candesartan, 32 mg daily, or placebo; the primary endpoint was the composite of cardiovascular death or hospital admission for congestive heart failure. The primary endpoint was significantly improved for the patients in both the ChARM-Added and ChARM-Alternative groups who were randomly assigned to receive candesartan (Figure 45-7).<sup>74,75</sup> Thus, the ChARM program demonstrated, in the most definitive way to date, that an ARB achieves significant improvement in clinical outcomes in a population with low ejection fraction who could not tolerate ACE inhibitors. Although a reduction in all-cause mortality did not reach statistical significance, the magnitude of benefit for the primary endpoint suggested that the clinical effect of an ARB in this population was at least comparable with that achievable with an ACE inhibitor. In addition, the ChARM-Added group demonstrated clearly for the first time that addition of an ARB to an ACE inhibitor would achieve additive clinical benefit. The ChARM-Added study, however, raised a number of questions. First, how can clinicians be sure that patients were optimally treated with ACE inhibitors? The authors dispelled this concern with a detailed analysis demonstrating that the population was indeed well treated with appropriate doses of ACE inhibitors and that the benefit was retained in patients receiving the highest doses of these medications.<sup>77</sup> Second, how is this finding reconciled with that of the VALIANT trial, which failed to demonstrate incremental benefit of combination treatment in a population with heart failure after myocardial infarction?<sup>78</sup> Arguably, the design of VALIANT was more suited to “purely” asking the question of relative benefit of each drug class and the combination, inasmuch as both valsartan and captopril were administered as study drugs under “blinded” conditions. However, the drug and patient populations tested were also different. It is difficult to argue with the implication of the “real world” question

**FIGURE 45-7** Effect of candesartan on cardiovascular mortality or hospital admission for heart failure. Data for two groups of patients who were randomly assigned to receive candesartan or placebo are depicted: (A) patients who were not receiving an ACE inhibitor (the Candesartan in Heart Failure Assessment in Reduction of Mortality [CHARM]-Alternative trial) and (B) patients who were receiving an ACE inhibitor (the ChARM-Added trial). The effect size of candesartan was reduced in the group of patients who were receiving an ACE inhibitor. ACE, angiotensin-converting enzyme; CHF, congestive heart failure; CI, confidence interval. (A modified from Granger CB, McMurray JJ, Yusuf S, et al. Effects of candesartan in patients with chronic heart failure and reduced left-ventricular systolic function intolerant to angiotensin-converting-enzyme inhibitors: the ChARM-Alternative trial. *Lancet* 2003;362:772-776; and McMurray JJ, Ostergren J, Swedberg K, et al. Effects of candesartan in patients with chronic heart failure and reduced left-ventricular systolic function taking angiotensin-converting-enzyme inhibitors: the ChARM-Added trial. *Lancet* 2003;362:767-771.)

asked by ChARM-Added: namely, what happens when an ARB is added in a population already well treated with an ACE inhibitor? Third, how do clinicians weigh the relative merits of adding an ARB versus an aldosterone blocker to an ACE inhibitor-treated patient who continues to be symptomatic, and what about the combination of all three drugs? Unfortunately, no studies have addressed this specific question, and thus there are no definitive answers. Most clinicians have chosen to add an aldosterone blocker, rather than an ARB, in this setting. Seventeen percent of the ChARM-Added population was also receiving an aldosterone blocker, and there was no clear difference in the outcome benefit from candesartan in this subgroup. However, the numbers were too small to draw any conclusions, and concern exists about the potential for hyperkalemia with the three-way combination. Therefore, clinical practice guidelines have refrained from recommending this combination.

CHARM-Preserved produced a more ambiguous result. Candesartan demonstrated a favorable trend for the primary endpoint, but it did not reach statistical significance. This

finding, coupled with a negative result in the more recent Irbesartan in Heart Failure with Preserved Systolic Function (I-PRESERVE) study conducted in a similar population,<sup>79</sup> has left considerable doubt about the value of RAAS blockade in patients with heart failure and preserved LVEF. However, favorable findings for ARBs on cardiovascular endpoints in populations with normal LVEF, hypertension, and LV hypertrophy<sup>80</sup> and in populations with diabetes and microalbuminuria<sup>81</sup> continue to suggest potential value in the population with heart failure and normal LVEF. More work is needed in targeting the specific population that stands to benefit and the nature of the endpoints that might demonstrate such a benefit.

#### Heart Failure Endpoint Evaluation of Angiotensin II Antagonist Losartan (HEAAL)

Based on the assumption that a higher losartan dose might have produced greater benefit in ELITE-II, the HEAAL study<sup>120</sup> randomized 3846 patients with NYHA class II-IV heart failure, LVEF  $\leq 40\%$ , and ACE inhibitor intolerance to losartan 150 mg daily or 50 mg daily. With a median followup of 4.7 years, compared with the lower dose, the higher losartan dose was associated with a 10% reduction in the rate of the primary endpoint of death or heart failure hospitalization (hazard ratio 0.90, 95% confidence interval 0.82–0.99;  $p=0.027$ ) (Table 45-2). The higher dose was associated with increased incidence of hyperkalemia, renal impairment, and hypotension; however the frequency of discontinuation for adverse event was low (overall  $<2$  per 100 patient-years) and not significantly different between the two groups. HEAAL is the only study to examine ARB dose-effect on clinical outcomes, and one of the few such studies of any cardiovascular therapy. It demonstrated incremental clinical benefit of greater RAAS inhibition in heart failure, and displayed the importance of targeting the same dosing strategy in clinical practice as was used in clinical trials to replicate the demonstrated population benefit on clinical outcomes.

#### Aldosterone Receptor Blockers

Clinical studies have shown a “breakthrough” of aldosterone levels after prolonged treatment with an ARB or an ACE inhibitor in chronic heart failure, which indicates that

aldosterone secretion is not fully under control of angiotensin II.<sup>52,82</sup> This observation, coupled with the fact that the mineralocorticoid receptor may be activated by alternative stimuli and the multifaceted means through which such activation may accelerate the advance of cardiovascular disease, represents a rationale for exploring the benefits of mineralocorticoid receptor antagonists, on top of ACE inhibitors or ARBs.

Two studies demonstrated reduced mortality when patients with heart failure and reduced LVEF were treated with a mineralocorticoid receptor blocker. In the Randomized Aldactone Evaluation Study (RALES),<sup>27</sup> researchers investigated the effect of spironolactone in patients with reduced LVEF and with current or recent symptoms of NYHA class IV heart failure. In this population, those randomly assigned to receive spironolactone, 25 to 50 mg once daily, manifested significant reduction in mortality (Figure 45-8). Within this study, there was a high proportion of patients taking background ACE inhibitor but not  $\beta$ -blocker therapy. The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS)<sup>83</sup> was an investigation of the effect of eplerenone in patients with heart failure and reduced LVEF in the setting of acute myocardial infarction. EPHESUS demonstrated reduced mortality in patients randomly assigned to receive eplerenone, 50 mg once daily, in comparison with those randomly assigned to receive placebo, on top of ACE inhibitor and  $\beta$ -blocker treatment (see Figure 45-7).

Results of the RALES and EPHESUS trials support the use of mineralocorticoid receptor-blocking agents (see Table 45-5) in at least subsets of patients with heart failure and reduced LVEF. It is uncertain whether their benefits derive principally from effects on fluid and electrolyte balance or from effects on processes such as fibrosis and inflammation in cardiac or vascular tissues. It is also uncertain whether similar benefits would be apparent in patient groups with different clinical characteristics, such as those who have not had recent myocardial infarction and those whose symptoms were less severe than those in the RALES population.

Serious hyperkalemia, defined as a serum potassium concentration of 6.0 mmol/L or higher, was reported in 1.7% of patients in RALES who took spironolactone, in comparison with 1.2% of those taking placebo, and in 5.5% of patients in

**FIGURE 45-8** Mortality curves from the Randomized Aldactone Evaluation Study (RALES), demonstrating a 30% relative reduction in mortality among patients with left ventricular systolic dysfunction (left ventricular ejection fraction  $<35\%$ ) and New York Heart Association class III to IV heart failure. (From Pitt B, Zannad F, Remme WJ, et al. The effect of spironolactone on morbidity and mortality in patients with severe heart failure. Randomized Aldactone Evaluation Study Investigators. *N Engl J Med* 1999;341:709-717.)

EPHESUS who took eplerenone, in comparison with 3.9% of those taking placebo. Despite these low incidences, concern has been raised regarding the adverse potential of hyperkalemia in patients treated with spironolactone or eplerenone in the clinical setting, in view of the greater likelihood of comorbidity and because the degree of patient monitoring is likely to be less.<sup>84</sup> After mineralocorticoid receptor–blocking treatment is initiated, frequent monitoring of serum electrolyte levels is warranted, particularly with concomitant ACE inhibitor or ARB use and particularly in patients with impaired renal function.

## Clinical Implications

ACE inhibitors represented the first major success story in the effort to improve clinical outcomes for patients with heart failure. Because of the wealth of data demonstrating reduced morbidity and mortality, they remain a mainstay of therapy for patients with heart failure and reduced ejection fraction. Results in other populations with established atherosclerosis or multiple cardiovascular risks, such as those reported in the Heart Outcomes Prevention Evaluation (HOPE) trial, have further expanded the indications for this class of agents.<sup>85</sup> Agents that block the AT<sub>1</sub> receptor, possessing mechanisms of action that overlap but differ from those of ACE inhibitors, have been difficult to investigate fully because of the ethical imperative to treat patients with an ACE inhibitor when it is tolerated. Nevertheless, results of available trials support the clinical efficacy of these agents. They clearly produce fewer side effects than do ACE inhibitors. In patients who cannot tolerate ACE inhibitors because of cough or angioedema, their use is justified, and their use as add-on treatment may be justified in select populations. Furthermore, guideline and quality metric panels have indicated that ARBs are acceptable alternatives to ACE inhibitors as first-line agents in patients with heart failure and reduced LVEF.<sup>86</sup>

For patients who continue to be symptomatic while receiving ACE inhibitors and  $\beta$ -blockers, clinicians have a choice between adding an ARB or an aldosterone receptor blocker. Most have chosen an aldosterone receptor blocker, on the basis of the mortality reduction in RALES and EPHESUS and because of a belief in greater mechanistic overlap between ACE inhibitors and ARBs. Limited experience, coupled with a concern regarding the risk of hyperkalemia, has precluded a general recommendation for consideration of the combination of all three classes of agents. Use of any of these agents, but particularly aldosterone receptor blockers in combination with either an ACE inhibitor or an ARB, warrants careful monitoring of serum potassium levels.

## PATIENT CHARACTERISTICS AND THE BENEFITS OF RENIN-ANGIOTENSIN-ALDOSTERONE SYSTEM BLOCKADE

On the basis of the clinical trials described previously, clinical practice guidelines for heart failure have advocated prescription of ACE inhibitors for all patients with reduced LVEF,<sup>87</sup> and guidelines since 2006 have advocated ARBs for patients intolerant of ACE inhibitors.<sup>86</sup> As with other classes of agents that have proved efficacious in clinical trials, these trials provide only modest guidance for identifying patients, beyond these criteria, who are either more or less likely to benefit clinically from treatment designed to inhibit the RAAS.

## Disease Severity and Drug Effects

It stands to reason that patients with the greatest degree of activation of the RAAS would have the greatest opportunity for benefit from ACE inhibitors or ARBs. However, the degree of activation is difficult to gauge within a particular patient,

because plasma renin activity varies with sodium loading and because production of angiotensin II and expression of angiotensin receptor are regulated at a local tissue level. Nevertheless, there is approximate correlation between RAAS activation and severity of the clinical syndrome of heart failure.<sup>34,88,89</sup>

Across the trials demonstrating clinical benefit for ACE inhibitors in patients with heart failure, the differential in outcomes between active drug and placebo appears to be more marked in the trials in which clinical heart failure was most severe (see Table 45-1). CONSENSUS demonstrated a 31% reduction in mortality after 1 year of therapy among patients with class IV heart failure treated with enalapril. The SOLVD treatment trial, whose population consisted predominantly of patients with class II and III symptoms, demonstrated a 16% reduction in mortality with enalapril. The SOLVD prevention trial, enrolling patients who did not require treatment for symptoms of heart failure, showed only an 8% nonsignificant trend toward reduced mortality with enalapril.

Within the SOLVD treatment trial, in which entry required an ejection fraction of 35% or less, subgroup analysis revealed that patients with the lowest baseline ejection fraction manifested the greatest benefit from enalapril treatment. In a substudy of the effect of the ACE inhibitor on LV function and volumes across both SOLVD trials, enalapril prevented LV dilation across various subgroups, although greater effect was observed among patients in the treatment trial (who were symptomatic) than among those in the prevention trial (who were asymptomatic).<sup>49,50</sup> The latter group had smaller LV cavity volumes at baseline. Median plasma renin activity was near normal among patients in the prevention trial.<sup>89</sup>

Hyponatremia has been linked to greater sensitivity to ACE inhibitor treatment,<sup>90</sup> probably because the population with hyponatremia included a higher proportion of patients with excessive plasma renin levels. The presence of hyponatremia indicates a higher likelihood of developing hypotension with initiation of an ACE inhibitor, but it also indicates a higher likelihood of achieving short-term symptomatic benefit if the drug can be tolerated. The presence of azotemia and hypotension also identify patients in whom ACE inhibitors and ARBs, which must be titrated cautiously, beginning with small doses of shorter-acting agents (e.g., captopril, 6.25 mg three times daily). However, if the appropriate dosing regimen can be established, such patients are likely to benefit from long-term treatment with these agents.

Despite the greater magnitude of demonstrable clinical outcome benefits of ACE inhibitors in patients with more severe clinical heart failure, there is ample evidence—notably, the marked reduction in progression to overt clinical heart failure and in hospitalizations for heart failure as a result of enalapril treatment in the SOLVD prevention trial—to support the use of ACE inhibitors in asymptomatic patients with reduced LVEF.

## Inhibition of the Renin-Angiotensin System as a Preventive Strategy

There is increasing evidence that agents that inhibit the RAAS in selective patients without heart failure or reduced LVEF can be used as a means for preventing the development of heart failure. The HOPE trial provides strong support for ACE inhibitor use in patients with clinically overt atherosclerotic disease and in those with diabetes and an additional risk factor for atherosclerotic disease but with absence of clinical heart failure or reduced ejection fraction.<sup>85</sup> Among the effects of ramipril in this study was a 23% reduction in the development of heart failure. The extent to which this effect is mediated through reduction in the incidence of myocardial infarction, as opposed to a direct protective effect on the myocardium, is uncertain. Two studies, the Irbesartan and Diabetic Nephropathy Trial (IDNT)<sup>91</sup> and the Reduction

of End points in Non-Insulin Dependent Diabetes Mellitus (RENAAL) Trial,<sup>81</sup> have demonstrated improved clinical outcomes with the use of ARBs in patients with altered renal function. Among diabetic patients with mild increases in urinary protein and serum creatinine levels, ARBs prevented the progression to more advanced renal failure, in addition to preserving renal function. In addition, treatment appeared to reduce the incidence of heart failure, although the latter was not a prespecified endpoint.

### Inhibition of the Renin-Angiotensin System in Patients with Preserved Left Ventricular Ejection Fraction (see Chapter 48)

For the large-scale clinical trials to date in which the effects of either ACE inhibitors or ARBs on clinical outcomes in heart failure were reported, entry criteria have included reduced LVEF. There is ample rationale to anticipate that ACE inhibitors or ARBs, or both, would provide benefits in clinical outcomes among many patients with preserved LVEF as well. The majority of patients with heart failure and preserved LVEF, with a nondilated left ventricle, have LV hypertrophy as a result of long-standing hypertension. Both ACE inhibitors and ARBs have been shown to slow the progression, or induce regression, of LV hypertrophy in hypertensive patients<sup>92,93</sup> through their antihypertensive effects and perhaps through direct effects on the myocardium. Angiotensin II has been shown to have a negative lusitropic effect (i.e., it improves myocardial relaxation) in animal models of LV hypertrophy,<sup>94</sup> and in human studies, relaxation is accelerated during intracoronary infusion of an ACE inhibitor in patients with LV hypertrophy.<sup>95</sup>

To date, direct support for inhibition of the RAAS in patients with heart failure and preserved LVEF is available only from small trials that have suggested improvement by ACE inhibitors or ARBs in symptoms or measures of functional capacity within such patients.<sup>96</sup> CHARM-Preserved provided only ambiguous results, with only marginal statistical significance for the primary endpoint. Results of the I-PRESERVE trial showed no clear evidence of benefit.<sup>79</sup>

Until more data are available, use of agents that inhibit the RAAS remains a reasonable consideration within the majority of patients with heart failure and preserved LVEF, especially those with hypertensive, hypertrophic disease. Beyond the efficacy of ACE inhibitors and ARBs as effective antihypertensive agents, large numbers of these patients with atherosclerotic disease, with diabetes, and with renal impairment are likely to fulfill the inclusion criteria for trials that have reported improved clinical outcomes with one or another of these agents. It is hoped that results of ongoing investigation with RAAS antagonists will provide clearer direction in the treatment of patients with heart failure and preserved LVEF.

### Genetic and Racial Factors Influencing the Response to Inhibition of the Renin-Angiotensin-Aldosterone System (see Chapters 42 and 49)

The future holds promise for identifying genetic factors that may influence response to a particular pharmacological approach. Both the opportunities and the obstacles in this area are evident in the case of ACE gene polymorphism, which has been widely explored for its effect on the development of cardiovascular disease. In particular, a homozygous deletion of a 287-base pair marker (d,d) in the human ACE gene is associated with greater levels of myocardial ACE expression and has been variably linked to increased incidence of myocardial infarction, LV hypertrophy, and heart failure.<sup>97</sup> Such observations could naturally lead to identifying the sensitivity of particular patients within the population to treatment with an ACE inhibitor or ARB. However, these observations

have been extremely variable; many studies have revealed no relationship at all. It is likely that the ACE polymorphism interacts with many other unknown genetic factors, and so its importance is dependent on the population investigated. Even within populations that have displayed a significant relationship, the contribution of the ACE polymorphism to the overall statistical risk of disease has been relatively small.

A number of observations have supported the view of variability in response to RAAS intervention on the basis of race. As a generality, African Americans tend to have a greater proportion of low-renin hypertension than do their non-African American counterparts.<sup>98</sup> Post hoc analysis of the SOLVD trial<sup>99</sup> demonstrated a treatment  $\times$  race interaction that supported a greater clinical response to ACE inhibitors by non-African American patients. Similar findings were observed in a post hoc analysis of V-HeFT I and II trials.<sup>100</sup> However, such findings should not be interpreted as a rationale for withholding ACE inhibitor or ARB treatment from African American patients. The proportion of African American patients investigated in SOLVD was small, and no conclusion can be drawn from an analysis of treatment effect solely within this subgroup. Furthermore, African Americans are by no means genetically homogeneous, and although a general population trend may be present, many African Americans would probably benefit from treatment directed toward the RAAS. The only way to resolve this question would be to conduct a placebo-controlled trial exclusively among African Americans, but a trial in which placebo is substituted for an ACE inhibitor would be unethical.

Ongoing and future clinical trials will incorporate methods for screening particular genotypes for their correlation with clinical effect. Genomic linkage to the response to a particular treatment will be demonstrated more slowly for heart failure—a multiform syndrome that is the complex product of multiple genetic and environmental factors—than for conditions that are more directly linked to a small number of genetic variables.

## CHARACTERISTICS AND DOSING RECOMMENDATIONS FOR SPECIFIC AGENTS

The two factors that have displayed the greatest variability among ACE inhibitors are pharmacokinetics and tissue binding. On the basis of differences in plasma half-lives, which have driven clinical trial design, the recommended dosing intervals for ACE inhibitors range from once daily to three times daily (Table 45-3). Most patients tolerate initiation of an ACE inhibitor or ARB quite well. However, when treatment is initiated in patients at risk for toxicity, particularly those with marginal blood pressure or marginal renal function, it is wise to begin with small doses and to consider an agent with a short plasma half-life, such as captopril.

In one study, a relative sparing of renal function was observed with captopril, in comparison with enalapril,<sup>101</sup> presumably because of an intermittent sparing of glomerular filtration pressure. Over days or weeks of treatment, it is not clear that this difference represents a significant advantage, inasmuch as variation in drug effect across the dosing interval is likely to confer intermittent efficacy, as well as intermittent sparing of glomerular filtration. Reduced glomerular filtration rate with ACE inhibitors and with ARBs does not represent a renal toxic effect. In fact, chronic reduction in glomerular filtration pressure is thought to contribute to renal protection with long-term inhibition of the RAAS, particularly in diabetic patients.<sup>102</sup> However, initiation with a short-acting agent enables more rapid reversal of renal function when function declines to a clinically unacceptable range. Once it is demonstrated that a patient tolerates inhibition of the RAAS, a

**TABLE 45-3** Properties of Selected Angiotensin-Converting Enzyme Inhibitors

Agent	Half-Life (Hours)	Recommended Dosing Schedule	Recommended Starting Dose	Recommended Target Dosage	Relative Tissue Binding
Captopril	3	Three times daily	6.25 mg	50 mg tid	+
Enalapril	11	Twice daily	2.5-5 mg	10 mg bid	+
Lisinopril	12	Daily	5 mg	20 mg qd	+
Ramipril	9-18	Twice daily	2.5 mg	5 mg bid	++
Quinapril	2*	Twice daily	5 mg	20 mg bid	+++
Trandolapril	6	Twice daily	1 mg	1-2 mg bid	NA

\*Half-life of the active metabolite is 25 hours.  
NA, not applicable.

transition may then be made to a longer-acting agent, which will be more conducive to patient compliance.

The tissue binding of different ACE inhibitors is significantly variable. The clinical importance of this variability has been suggested by animal studies that have shown differential effects on cardiovascular remodeling across agents with varied tissue binding, in the presence of comparable effects on systemic hemodynamics. It is not clear whether these differences translate into clinically relevant differentiating features. Enalapril, which has low tissue binding in relation to other ACE inhibitors, has been shown in a variety of clinical trials to be highly effective at reducing morbidity and mortality among patients with heart failure. A large-scale individual comparison of clinical outcomes would help resolve the issue of the relevance of tissue binding to clinical efficacy.

It has been similarly difficult to establish the optimal dosages for ACE inhibitors and ARBs, and aldosterone receptor blockers (Tables 45-3, 45-4, and 45-5, respectively). Selection of dosage within clinical outcome trials has been based on small dose-ranging studies, in which researchers have tended to examine acute hemodynamic effects of these agents. Available dose-response data are not likely to be definitive, even with regard to hemodynamic effects, because it is likely that the highest hemodynamic dose-response relationships are nonlinear. Furthermore, there is little reason to expect that a dosage that is “optimal” for achieving a given acute hemodynamic response will represent the dosage that is optimal for achieving improved clinical outcomes with an acceptable frequency of adverse events.

The practical answer to the question of dosage has been to recommend the dosing strategy that has been shown to achieve a given clinical outcome across a population, with acceptance of the possibility that an alternative dose or strategy, if tested, would have performed even better. It is typical that such strategies entail upward titration to a particular target, whereby the titration is halted or reversed if an adverse effect is observed. The maximum recommended doses listed in Table 45-3 tend to represent the target doses in trials that have demonstrated reduced morbidity, mortality, or both. For example, the target dosage of enalapril in the SOLVD studies was 10 mg twice daily. The titration strategy resulted in a mean dosage within the active treatment groups of 16.6 mg/day in the treatment trial and 16.7 mg/day in the prevention trial.

Attempts have been made to clarify the dosing issue in trials in which clinical outcomes of administration of high versus low dosages of an ACE inhibitor were compared. In the ATLAS trial, researchers compared low-dose with high-dose lisinopril in patients with heart failure and LV systolic dysfunction (LVEF  $\leq 30\%$ ). Mean dosages for the high-dose recipients reached 33.4 mg/day, in contrast to 4.5 mg/day for the low-dose recipients. In this long-term study, the high-dose recipients demonstrated a trend toward improved mortality rates (8% relative risk reduction,  $P = .13$ ) but a significant

reduction in the combined endpoint of death and hospitalization (24% relative risk reduction,  $P = .002$ ).<sup>103</sup> These data suggest that high-dose ACE inhibitor treatment is superior to low-dose therapy, although not by a large margin. Further evidence of this dose-outcome interaction was provided by Luzier and associates,<sup>104,105</sup> who analyzed ACE inhibitor dose and rehospitalization rates from a retrospective analysis of patients with heart failure. They reported that rehospitalization rates were significantly higher (28%) among patients taking lower dose enalapril ( $\leq 5$  mg/day, or ACE inhibitor equivalent) than among those receiving recommended doses of enalapril ( $\leq 20$  mg/day, or ACE inhibitor equivalent). Thus, these data support the notion that titration of ACE inhibitor dosages to recommended or maximal levels is superior to low-dose therapy in preventing hospitalizations for heart failure.

### POTENTIAL DRUG INTERACTIONS OF ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Clinical evidence suggests that aspirin use may prevent or limit the hemodynamic and survival benefits of ACE inhibitors. Guazzi and colleagues<sup>106</sup> measured diffusing lung capacity for carbon monoxide ( $DL_{CO}$ ) and peak exercise oxygen consumption ( $VO_{2max}$ ) before and after 8 weeks of aspirin therapy (325 mg/day) in patients with dilated cardiomyopathy taking enalapril. They reported that aspirin decreased  $DL_{CO}$  by 15%, with an associated and significant decrease in  $VO_{2max}$  and in exercise time. Spaulding and associates<sup>107</sup> administered aspirin (325 mg/day) or ticlopidine for 7 days to patients with heart failure and studied the hemodynamic response to a single 10-mg dose of enalapril. Contrary to the hemodynamic changes observed in the patients who received ticlopidine, enalapril administration to those who took aspirin did not decrease systemic vascular resistance or mean arterial pressure, and no increase in cardiac output was observed. In a cohort analysis from the SOLVD trial, Al-Khadra and coworkers<sup>108</sup> demonstrated that use of antiplatelet agents was associated with lack of an additive survival benefit from the ACE inhibitor enalapril. In a meta-analysis of ACE inhibitor trials, improvement in clinical outcomes continued to be evident in patients receiving aspirin at baseline, although the magnitude of the benefit tended to be lower.<sup>109</sup> The dose of aspirin chosen may be important. Studies in which less than 325 mg were used have not shown aspirin to be detrimental to hemodynamic effects of ACE inhibitors.<sup>110</sup>

Current recommendations advocate independent assessment of the indication for ACE inhibitors and aspirin.<sup>86</sup> Clopidogrel, an adenosine diphosphate receptor antagonist, would not be expected to interact adversely with the therapeutic benefit of ACE inhibitors. The Warfarin and Antiplatelet

**TABLE 45-4 Properties of Selected Angiotensin Receptor Blockers**

Agent	Half-Life (Hours)	Recommended Dosing Schedule	Recommended Starting Dose	Recommended Target Dosage
Losartan	6-9*	Daily	12.5 mg	50 mg qd
Valsartan	9	Daily	40 mg	160 mg bid
Irbesartan	11-15	Daily	75 mg	150 mg qd
Candesartan	3.5-4	Daily	4 mg	32 mg qd
Telmisartan†	24	Daily	20 mg	80 mg qd
Eprosartan	5-7	Daily or twice daily	200 mg	400 mg bid

\*Half-life of the active metabolite.

†Decreases digoxin clearance.

**TABLE 45-5 Properties of Aldosterone Receptor Blockers**

Agent	Half-Life (Hours)	Recommended Dosing Schedule	Recommended Starting Dose	Recommended Target Dosage
Spironolactone	9-23*	Daily	12.5 mg	25-50 mg qd
Eplerenone	3.5-6	Daily	25 mg	50 mg qd

\*Half-life of the active metabolite.

Therapy in Chronic Heart Failure (WATCH) trial randomly assigned more than 1500 patients with NYHA classes II to IV heart failure and with LVEF of less than 35% to receive warfarin, aspirin, or clopidogrel. The primary endpoint was all-cause mortality, nonfatal stroke, and nonfatal myocardial infarction. After a mean follow-up period of 2.5 years, there were no differences in the primary endpoint across the three groups. The warfarin-treated patients demonstrated fewer hospitalizations for heart failure than did the aspirin-treated patients.<sup>111</sup> Further insight into this issue may be shed by the results of the ongoing Warfarin Versus Aspirin in Reduced Cardiac Ejection Fraction (WARCEF) trial.

## FUTURE DIRECTIONS

There is active research on the potential incremental value of renin antagonists, which, when added to standard ACE inhibitor therapy, should produce more complete inhibition of the RAAS and, hence, minimize both angiotensin II and aldosterone “breakthrough.”<sup>112,113</sup>

The future holds promise for selection of patient populations that are mostly likely to benefit from antagonists of the RAAS. The technology enabling genomic analysis of defined gene polymorphisms is advancing rapidly. Such genetic analyses have already enabled the characterization of multiple polymorphisms within the adrenergic receptor system, some of which identify patients at high risk of developing heart failure or rapid progression once symptoms ensue.<sup>114-116</sup> Similar work for the RAAS may follow. However, heart failure is a complex disease that progresses in response to a myriad of both genetic and environmental factors. Thus, identification of specific genotype-phenotype relationships within this complex syndrome requires large, prospective, population-based studies. The EUROpean trial On reduction of cardiac events with Perindopril in stable coronary Artery disease (EUROPA), which enrolled more than 12,000 patients with stable chronic coronary artery disease, demonstrated a favorable effect of the ACE inhibitor perindopril on mortality and morbidity. The purpose of the PERindopril GENetic association study (PERGENE), a pharmacogenomic substudy of EUROPA,<sup>117</sup> was to identify gene polymorphisms that influence responsiveness to ACE inhibitor treatment in this population and thereby point to a more personalized therapeutic approach.

In two separate small studies, the significance of the AT<sub>1</sub> receptor polymorphism A1166C was analyzed for any interaction with the ACE deletion polymorphism. Among patients with symptomatic heart failure who were homozygous for the ACE deletion allele (d,d), survival rates were worse when they were homozygous or heterozygous for the 1166C allele.<sup>118</sup> This combination of apparently unfavorable genotypes was associated with the presence of diastolic filling abnormalities, determined by echocardiography in patients with a normal LVEF.<sup>119</sup> Results of both these rather small studies require confirmation in larger scale prospective clinical trials. Nonetheless, they demonstrate the potential strength of genomic analyses in identifying patients at high risk. Even more exciting will be the determination of those genotypes that confer a high likelihood of response to a given therapy; the ultimate goal is individualized, targeted therapy to optimize clinical outcomes.

The demonstration of the beneficial effects of  $\beta$ -blocker therapy in patients with chronic heart failure is one of the most important steps forward in the treatment of this syndrome. Because of their acute negative inotropic effects resulting from interruption of adrenergic support of the failing heart, these agents were initially contraindicated in patients with heart failure. However,  $\beta$ -blocking agents also prevent the adverse biological effects of chronically elevated adrenergic signaling in the failing heart, which is the basis for their salutary therapeutic effects. Indeed, demonstration of the beneficial effects of  $\beta$ -blocking agents on cardiac function and outcomes is the final proof of the hypothesis that chronic adrenergic activation is a major determinant of the progressive clinical course of heart failure. In addition, detailed functional, structural, and gene expression analyses have somewhat surprisingly demonstrated that with  $\beta$ -blocker treatment, the dysfunctional, remodeled human left or right ventricle can revert toward normal and, in some cases, completely so (see Chapter 11). This in turn has led to the concept that so-called end-stage myocardial disease is not irreversibly end stage at all and that it is possible to develop therapies that improve the underlying biological abnormalities in the failing heart.<sup>1,2</sup>

## HISTORICAL NOTES

The history of  $\beta$ -blocker treatment of heart failure is an example of investigator-initiated therapeutic development. This form of therapy was conceived and initially proceeded from outside the boundaries of conventional pharmaceutical company drug development. Carefully performed small

study was to therapeutically reduce heart rate, prolong the diastolic filling time, and decrease myocardial energy consumption.<sup>3</sup>  $\beta$ -Blocker treatment resulted in an improvement in clinical conditions, working capacity, and both systolic and diastolic cardiac function, as assessed by phonocardiography, carotid pulse curve, apexcardiography, and M-mode echocardiography.<sup>3</sup> Further small studies by the same researchers confirmed these results. Of importance was that survival rates with  $\beta$ -blocker therapy, in comparison with historical controls, apparently improved in one of the first long-term heart failure trials in which a clinical outcome was an endpoint (Figure 46-1).<sup>4</sup> This nonrandomized, retrospective study, which included only 37 patients (24 taking  $\beta$ -blockers, 13 taking placebo), achieved significant results and predicted the outcome of trials that were concluded almost 20 years later. Contemporaneous with this study, analyses of major postinfarction trials by investigators in the United States<sup>7</sup> and Norway<sup>8</sup> revealed that  $\beta$ -blockade had its most favorable effects on outcomes in patients with signs of heart failure or left ventricular (LV) dysfunction.

Around the same time, data were reported that appeared to resolve the debate of whether the failing heart was subjected to too little or too much adrenergic stimulation. Investigators at the National Institutes of Health had found that biopsy samples from failing human hearts were depleted of the adrenergic neurotransmitter norepinephrine<sup>9</sup> and that plasma norepinephrine or urinary catecholamine metabolites were elevated in patients with heart failure.<sup>10</sup> In order to address the question of whether adrenergic activity and  $\beta$ -adrenergic signaling were increased or decreased in the failing human heart, end-stage failing hearts from cardiac transplant recipients were compared with nonfailing unused organ donor hearts; in failing hearts,  $\beta$ -receptor density and signaling were found to be markedly reduced, which was interpreted as evidence both of exposure to increased adrenergic activity and of a mechanism responsible for compromised myocardial reserve.<sup>5</sup> A short time later, it was proved—first by direct coronary sinus norepinephrine measurements<sup>11</sup> and then by isotope dilution techniques to

clinical studies,<sup>3,4</sup> which today would be considered anecdotal, played a major role, as did translational investigations<sup>5</sup> that provided a pathophysiological framework for the clinical results. Another lesson learned from the history of the development of  $\beta$ -blocker therapy for heart failure is that small collaborative groups composed of dedicated and determined investigators<sup>6</sup> can achieve major results, in the absence of a centralized source of major funding.

In 1975,  $\beta$ -blockers were contraindicated in patients with heart failure. This was because of reports of clinically serious negative inotropic effects resulting in worsening heart failure, which had occurred when therapy was initiated with the standard large doses typically given to treat cardiovascular diseases other than heart failure. The researchers in Goteborg, Sweden, were the first to report the administration of a  $\beta$ -blocker to multiple patients, seven, with severe refractory heart failure and tachycardia.<sup>3</sup> The aim of this initial

measure norepinephrine spillover<sup>12</sup>—that adrenergic activity is increased in the failing human heart.

In the ensuing years, randomized, placebo-controlled trials demonstrated the beneficial effects of  $\beta$ -blockers on LV function, on symptoms, and on the clinical course of patients with chronic heart failure.<sup>6,13-20</sup> All these trials were conducted with extremely low initiating doses, followed by slow upward titration to target doses that were in the range of full  $\beta$ -blockade. The administration of  $\beta$ -blockers was associated with LV reverse remodeling (see also Chapter 8) and an improvement in cardiac contractility and energetics.<sup>14-18,21</sup> These changes were related to the beneficial effects of  $\beta$ -blockade on the intrinsic mechanisms that lead to progressive myocardial dysfunction and remodeling,<sup>17</sup> including myocardial metabolism, myocardial myosin heavy chain isoform and sarcoplasmic reticulum calcium-dependent adenosine triphosphatase (SERCA) gene expression,<sup>22</sup> ryanodine receptor phosphorylation,<sup>23</sup> and myocyte apoptosis.<sup>24</sup>

Despite favorable results from most of the initial studies, the efficacy of  $\beta$ -blockers in patients with heart failure remained controversial mainly because of neutral results from two short-term studies<sup>25,26</sup> and encouraging but conventionally nonsignificant statistical results in early underpowered outcome studies.<sup>6,27</sup> Any controversy was finally dispelled when landmark trials demonstrated a reduction

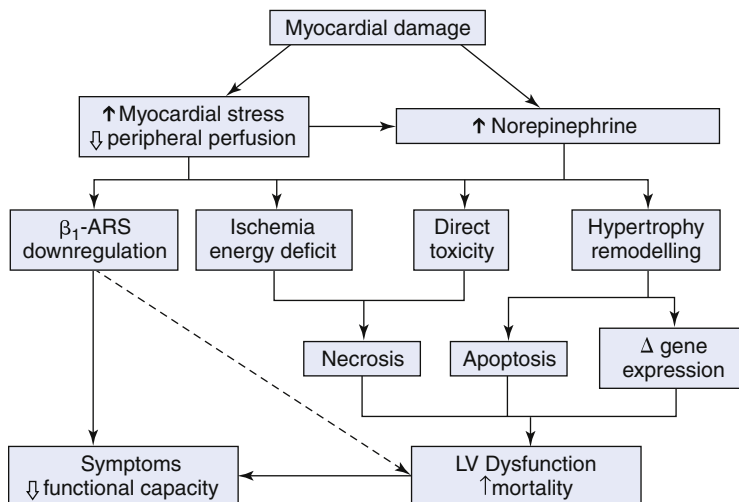

in mortality and hospitalizations among patients with heart failure who received  $\beta$ -blockers, in comparison with those receiving placebo; these studies were, accordingly, terminated prematurely.<sup>28-33</sup> The effects on survival were additive to that of angiotensin-converting enzyme (ACE) inhibitors and were of greater magnitude than those previously found with these agents.<sup>34</sup> Subsequent studies were aimed at broadening the indications to  $\beta$ -blocker therapy to early postinfarction LV dysfunction,<sup>35</sup> severe heart failure or LV dysfunction,<sup>32,33</sup> older age,<sup>36,37</sup> and extreme young age.<sup>38</sup> A further series of studies focused on the implementation of  $\beta$ -blocker therapy and how to increase the proportion of patients receiving them. Comorbid conditions, older age, and severe heart failure have been found to be the most important reasons why  $\beta$ -blockers are not prescribed.<sup>39,40</sup> When treatment is implemented on the basis of either early administration during a hospitalization for heart failure<sup>41,42</sup> or physicians' and patients education,<sup>39,43,44</sup> the number of patients receiving  $\beta$ -blockers increases, which results in better outcomes.

## MECHANISMS OF ACTION (see Chapter 10)

LV structural remodeling (see Chapter 15), loss of myocardial cells, and changes in gene expression appear to be the main mechanisms that mediate myocardial damage induced by chronic adrenergic stimulation (Figure 46-2). Remodeling is caused by increased mechanical stress and by neurohormonal activation, and a key role is played by adrenergic stimulation.<sup>2,20,21,34</sup> In accordance with the effects of chronic isoproterenol infusions<sup>45</sup> and the results of studies on  $\beta_1$ -adrenergic receptor myocardial overexpression,<sup>46</sup> chronic  $\beta$ -blockade may reverse changes associated with remodeling (i.e., LV dilation, depression of myocardial contractility, more spherical shape of the left ventricle). This demonstrates the central role of adrenergic stimulation in the remodeling process. Increased cardiac adrenergic drive may induce changes in myocardial gene expression,<sup>22</sup> which may explain the progressive worsening of myocardial contractility, as well as the induction of hypertrophy. The hallmark of adrenergically mediated alteration in cardiac myocyte gene expression is  $\beta_1$ -adrenergic receptor-mediated induction of the “fetal” gene program, consisting of an upregulation of natriuretic peptide and  $\beta$ -myosin heavy chain genes ordinarily expressed in fetal development, and downregulation of  $\alpha$ -myosin heavy chain and SERCA genes, ordinarily expressed only in adult cardiac myocytes (Figure 46-3; see also Chapter 2).<sup>22,47,48</sup> Because the  $\alpha$  isoform of myosin heavy

**FIGURE 46-1** Effects on survival of  $\beta$ -blocker therapy in patients with cardiomyopathy. Results from Swedberg and colleagues' first study<sup>4</sup> with assessment of survival. (From Swedberg K, Hjalmarson A, Waagstein F, et al. Prolongation of survival in congestive cardiomyopathy by beta-receptor blockade. *Lancet* 1979;1:1374-1376.)

**FIGURE 46-2** Sympathetic nervous system-mediated mechanisms of cardiac damage and reduced exercise tolerance in the failing heart. (From Metra M, Nodari S, D'Aloia A, et al. A rationale for the use of beta-blockers as standard treatment for heart failure. *Am Heart J* 2000;139:511-521.)

chain has much higher adenosine triphosphatase activity than does the  $\beta$  isoform, the change to favor the latter expression reduces the myocyte velocity of shortening and chamber contractile function. The downregulation of SERCA also contributes to a reduction in contractile function, whereas the upregulation in  $\beta$  myosin heavy chain produces cellular hypertrophy.  $\beta$ -Adrenergically mediated hyperphosphorylation of ryanodine receptors may contribute to myocardial dysfunction and predispose to arrhythmias.<sup>23</sup>  $\beta$ -Blockers reverse these  $\beta_1$ -adrenergically mediated effects, and the reversal of molecular remodeling is highly correlated with reversal of structural remodeling and improvement in contractile function (see Figure 46-3).<sup>22</sup>

Another untoward effect of increased adrenergic drive is accelerated myocardial cell loss. Norepinephrine, at concentrations similar to those found in the failing heart (10 to 100 nmol), can have direct toxic effects and may induce apoptosis.<sup>24</sup> The induction of apoptosis by  $\beta$ -adrenergic receptor stimulation has been consistently shown both in vitro and in vivo. Apoptosis associated with ischemia and reperfusion, or with postinfarction LV remodeling, may be almost completely abolished by the administration of  $\beta$ -blockers. However, the role of apoptosis in the natural history of chronic heart failure is somewhat controversial,<sup>49</sup> and the degree of  $\beta$ -blocker benefit ascribed to this mechanism is therefore uncertain.

In addition to the improvement in cardiac function, protection from lethal arrhythmias is another major favorable effect of  $\beta$ -blocker therapy, with a major effect on outcomes.<sup>50</sup> A discussion of this mechanism is beyond the scope of this chapter, but the beneficial effects of  $\beta$ -blockers on sudden death are discussed later in this chapter.

## PHARMACOLOGICAL CHARACTERISTICS OF $\beta$ -BLOCKING AGENTS

The foundation of  $\beta$ -blocker treatment of patients with heart failure has been cardiac protection from the deleterious effects of adrenergic stimulation, which are transduced mainly by  $\beta_1$ -adrenergic receptors. However, the  $\beta$ -blockers that are recommended by guidelines<sup>51-53</sup> or are in development to treat heart failure are an extremely heterogeneous class of agents, both with regard to  $\beta_1$ -adrenergic receptor blockade and from the standpoint of other properties. Pharmacokinetic and chemical differences include metabolism, plasma half-life, and lipid solubility. Pharmacodynamic differences include intrinsic sympathomimetic activity (ISA), selectivity of  $\beta_1$ -adrenergic receptor blockade, characteristics of binding to  $\beta_1$ -adrenergic receptors, inverse agonism, and ancillary properties unrelated to adrenergic receptor blockade (Table 46-1).<sup>54</sup>

**FIGURE 46-3** Changes in myocardial messenger RNA steady-state abundance (6-month value minus baseline value) for the six measured gene products in subjects treated with  $\beta$ -blocking agents. “Responder” subjects demonstrated an improvement in left ventricular ejection fraction (LVEF) (defined as an increase of  $>5$  ejection fraction units), whereas “nonresponders” demonstrated either no change or a decline in LVEF. Messenger RNA abundance is in molecules  $\times 10^{-5}/\mu\text{g}$  total RNA  $\pm$  standard error of the mean (SEM), displayed on a log scale (y axis); the SEM values are plotted within the unit scales of the nominal absolute changes. (From Lowes BD, Gilbert EM, Abraham WT, et al. Myocardial gene expression in dilated cardiomyopathy treated with beta-blocking agents. *N Engl J Med* 2002;346:1357-1365.)

**TABLE 46–1 Pharmacological Characteristics of  $\beta$ -Blockers**

Drug	K( $\beta_1$ ) (nmol)	K( $\beta_2$ ) (nmol)	$\beta_1/\beta_2$ Selectivity	Inverse Agonism	Ancillary Properties	Initial Dosage	Final Dosage
Propranolol	4.1	8.5	2.1	Moderate	None	Not recommended in heart failure	
Metoprolol succinate	45	3.34	74	Strong	None	12.5/25 mg	200 mg/day
Bisoprolol	121	14.39	119	Moderate to weak	None	1.25 mg	10 mg/day
Carvedilol	4	29	7.3	Moderate to weak	Vasodilation ( $\alpha_1$ -blockade), antioxidant	3.125 mg bid	25–50 mg bid
Nebivolol	0.7	225	352	Moderate	Vasodilation, nitric oxide release, $\beta_3$ agonist	1.25 mg	10 mg/day
Bucindolol	3.6	5.0	1.4	Weak	Vasodilation, sympatholysis	3 mg bid	50–100 mg bid

K( $\beta_1$ ), average of high-affinity dissociation constant; K( $\beta_2$ ), average of low-affinity dissociation constant.

## Lipophilic Versus Hydrophilic $\beta$ -Blockers

All of the agents shown to be clinically effective in heart failure are lipophilic. Such agents are likely to reside longer or at higher concentrations in cell membranes, which may be important for their effects on cardiac myocytes and arrhythmias. Atenolol, a hydrophilic agent, has not been tested in large prospective outcome studies in patients with heart failure. However, it has been associated with an improvement in LVEF and in exercise capacity in small single-center studies<sup>54</sup> and with favorable outcomes in retrospective analyses of patient databases.<sup>55,56</sup> These data should be interpreted as hypothesis generating and should be confirmed by randomized studies.

## Intrinsic Sympathomimetic Activity

The untoward effects of ISA were first shown by postinfarction trials<sup>57</sup> and were then confirmed by the finding that the administration of a  $\beta$ -blocker with high ISA, xamoterol, was associated with increased mortality among patients with heart failure.<sup>58</sup> However, another  $\beta$ -blocker with ISA, celiprolol,<sup>59</sup> was not obviously associated with increased mortality in small randomized studies among patients with heart failure, and it is possible that explanations other than ISA, such as initiating therapy with a high  $\beta$ -blocking dose, could have caused the untoward effects with xamoterol. In addition, some  $\beta$ -blockers such as bucindolol may have ISA in small animal models,<sup>60</sup> in which G-protein amplification of  $\beta$ -receptor signaling is greater, but not in the human heart<sup>61–63</sup> in which signal amplification is lower. The issue of ISA of a  $\beta$ -blocker is obviously relevant only in the human heart, in which the most sensitive test of ISA is either forskolin-augmented contractile effects in isolated human heart preparations<sup>63</sup> or nighttime heart rate effects measured against placebo by 24-hour Holter monitoring.<sup>61</sup>

## Selectivity of $\beta_1$ -Adrenergic Receptor Blockade

The development of agents with a selective action on  $\beta_1$ -adrenergic receptors represents a step forward in the development of  $\beta$ -blockers.<sup>64</sup> In comparison with earlier non-selective agents (e.g., propranolol), so-called second generation<sup>64</sup>  $\beta_1$ -selective agents were shown to be better tolerated in patients with concomitant peripheral vascular disease or with chronic pulmonary disease.  $\beta_1$ -Selective agents are less likely to increase airway resistance and should not influence alveolar gas diffusion, inasmuch as they do not act on alveolar  $\beta_2$ -adrenergic receptors, which regulate reabsorption of alveolar fluid.<sup>65</sup> However, the comparative advantages of  $\beta_1$ -selective agents on pulmonary function has not always been demonstrated.

Blockade of  $\alpha_1$ - and  $\beta_2$ -adrenergic receptors may also be clinically important.<sup>20,34,54</sup>  $\alpha_1$ -Adrenergic receptors cause peripheral and renal vasoconstriction and myocardial hypertrophy. However, it is unlikely that they are important for the treatment of heart failure. Pure  $\alpha_1$ -adrenergic antagonists have not been associated with beneficial effects on either the incidence of heart failure when they are used to treat hypertension or on outcomes in heart failure trials. In addition, there is evidence of the development of tolerance to the hemodynamic  $\alpha_1$ -mediated effects of carvedilol in the patients with heart failure.<sup>13,66</sup>

The effects of cardiac myocyte  $\beta_2$ -adrenergic receptors are distinct from those of  $\beta_1$ -adrenergic receptors; one difference is that  $\beta_2$ -adrenergic receptors are strongly coupled to counterregulatory inhibitory G-protein signaling.<sup>67</sup> However, transduction of  $\beta_2$ -adrenergic receptor signal mediates both positive inotropic and chronotropic effects, through the  $G_s$ -cyclic adenosine monophosphate pathway,<sup>34,68,69</sup> in addition to negative inotropic and lusitropic effects mediated through  $G_i$  stimulation.<sup>67</sup> In addition,  $\beta_2$ -adrenergic receptors have a  $G_i$ -mediated antiapoptotic action.<sup>70</sup> The  $G_i$ -mediated effects are probably enhanced in the failing heart because of  $\beta_1$ -adrenergic receptors are downregulated and  $G_i$  protein is upregulated. These  $\beta_2$ -adrenergic effects could be considered adaptive inasmuch as they may protect the failing heart from excessive adrenergic stimulation.<sup>71</sup> In contrast, intense stimulation of  $\beta_2$ -adrenergic receptors may exert a dose-dependent adverse effect on the failing heart and promote LV remodeling and fibrosis, pulmonary congestion, and increased mortality.<sup>69,72</sup> The exact role of nonselective blockade of the  $\beta_2$ -adrenergic receptors may therefore vary from patient to patient, depending on the degree of sympathetic stimulation,  $\beta_1/\beta_2$ -receptor ratio, and  $G_s/G_i$  protein expression. According to limited clinical data  $\beta_2$ -receptor manipulation in chronic heart failure may not have major therapeutic consequences. The ISA of celiprolol results from  $\beta_2$ -receptor partial agonism, and in a small clinical study,<sup>61</sup> celiprolol did not produce results that are obviously different from those of  $\beta$ -selective blockers. In addition, when given in comparable  $\beta_1$ -blocking doses,  $\beta_1$ -selective blockers<sup>28,29</sup> have generally not produced results that are different from those of nonselective<sup>31</sup>  $\beta$ -blockers.

## $\beta_1$ -Receptor Density

Second-generation agents, such as metoprolol, upregulate  $\beta_1$ -adrenergic receptors,<sup>73,74</sup> and this explains the potential occurrence of rebound responses when these agents are abruptly withdrawn.<sup>75</sup> In contrast, agents such as carvedilol or bucindolol do not obviously upregulate  $\beta_1$ -receptors<sup>34</sup>; thus, the heart is rendered less sensitive to the effects of any adrenergic stimulation that competitively overcomes

receptor blockade. Upregulation of  $\beta_1$ -adrenergic receptor may increase cardiac sensitivity to high levels of adrenergic drive, as during maximal exercise, with maintenance or an improvement in exercise capacity.<sup>76</sup> On the other hand, lack of upregulation of  $\beta_1$ -adrenergic receptors may better protect the heart from chronic adrenergic stimulation.

### $\beta_1$ -Adrenergic Receptor Binding

Carvedilol is characterized by tight binding to  $\beta_1$ -receptors; this property may not be shared by other  $\beta$ -blockers.<sup>77,78</sup> In a direct comparison between carvedilol and metoprolol tartrate, the hemodynamic response to dobutamine infusion was blunted by concomitant carvedilol, but not by metoprolol tartrate, administration.<sup>79</sup> In another comparison study, the  $\beta$ -blocking activity of carvedilol persisted, because of its binding characteristics, for up to 44 hours after it was withdrawn.<sup>78</sup> Because of this tight receptor binding, the  $\beta_1$ -blocking activity of carvedilol may be more stable throughout the day, and the risks of rebound phenomena when a dose is missed may be lower.

### Inverse Agonism

In inverse agonism, a  $\beta$ -blocker stabilizes a receptor in its inactive state, which thus leads to a reduction in the proportion of receptors that are constitutively active. Compounds with higher degrees of inverse agonism, such as propranolol, are expected to produce more substantial negative chronotropic and inotropic effects and thus to be less well tolerated.<sup>80</sup> On the other hand, in model systems transfected with recombinant human  $\beta_1$ -receptors, it has been shown that carvedilol, but not metoprolol, has a very specific and marked inverse agonist effect on the more frequent Arg389 variant, which is associated with increased sensitivity to adrenergic stimulation.<sup>81</sup> However, in isolated human heart preparations, carvedilol does not exhibit inverse agonism in the Arg389 variant of the  $\beta_1$ -receptor, whereas bucindolol does.<sup>63</sup> Inverse agonism could be important also at the  $\beta_2$ -receptor level, whereby non-selective  $\beta$ -blockers could theoretically act as inverse agonists that stabilize  $\beta_2$ -receptors in their  $G_i$ -coupled conformation and enhance their favorable effects.<sup>82</sup>

### Sympatholytic (Norepinephrine-Lowering) Effects

Cardiac norepinephrine release is stimulated by prejunctional  $\beta_2$ -adrenergic receptors and inhibited by prejunctional  $\alpha_2$ - as well as  $\alpha_1$ -adrenergic receptors. Inhibition of cardiac norepinephrine release may have favorable effects by reducing cardiac adrenergic stimulation. However, when excessive or too rapid, this inhibition may be detrimental because of excessive withdrawal of cardiac adrenergic support. This was shown in the MOXonidine CONgestive Heart Failure (MOXCON) trial,<sup>83</sup> in which placebo was compared with moxonidine, an agent that inhibits norepinephrine release through the stimulation of central  $\alpha_2$ -adrenergic receptors. This trial was prematurely stopped because mortality increased among patients randomly assigned to receive moxonidine, in contrast to placebo (5.5% versus 3.4%).<sup>83</sup>

Although metoprolol does not affect cardiac or systemic norepinephrine release, carvedilol has been associated with a slight decrease in coronary sinus levels of norepinephrine and in cardiac norepinephrine release.<sup>84,85</sup> However, in patients with heart failure, carvedilol does not produce a reduction in systemic adrenergic activity.<sup>84</sup> Carvedilol's effects on cardiac adrenergic activity are probably caused by blockade of prejunctional  $\beta_2$ -receptors, and the effects are probably attenuated by concomitant prejunctional  $\alpha_1$ -receptor blockade. In contrast, the potent  $\beta_2$ -blocker bucindolol, which has only

minimal  $\alpha_1$ -blocking activity, does reduce systemic adrenergic activity and, as such, is moderately sympatholytic.<sup>86,87</sup> This sympatholytic, moxonidine-like effect,<sup>87</sup> along with the characteristics of the patients studied (more advanced heart failure), may have compromised the mortality-reducing effects of bucindolol in the Beta-Blocker Evaluation of Survival Trial (BEST).<sup>86,88</sup>

### Ancillary Properties

Ancillary properties of some  $\beta$ -blockers include properties unrelated to blockade of  $\beta$ -adrenergic receptors, including the type III antiarrhythmic activity of sotalol, the  $\alpha_1$ -blocking and antioxidant effects of carvedilol, and the induction of nitric oxide release by nebivolol,<sup>89,90</sup> bucindolol,<sup>91</sup> and celiprolol.<sup>92</sup> With the exception of the type III antiarrhythmic effects of sotalol, the clinical relevance of these properties is uncertain. Nitric oxide release after nebivolol<sup>89</sup> or bucindolol<sup>91</sup> administration has been ascribed to  $\beta_3$ -adrenergic receptor stimulation. The nitric oxide-generating properties of nebivolol<sup>92</sup> have been associated with an improvement in endothelial function, decreased peripheral vascular resistance, decreased aortic central pressure, and decreased aortic stiffness. Nitric oxide generation may be important for nebivolol's or celiprolol's efficacy and tolerability in patients with hypertension. However, the clinical significance of nitric oxide generation in patients with heart failure has not been assessed in comparison trials.<sup>93,94</sup>

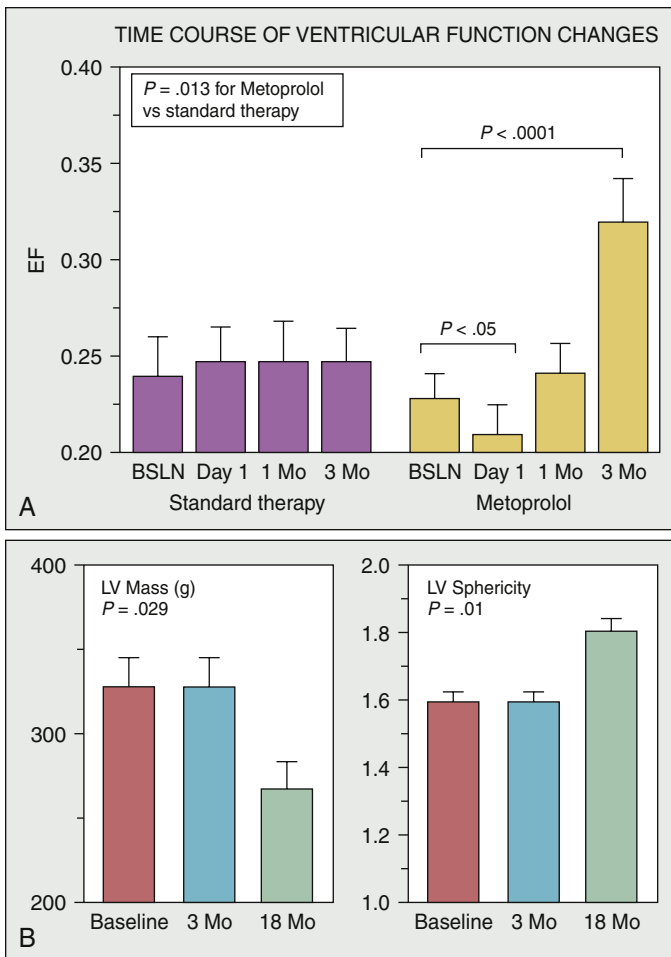

## CLINICAL RESULTS

### Effects on Cardiac Function

Multiple studies have consistently shown the beneficial effects of chronic  $\beta$ -blocker therapy on LV function and structure. Long-term benefits include an increase in LVEF, a decrease in LV volumes and in mitral regurgitation (when present), and a reversion of the left ventricle to a more elliptical shape. Improvement in load-independent indexes of myocardial contractility has also been shown, which demonstrates that the improvement is related to changes in the intrinsic properties of the myocardium.<sup>17,21</sup> LV diastolic function and right ventricular function are also improved by long-term  $\beta$ -blocker therapy.<sup>95-97</sup> Thus, all the changes associated with LV remodeling are, on average, counteracted by long-term  $\beta$ -blocker therapy. These studies were the first to demonstrate the reversibility of LV dysfunction and remodeling in the failing heart (see also Chapter 8).

The functional effects of  $\beta$ -blocker therapy on the failing heart are biphasic (Figure 46-4).<sup>16,73</sup> Administration of  $\beta$ -blockers is associated with an early, short-term deterioration in cardiac function, which is consistent with the negative inotropic effects of adrenergic drive withdrawal and is enhanced in the failing heart because of its dependence on adrenergic support. Carefully performed studies with serial echocardiography have shown a decrease from baseline in LVEF in the first few days of treatment, followed by return to baseline values after 1 month. An increase in LVEF from baseline values starts to become apparent after 3 to 4 months of treatment and tends to improve further for at least another year. At 3 to 4 months, decrease in LV volumes and favorable changes in shape also become apparent.<sup>16,20</sup>

Predictors of changes in parameters of LV function have been identified and are rather consistent across multiple studies. Predictors of an improvement in LVEF include a nonischemic cause of heart failure, higher blood pressure at baseline, the administration of a higher  $\beta$ -blocker dose, and higher baseline heart rates.<sup>98-101</sup> Patients with a nonischemic cause generally show a greater contractile reserve. Higher heart rate at baseline and the administration of a higher, rather than lower,

**FIGURE 46-4** Time course of changes in left ventricular ejection fraction (LVEF) after  $\beta$ -blocker therapy in chronic heart failure. **A**, Time course of left ventricular function changes with no  $\beta$ -blocker (left) and with metoprolol tartrate (right) at baseline and after 1 day, 1 month, and 3 months. **B**, Reverse remodeling with a regression of left ventricular mass and an increase in the length to radius ratio (sphericity) after long-term  $\beta$ -blockade with metoprolol tartrate. (Data From Hall SA, Cigarroa CG, Marcoux L. Time course of improvement in left ventricular function, mass, and geometry in patients with congestive heart failure treated with beta-adrenergic blockade. *J Am Coll Card*, 25(5): 1154–1161, 1995, and Eichhorn EJ, Bristow MR. Antagonism of  $\beta$ -adrenergic receptors in heart failure. In Mann DL, (ed.) *Heart failure: a companion to Braunwald's heart disease*, Philadelphia, 2004, Elsevier, pp 619–639.)

$\beta$ -blocker dosage are related to the level of adrenergic drive and the degree of  $\beta$ -blockade, respectively. A higher blood pressure at baseline is a rather accurate index of contractile reserve in left ventricles with systolic dysfunction. Accordingly, the demonstration of contractile reserve by dobutamine echocardiography is an excellent predictor of a favorable response to  $\beta$ -blocker therapy.<sup>102,103</sup> In patients with heart failure of ischemic origin, a direct relation exists between the number of LV segments showing myocardial hibernation and change in LVEF after  $\beta$ -blocking treatment.<sup>104</sup> The basis of all these observations is the fact that the magnitude of the improvement in LV function after chronic  $\beta$ -blockade is directly related to the amount of viable myocardium present at baseline.

Changes in LV function are related to subsequent prognosis. Patients with the greatest increase in LVEF and reduction in volumes have an excellent long-term prognosis.<sup>98,99,105</sup> A post hoc analysis of the Cardiac Insufficiency Bisoprolol Study (CIBIS) confirmed these findings. Patients who showed an improvement in LV fractional shortening after 5 months of treatment had a survival advantage over other patients.<sup>106</sup>  $\beta$ -Blocker therapy and, more recently, cardiac resynchronization therapy are the two interventions that have shown the

value of LV function for the prediction of outcomes in chronic heart failure.<sup>2,17</sup>

## Effects on Exercise Capacity and Symptoms

The impairment of exercise capacity in patients with heart failure is related both to myocardial dysfunction and to the abnormalities in  $\beta$ -adrenergic receptor signal transduction that result in reduced cardiac sensitivity to sympathetic stimulation (see Figure 46-2).<sup>34,107</sup>  $\beta$ -Blocker therapy improves myocardial function and, on that basis, would be expected to improve exercise performance. However, if  $\beta$ -adrenergic receptors are blocked by higher doses of  $\beta$ -blocking agents or are not upregulated by therapy, then exercise tolerance may not improve. This is because the failing heart is dependent on increasing heart rate for improving exercise capacity, more so than is the nonfailing heart. Thus, despite the improvement in cardiac function and stroke volume, both at rest and during exercise, the  $\beta$ -blocker–related reduced chronotropic response to exercise may prevent cardiac output to rise sufficiently during exercise to allow an improvement in exercise capacity.<sup>13,20</sup> A direct correlation between change from baseline in maximal exercise capacity and change from baseline in peak exercise heart rate after  $\beta$ -blocker therapy has been observed in multiple-dose studies<sup>61</sup> and in comparisons of multiple  $\beta$ -blockers (Figure 46-5).<sup>76</sup>

In general,  $\beta_1$ -selective  $\beta$ -blocking agents, such as metoprolol, which at lower doses do not block myocardial  $\beta_2$ -adrenergic receptors and upregulate myocardial  $\beta_1$ -receptors<sup>84,85</sup>—slightly improve maximal exercise capacity.<sup>6,74</sup> In contrast, agents such as carvedilol and bucindolol—which may not alter myocardial  $\beta_1$ -adrenergic receptor density, have slower offset kinetics from  $\beta_1$ -adrenergic receptors, and also block  $\beta_2$ -adrenergic receptors—may not allow an increase in peak exercise cardiac output and heart rate sufficient to improve exercise capacity and peak oxygen uptake ( $\text{VO}_2$ ).<sup>13–15</sup> On the basis of results of a few single-center studies, it was initially thought that  $\beta$ -blockers might be able to improve submaximal exercise.<sup>13,14</sup> However, multicenter trials failed to show any change also in submaximal exercise capacity.<sup>108–110</sup>

In contrast to direct measurements of exercise tolerance, most controlled studies have shown a significant improvement in symptoms and functional class in patients with heart failure treated with  $\beta$ -blockers. The results obtained are consistent in single-center<sup>13–15</sup> and in multicenter trials.<sup>6,105,108,109</sup> According to a meta-analysis by Lechat and associates,<sup>18</sup> patients treated with a  $\beta$ -blocker were 32% more likely to experience an improvement and 30% less likely to experience a worsening in New York Heart Association (NYHA) class ( $P < .05$  in both cases). Direct assessment of heart failure symptoms, as well as global clinical assessment (a quality-of-life measurement) by either the patient or the physician, has been similarly sensitive, showing an improvement in clinical status.<sup>6,108,109</sup> The interpretation of the functional capacity and symptom outcomes of these studies is that  $\beta$ -blockade does not worsen exercise capacity, and the improvement in cardiac function is associated, albeit indirectly, with an improvement in symptoms and quality-of-life measures.

## Effects on the Clinical Course: Initial Trials

Although the effects of  $\beta$ -blockers on cardiac function are novel and impressive, their most significant effects in patients with heart failure are on the clinical course. Major clinical outcomes such as mortality and hospitalizations for heart failure are, of course, the most important clinical trial endpoints, as well as being of paramount importance to physicians and patients. The clinical course and prognosis of patients with heart failure have been radically changed since the introduction of  $\beta$ -blocker therapy.

Multicenter trials have consistently shown a highly significant reduction in the incidence of hospitalizations,<sup>6,28,29,31,105,109,111</sup> cardiovascular events,<sup>16,27,29,105,109</sup> episodes of worsening heart failure,<sup>6,27,29,105,109</sup> and in indications for heart transplantation<sup>6</sup> in patients treated with a  $\beta$ -blocker, in comparison with patients treated with placebo. A meta-analysis revealed that the hospitalization rate for heart failure was 9.6% among patients treated with a  $\beta$ -blocker, in comparison with 17% in those taking placebo ( $-41\%$ ; 95% confidence interval,  $-26\%$  to  $-52\%$ ;  $P < .001$ ).<sup>18</sup>

The results on mortality were initially controversial, mostly because the early studies were underpowered. The

Metoprolol in Dilated Cardiomyopathy trial,<sup>6</sup> the first significant multicenter study of  $\beta$ -blockade in heart failure, and the CIBIS-II<sup>27</sup> did not yield significant findings about mortality, despite the overall improvement in LV function and clinical course. This can be attributed to methodological limitations of these studies: Too few patients were randomly assigned to treatment conditions, the incidence of events was low, and follow-up was relatively short. The United States Carvedilol program included four trials designed to assess the effects of carvedilol on exercise tolerance and heart failure progression. Data and safety monitoring board analysis of the four trials combined revealed a reduction in mortality with carvedilol, in comparison with placebo. However, these data were deemed inconclusive because of the small number of events, short follow-up, and open-label run-in period before randomization. In addition, mortality benefit was largely driven by the results of one of the four studies in which the effects on LVEF and mortality were shown to be dose dependent (Figure 46-6).<sup>105</sup> The low number of patients enrolled and the low number of events can also explain the nonsignificant 14% decrease in mortality with carvedilol, in comparison with placebo, in the Australia/New Zealand Heart Failure Research Collaborative Group trial.<sup>111</sup>

### Effects on the Clinical Course: Large-Scale Mortality Trials

Six large-scale placebo-controlled outcome trials have been performed in patients with heart failure (Table 46-2).<sup>27,30,32,35,36,86</sup> The second Cardiac Insufficiency Bisoprolol Study (CIBIS-II),<sup>29</sup> and the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF),<sup>30</sup> were large prospective trials in patients with mild to moderate heart failure; annual mortality rates in these studies were 11% to 13%. CIBIS-II enrolled 2647 European patients with NYHA class III or IV heart failure and LVEF of 35% or lower; MERIT-HF enrolled 3991 patients, most of whom were European, with NYHA classes II to IV heart failure and LVEF of 40% or lower. Both trials were prematurely terminated on the recommendation of the data and safety monitoring boards because of the survival benefit associated with the active agent. Both trials—in which the  $\beta_1$ -selective agents bisoprolol and metoprolol succinate CR/XL, respectively, were used—demonstrated a 34% reduction in mortality among subjects treated with these

**FIGURE 46-5** Relationship between the change in maximal functional capacity (percentage) and change in peak exercise heart rate (percentage) for multiple  $\beta$ -blocker trials with the selective agent metoprolol (circles) or the nonselective agents bucindolol (squares) and carvedilol (triangles). Only the selective agent produced improvement in functional capacity. (Data from Metra M, Nodari S, D'Aloia A, et al. Effects of neurohormonal antagonism on symptoms and quality-of-life in heart failure. *Eur Heart J* 1998;19(Suppl B):B25-B35; and from Eichhorn EJ, Bristow MR. Antagonism of  $\beta$ -adrenergic receptors in heart failure. In Mann DL, editor. *Heart failure: a companion to Braunwald's Heart Disease*, Philadelphia, 2004, Elsevier, pp 619-639.)

**FIGURE 46-6** Relationship between  $\beta$ -blocker dosage and improvement in left ventricular ejection fraction (left) and reduction in mortality (right). The higher the dosage was, the more left ventricular function improved. (Data from Bristow MR, Gilbert EM, Abraham WT, et al. Carvedilol produces dose-related improvements in left ventricular function and survival in subjects with chronic heart failure. *Circulation* 1996;94:2807-2816; and from Eichhorn EJ, Bristow MR. Antagonism of  $\beta$ -adrenergic receptors in heart failure. In Mann DL, editor. *Heart failure: a companion to Braunwald's Heart Disease*, Philadelphia, 2004, Elsevier, pp 619-639.)

TABLE 46-2 Prospective Outcome Trials with $\beta$ -Blockers in Patients with Heart Failure												
Trial	Agent	Entry Criteria	Number of Patients	Mean Follow-up Time	Annual Placebo-Related Mortality Rate	Mortality Risk Reduction			Numbers Needed to Treat to Save One Life	All-Cause Hospitalization Risk Reduction		
						Percentage	95% Confidence Interval	P		Percentage	95% Confidence Interval	P
CIBIS-II <sup>29</sup>	Bisoprolol	LVEF $\leq$ 35%, NYHA class III or IV	2647	1.3 years	13.2%	34%	19% to 46%	<.0001	22.7	18%	29% to 9%	.0006

 BEST, Beta-Blocker Evaluation of Survival Trial; CAPRICORN, Carvedilol Post-Infarct Survival Control in Left Ventricular Dysfunction; CIBIS II, Cardiac Insufficiency Bisoprolol Study; COPERNICUS, Carvedilol Prospective Randomized Cumulative Survival; LVEF, left ventricular ejection fraction; MERIT-HF, Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure; NA, not assessed; NYHA, New York Heart Association class; SENIORS, Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with Heart Failure.

drugs, in comparison with those treated with placebo. In both trials, as well as in the following outcome studies with  $\beta$ -blockers, the study drug was added to standard treatment of heart failure, including ACE inhibitors. Thus, these trials actually demonstrated the benefits of adding  $\beta$ -blockers to ACE inhibitors. The Kaplan-Meier survival curves for MERIT-HF and CIBIS II are shown in Figure 46-7, A and B, respectively. It is clear that the  $\beta$ -blocker and placebo curves are similar for the initial 2 to 3 months and then diverge throughout the course. Thus, 2 to 3 months of treatment is the time necessary for a favorable biological effect to occur.

The CIBIS-II trial demonstrated a 44% reduction in sudden death ( $P = .0011$ ), a 26% reduction in death from pump failure ( $P = .17$ ), a 36% reduction in hospitalizations for heart failure ( $P = .0001$ ), and a 20% reduction in all-cause hospitalization ( $P = .0006$ ). The MERIT-HF study demonstrated a 41% reduction in sudden death ( $P = .0002$ ), a 49% reduction in death from pump failure ( $P = .0023$ ), a 35% reduction in hospitalizations for heart failure ( $P = .00001$ ), and an 18% reduction in all-cause hospitalizations ( $P = .005$ ). Subgroup analysis of CIBIS-II and MERIT-HF by gender, age, cause of heart failure, history of prior myocardial infarction, diabetes, and heart rate at baseline consistently demonstrated a benefit or a trend toward benefit for active therapy across all strata.<sup>29,30</sup> A meta-analysis of 22 placebo-controlled randomized trials of  $\beta$ -blockers, including CIBIS-II and MERIT-HF, involving 10,132 patients with heart failure and low ejection fraction, revealed a 35% reduction in the risk of death with  $\beta$ -blocker therapy (95% confidence interval [CI], -20% to -47%) with 3.8 lives saved and 4 fewer hospitalization per 100 patients treated for 1 year.<sup>112</sup>

CIBIS-II and MERIT-HF results conclusively showed mortality- and morbidity-related benefit from bisoprolol and metoprolol succinate in NYHA class II and III heart failure. Results in NYHA class IV patients did not reach statistical significance, perhaps because there were so few such patients.<sup>29,30</sup> However, the point estimate of the all-cause mortality effect in both CIBIS-II and MERIT-HF was numerically less than that in class III patients, and because of the small numbers of patients with class IV enrolled in these trials, it remains uncertain as to whether these  $\beta$ -blockers can be safely and efficaciously administered to patients with a very advanced type of heart failure.<sup>113</sup> Certainly patients may reach a point in their clinical course when  $\beta$ -blocker therapy is neither tolerated or efficacious, but the clinical trial data do not enable clinicians to identify such a transition point beyond not recommending treatment in patients who are taking  $\beta$ -adrenergic agonists to support cardiac function.

The relationship between the  $\beta$ -blocker dose administered and its effects on outcomes was also assessed in CIBIS-II and MERIT-HF. Patients receiving lower doses of the study drugs had more severe heart failure, had lower blood pressure or heart rate at baseline (or both), and were older.<sup>114-117</sup> A post hoc analysis in CIBIS-II revealed an increased risk of death in the patients receiving the low dosage (i.e., <5 mg/day) of bisoprolol in comparison with patients taking medium and high dosages. This difference remained significant after adjustment for baseline variables.<sup>115</sup> Similar results were found in post hoc analyses in two other major outcome trials with carvedilol<sup>116</sup> and nebivolol,<sup>117</sup> respectively. In MERIT-HF, the benefit of metoprolol succinate on mortality was related to the heart rate achieved after treatment, independently of the dose administered.<sup>114</sup>

CIBIS-II and MERIT-HF established the beneficial effects on outcomes of  $\beta$ -blockers in patients with NYHA class II and class III heart failure caused by LV systolic dysfunction (ejection fractions < .35 and .40, respectively). Subsequently reported trials were aimed at broadening the spectrum of the indications to  $\beta$ -blocker therapy. In the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) trial,

**FIGURE 46-7** Kaplan-Meier analysis of the probability of survival among patients in the placebo and  $\beta$ -blocker groups in the Cardiac Insufficiency Bisoprolol Study (CIBIS-II), the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF), and the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) trial. (Data from CIBIS-II Investigators and Committees: The Cardiac Insufficiency Bisoprolol Study II (CIBIS-II): a randomised trial. *Lancet* 1999;353:9-13; MERIT-HF Study Group: Effect of metoprolol CR/XL in chronic heart failure: Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF). *Lancet* 1999;353:2001-2007; Packer M, Coats AJ, Fowler MB, et al. Effect of carvedilol on survival in severe chronic heart failure. *N Engl J Med* 2001;344:1651-1658; and Eichhorn EJ, Bristow MR. Antagonism of  $\beta$ -adrenergic receptors in heart failure. In Mann DL, editor. *Heart failure: a companion to Braunwald's Heart Disease*, Philadelphia, 2004, Elsevier, pp 619-639.)

researchers studied the effects on outcomes of the nonselective  $\beta$ -blocker and  $\alpha_1$ -blocker carvedilol in 2289 mostly European, stable patients who had symptoms of heart failure at rest or with minimal exertion at the time of screening and severe LV systolic dysfunction, manifested by an ejection fraction of .25 or less.<sup>32</sup> Despite these criteria for severity, patients had to be

“euvolemic” (i.e., with no signs of pulmonary or peripheral congestion) and with no worsening renal function or hypotension (systolic blood pressure  $\leq 85$  mm Hg) at entry into the study. The greater degree of LV dysfunction in COPENICUS than in other trials was reflected in the higher 1-year mortality rate of 18.5%. COPENICUS was also stopped because the data and safety monitoring board concluded that efficacy had been achieved before the planned completion of the trial. As in CIBIS-II and MERIT-HF, carvedilol administration was associated with a 35% reduction in the risk of death ( $P = .0014$ ) and a 24% reduction in the risk of death or all-cause hospitalization ( $P < .001$ ; see Figure 46-7,C).<sup>32</sup> These effects of carvedilol were similar in direction and magnitude in all the prespecified subgroups according to age, gender, geographical location, cause of heart failure, whether hospitalization was recent, diabetes, LVEF, and pretreatment systolic blood pressure.<sup>32,118</sup> Fewer patients receiving carvedilol than placebo recipients required the permanent discontinuation of treatment because of adverse effects.<sup>32</sup> A further analysis revealed early evidence of the beneficial effects of  $\beta$ -blocker therapy, with a lower mortality rate and lower combined mortality and rehospitalization rate with carvedilol than for placebo, during the first 2 months of treatment. These effects on outcomes were similar to those observed during the entire study and were apparent also in the 624 patients with recent or recurrent decompensation or a very depressed LVEF. Worsening heart failure was the only serious adverse event with similar frequency in patients receiving placebo (6.4%) and those receiving carvedilol (5.1%).<sup>33</sup>

The Carvedilol Post Infarct Survival Control in Left Ventricular Dysfunction (CAPRICORN) study enrolled 1959 mostly European patients with LV systolic dysfunction (ejection fraction  $\leq 40$ ) after a recent myocardial infarction with mild or no symptoms of heart failure.<sup>35</sup> Carvedilol was not associated with a significant reduction of the primary endpoint of all-cause mortality or cardiovascular hospitalization, in part because of the hospitalization event rate was lower than expected. However, all-cause mortality alone was reduced by 27%, which was statistically significant, in comparison with placebo (95% CI,  $-2\%$  to  $-40\%$ ;  $P = .024$ ). These results were driven primarily by a 26% reduction in sudden death with carvedilol.<sup>35</sup>

The BEST researchers examined the effects of a nonselective  $\beta$ -blocker/vasodilator, bucindolol (which also has sympatholytic activity), on all-cause mortality and other endpoints in patients with NYHA class III or IV heart failure and an LVEF of .35 or lower.<sup>86</sup> Unlike COPENICUS, BEST allowed enrollment of patients who had clinical decompensation, as defined by overt fluid overload in the presence of a renin-angiotensin system inhibitor and diuretics.<sup>86,119</sup> Also in contrast to COPENICUS and the other large-scale trials, most patients (98%) in BEST were enrolled in U.S. centers. This study uniquely stratified patients at each site on the basis of gender, ejection fraction ( $>$  or  $\leq .20$ ), presence or absence of coronary artery disease, and race (African American vs. non-African American). The BEST study was prematurely terminated on the recommendation of the data and safety monitoring board after the enrollment of 2708 patients, because of “the totality of evidence regarding the usefulness of  $\beta$ -blocker treatment derived from BEST and other studies” as well as because of loss of equipoise in an increasing number of investigations. Loss of investigation equipoise was related to the premature discontinuation of CIBIS-II and MERIT-HF for benefit.<sup>86,120</sup> In contrast to CIBIS-II, MERIT-HF, and COPENICUS, the primary endpoint of all-cause mortality was not statistically significant when BEST was stopped, 12 months short of full follow-up, with 92% of the projected number of endpoints predicted from sample size calculations. However, for patients similar to those enrolled in CIBIS-II and MERIT-HF, the BEST results for all-cause mortality were comparable with those in the other trials.<sup>86,121</sup>

In BEST, the annual rate of mortality was 17% among the placebo recipients; after randomization stratification covariate adjustment according to the prespecified statistical analysis plan, it was reduced by 10% (95% CI,  $+2\%$  to  $-22\%$ ; unadjusted  $P = .10$ ) or 13% (95% CI,  $0\%$  to  $-24\%$ ;  $P = .053$ ). Mortality from cardiovascular causes was reduced with bucindolol by 14% (95% CI,  $1\%$  to  $26\%$ ; unadjusted  $P = .04$ ), and time to hospitalization for heart failure was reduced by 23% (95% CI,  $-13\%$  to  $-32\%$ ; unadjusted  $P = .00002$ ). In contrast to previous trials, prespecified subgroup analysis showed heterogeneity in the results; perhaps the subgroups exhibiting differential responses had not been investigated in adequate numbers in the previous trials. Bucindolol had no effect on survival in African American patients (23% of the total study group,  $P = .27$ ) whereas there was a survival benefit in non-African American subjects ( $P = .01$ ;  $P = .024$  for the interaction between treatment and race). A lack of effects on outcomes of  $\beta$ -blocker therapy in African American patients was confirmed in a prospective cohort study that included 2460 patients with heart failure.<sup>122</sup>

Survival was improved with bucindolol among patients with less advanced heart failure in BEST, a finding similar to those in the other  $\beta$ -blocker studies; the increase in survival was 13% (unadjusted;  $P = .06$ ) or 15% (adjusted;  $P = .03$ ) among patients with NYHA class III heart failure, but there was no evidence of benefit in patients with class IV heart failure.<sup>119</sup> In a post hoc analysis of a sample population from BEST with characteristics similar to those of the patients enrolled in CIBIS-II and MERIT-HF, the survival benefit of bucindolol was 23%, in comparison with placebo, which was similar in magnitude to that in the previous trials.<sup>121</sup> Another post hoc analysis revealed that patients who were euvoletic at baseline and had an LVEF of less than .25 (and thus were similar to the COPENICUS patient population) had an all-cause mortality reduction of 31% (95% CI,  $-12\%$  to  $-45\%$ ;  $P = .002$ ).<sup>88</sup> Thus, if comparable patient populations are examined, results of the CIBIS-II, MERIT-HF, COPENICUS and BEST trials are very similar.

Unique among  $\beta$ -blockers that have been used to treat heart failure, bucindolol is sympatholytic, meaning that it lowers systemic norepinephrine levels.<sup>86,87</sup> If the degree of norepinephrine lowering is mild, this property may be clinically beneficial, but if the degree of sympatholysis is pronounced, it may lead to untoward effects in patients with advanced heart failure.<sup>86,123</sup> When sympatholysis is extreme in patients with heart failure who are highly dependent on adrenergic drive to support cardiac function, mortality and hospitalizations for heart failure may increase. In BEST these effects canceled the clinical benefits of  $\beta$ -blockade,<sup>86,123</sup> whereas in MOXCON, pronounced sympatholysis from moxonidine was associated with increased mortality and hospitalizations related to heart failure.<sup>83</sup>

The Study of Effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with Heart Failure (SENIORS) was aimed at the assessment of the effects of the  $\beta_1$ -selective vasodilator compound nebivolol on outcomes in elderly patients with heart failure independent of their LVEF.<sup>36</sup> This European study included 2128 patients aged 70 years or older who either had an LVEF of 0.35 or lower or had been admitted to a hospital for heart failure in the previous 12 months. The primary composite endpoint was all-cause mortality or hospitalization for cardiovascular reasons. The incidence of this endpoint was reduced by 14% in the patients receiving nebivolol, in comparison with those receiving placebo (95% CI,  $-1\%$  to  $-26\%$ ;  $P = .039$ ) (Figure 46-8, A). The cardiovascular mortality or hospitalization rate was also lower by 16% among the nebivolol recipients, in contrast to the placebo recipients (95% CI,  $-2\%$  to  $-28\%$ ;  $P = .027$ ). Mortality alone was not significantly reduced by nebivolol ( $-12\%$ ; 95% CI,  $+8\%$  to  $-29\%$ ;  $P = .21$ ) (see Figure 46-8, B).

**FIGURE 46-8** Clinical outcomes in the Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with Heart Failure (SENIORS) trial. **A**, Time to first occurrence of events (primary endpoint was all-cause death or hospital admission for a cardiovascular reason). **B**, All-cause death. (From Flather MD, Shibatal MC, Coats AJS. Randomized trial to determine the effect of nebivolol on mortality and cardiovascular hospital admission in elderly patients with heart failure (SENIORS). *Eur Heart J* 2005;26:215-225.)

Prespecified subgroup analyses did not reveal significant interactions among gender, ejection fraction, age, diabetes and prior myocardial infarction, baseline renal function,<sup>124</sup> and the effects of nebivolol on outcomes. However, the relative risk for the primary endpoint was reduced by 21% (95% CI, -2% to -37%) in patients younger than the median of 75.2 years and by 8% (95% CI, +12% to -25%) in those older than 75.2 years (test for interaction  $P = .51$ ).<sup>36</sup>

Although in the same direction, the results of SENIORS were less significant than those of the previous  $\beta$ -blocker trials, which enrolled younger patients and excluded patients with higher ejection fractions. To evaluate the effects of nebivolol in patients similar to those of other trials, the SENIORS investigators assessed patients younger than the median of 75.2 years and with an LVEF of 35% or lower (342 subjects took nebivolol and 342 took placebo). In this subgroup, the risk for the primary outcome was reduced by 27% (95% CI, -4% to -44%) with nebivolol, and the risk of all-cause mortality alone was 38% lower (95% CI, -12% to -57%) with nebivolol; these findings were similar to the results of previous  $\beta$ -blocker trials.<sup>36</sup> In a prespecified analysis, the effects of nebivolol on outcomes were independent of baseline LVEF; that is, the drug had similar favorable effects on outcomes in the patients with heart failure and preserved ejection fraction.<sup>37</sup> Another analysis revealed that the beneficial effects of nebivolol on outcomes were greater when dosages were higher (>5 mg/day).<sup>117</sup>

All five  $\beta$ -blockers that have been tested in large clinical trials have thus demonstrated clinical benefit. Furthermore, when similar enrollment criteria are analyzed, the mortality- and hospitalization-reducing effects of these agents are found

to be similar. In patients who have reduced ejection fractions, are younger than 75 years, and do not have evidence of clinical decompensation while taking renin-angiotensin inhibitors and diuretics, the reduction in the major clinical endpoints of mortality or hospitalizations for heart failure ranges from 25% to 35%, both in randomized placebo-controlled clinical trials and in post hoc analyses. These similarities suggest that, despite other differences, blockade of  $\beta_1$ -adrenergic receptors is by far the most important mechanism in the therapeutic effects of  $\beta$ -blockers.<sup>125</sup>

$\beta$ -Blockers remain, however, a highly heterogeneous group of drugs,<sup>34,54</sup> as discussed previously. The hypothesis that differences between  $\beta$ -blockers might have a clinical effect in patients with heart failure has been tested in relatively small trials<sup>126-128</sup> and in the Carvedilol or Metoprolol European Trial (COMET),<sup>129</sup> which was powered to assess a difference in mortality. In COMET, 3029 patients with chronic heart failure were randomly assigned to receive carvedilol, at the target dose of 25 mg twice a day, or immediate-release metoprolol tartrate, at the target dose of 50 mg twice a day, and were monitored for a mean of  $58 \pm 6$  months. All-cause mortality was reduced by 17% in patients taking carvedilol, in comparison to metoprolol tartrate ( $P = .0017$ ).<sup>129</sup> The results of COMET have been widely discussed. Differences in mortality found in COMET have been related to the ancillary properties of carvedilol (i.e.,  $\alpha$ -blockade, antioxidant activity, anti-apoptotic effects), to nonselective blockade of  $\beta_2$ -adrenergic receptors, and to more effective blockade of  $\beta_1$ -adrenergic receptors.<sup>54,130,131</sup> The slight difference in the heart rate achieved during maintenance therapy and the suboptimal dosing of metoprolol tartrate have also been claimed as potential causes of the differences found.<sup>125,132,133</sup> Regardless of the explanation, COMET did demonstrate the inferiority of metoprolol tartrate to carvedilol in the dosages tested. These dosages of metoprolol tartrate, although lower than those used in the Metoprolol in Dilated Cardiomyopathy trial,<sup>6</sup> are often used in clinical practice. The long-term formulation metoprolol succinate CR/XL that was shown to be effective in comparison with placebo in MERIT-HF has never been compared with carvedilol or with metoprolol tartrate in outcome trials. Thus, it is not possible to draw conclusions regarding the efficacy of metoprolol succinate in comparison with carvedilol. The COMET trial appropriately led to changes in various guidelines. Metoprolol tartrate is no longer recommended for the treatment of heart failure, and only  $\beta$ -blockers shown to be effective in outcomes trials—bisoprolol, carvedilol, metoprolol succinate, and, in Europe, nebivolol—are now recommended.<sup>51,53</sup>

## PRACTICAL GUIDELINES FOR $\beta$ -BLOCKER USE

The indications and practical aspects of  $\beta$ -blocker therapy are clearly outlined in all major guidelines for the diagnosis and treatment of heart failure.<sup>51,52,53,134</sup> The indication for  $\beta$ -blocker treatment is based on the highly significant association with an improvement in cardiac function, LV remodeling, and major clinical endpoints, including mortality and hospitalizations.<sup>17,18,20,51-53,112,134</sup> This clinical endpoint evidence is consistent and substantial, data being obtained from more than 10,000 patients in major randomized, placebo-controlled trials. It is important to remember—when  $\beta$ -blocker therapy is started, titrated upward, and maintained chronically—that  $\beta$ -blockade is not indicated for short-term improvement in symptoms, which may actually worsen transiently when treatment is started.  $\beta$ -Blockers are indicated for their biological long-term effects involving protection of the heart from excessive adrenergic drive, mediated mainly through  $\beta_1$ -adrenergic receptor signaling.

**TABLE 46–3 Practical Guidelines for  $\beta$ -Blocker Therapy in Patients with Heart Failure****Indications**

Current or prior symptoms of heart failure and LVEF  $\leq$  40%  
LVEF  $\leq$  40% after a myocardial infarction, regardless of symptoms\*

**When to Start**

Possibly in euvoletic state and in stable clinical conditions  
When patient is receiving stable doses of diuretics and ACE inhibitors or angiotensin receptor blockers (initiation before ACE inhibitors may be considered in selected patients, such as those with tachycardia or chronic kidney dysfunction)<sup>135,137</sup>

**When Not to Start (Contraindications)**

Bronchial asthma with sensitivity to the administration of  $\beta$ -agonists  
Severe bradycardia ( $<60$ /min) or second- or third-degree heart block  
Hypotension (systolic blood pressure  $\leq$  85 mm Hg)  
Unstable clinical conditions with signs of severe fluid retention

**Agent (Drug, Starting Dose, Target Dose)**

Bisoprolol, 1.25 mg once daily to 10 mg once daily  
Carvedilol, 3.125–6.25 mg bid to 25–50 mg bid  
Metoprolol succinate CR/XL, 12.5–25 mg once daily to 200 mg once daily  
Nebivolol† 1.25 mg once daily to 10 mg once daily

**How to Administer**

Start with low dose (see under “Agent”) and double the dose every 2 weeks (every week in stable patients) up to target dose or maximal tolerated dose  
Educate the patients regarding benefits of treatment (i.e., improvement in cardiac function and symptoms, reduced episodes of decompensation and hospitalizations, prolonged survival) and the need of 3–6 months of treatment to achieve full benefit

Ask the patient to monitor her or his body weight every 1–2 days and refer to her or his physician in case of increase in body weight, worsening symptoms, or development of signs of congestion (e.g., ankle swelling) during the upward-titration phase (monitoring to be done by the attending physician or nurse in case of patients with severe heart failure and in unstable clinical condition)

Measure heart rate and blood pressure before each dose increment and avoid increasing dosage in case of contraindication (see contraindications)  
Measure serum creatinine, BUN, sodium, potassium, and bilirubin levels approximately 2 weeks after start of therapy and 1–2 weeks after patient reaches the final dose

**Possible Complications and Their Treatment**

Symptomatic hypotension (asymptomatic hypotension does not necessitate any specific treatment)

- Stop or reduce the doses of other vasodilators
- If such reduction is not possible, consider dose reduction of ACE inhibitor or angiotensin receptor blocker

Bradycardia ( $<50$  bpm)

- Stop other bradycardic agents (if possible)
- If cessation of bradycardic agents is not possible or not effective, reduce the dose of or stop the  $\beta$ -blocker

Worsening heart failure or fluid retention

- Increase the dose of the diuretic (at least double the usual dose)
- If increasing diuretic dose is not possible or not effective, reduce the dose of the  $\beta$ -blocker or, in most difficult cases, stop it
- Restart  $\beta$ -blocker therapy at the doses administered before the episode of decompensation or start  $\beta$ -blockade, if it was not administered before; either action should be performed before discharge, if possible<sup>53</sup>

\* $\beta$ -Blockers are indicated in all patients with previous myocardial infarction regardless of ejection fraction and symptoms of heart failure.<sup>53</sup> †Nebivolol is approved for the treatment of heart failure only in Europe.<sup>52</sup>

ACE, angiotensin-converting enzyme; BUN, blood urea nitrogen; LVEF, left ventricular ejection fraction.

Modified from McMurray J, Cohen-Solal A, Dietz R, et al. Practical recommendations for the use of ACE inhibitors, beta-blockers, aldosterone antagonists and angiotensin receptor blockers in heart failure: putting guidelines into practice. *Eur J Heart Fail* 2005;7:710-772.

Practical aspects of  $\beta$ -blocker therapy in patients with heart failure are outlined in Table 46-3. Treatment is indicated only for patients with heart failure caused by LV systolic function. To date, no conclusive data have been obtained from patients with heart failure and preserved ejection fraction (discussed later). Only  $\beta$ -blockers associated with a favorable effect on outcomes in placebo-controlled trials are indicated, and modalities of initiation, upward titration, and dosing are based largely on the results of these trials. It is important to point out that the beneficial results in controlled trials have been obtained with the target dosages suggested for clinical practice. Lower doses have been associated with lack of effects or with lower efficacy in comparison with higher dosages.

Practical issues concern (1) the modality of initiation of  $\beta$ -blocker therapy with regard to concomitant therapy with ACE inhibitors and (2) maintenance of  $\beta$ -blocker treatment in patients hospitalized for acutely decompensated chronic heart failure. In the CIBIS-III trial, researchers compared initiation of medical treatment with either an ACE inhibitor (enalapril) or a  $\beta$ -blocker (bisoprolol) in 1010 patients who had heart failure and a low LVEF ( $\leq 35$ ) and had not been treated previously with these agents.<sup>135</sup> Patients were randomly assigned to receive open-label monotherapy with either enalapril or bisoprolol for 6 months, followed by their combination for up to 24 months. The primary endpoint was all-cause death or hospitalization and was blindly adjudicated. According to intention-to-treat analysis, the primary endpoint occurred in 178 patients who took bisoprolol first and in 186 who took enalapril first (absolute difference,  $-1.6\%$ ; 95% CI,  $-7.6$  to  $4.4\%$ ). Deaths occurred in 65 patients taking bisoprolol first and in 73 taking enalapril first (hazard ratio for bisoprolol vs. enalapril,  $-12\%$ ; 95% CI,  $-37\%$  to  $+22\%$ ). Hospitalizations occurred in 151 and 157 patients, respectively.<sup>135</sup> A trend toward fewer sudden deaths was observed with bisoprolol first. On the other hand, 67% more cases of worsening heart failure necessitating hospitalization or occurring during hospitalization were observed in the patients who took bisoprolol first ( $P = .03$ ).<sup>136</sup> The two groups were similar with regard to treatment cessations and early introduction of the second drug. Although this trial showed noninferiority of treatment initiation with bisoprolol, this result has not been included in guidelines, which continue to suggest initiation of treatment with a diuretic plus an ACE inhibitor, followed as soon as possible by the addition of a  $\beta$ -blocker.<sup>52,53</sup> This is, however, the sequence used in all the trials that demonstrated the benefits of  $\beta$ -blocker treatment. An individualized approach, based on the patient's clinical characteristics (fluid status, symptoms, blood pressure, heart rate, comorbid conditions), should always be preferred with regard to both sequence of drug initiation and, of more importance, dosage.<sup>137</sup>

Ongoing  $\beta$ -blockers have been usually withdrawn when patients are hospitalized because of acute decompensation of chronic heart failure with the belief that their short-term negative inotropic effects may have a negative effect on their clinical course. However, retrospective analyses of randomized controlled trials<sup>138-140</sup> or of database registries<sup>141,142</sup> of patients hospitalized for heart failure have shown that the discontinuation of ongoing  $\beta$ -blocker therapy is associated with an increased risk of death, which is still significant after adjustment for baseline variables and parameters related to the severity of heart failure. No differences in symptoms' relief and clinical course were found, in one prospective study, between patients hospitalized for acutely decompensated heart failure who discontinued previous  $\beta$ -blocker therapy and patients who maintained ongoing treatment.  $\beta$ -Blocker therapy at 3 months was given to 90% of patients who had continued it, in contrast to 76% who had discontinued it ( $P < .05$ ), and this may be important for long-term outcomes.<sup>143</sup>

In addition, it has also been generally deemed as appropriate not to start  $\beta$ -blockers during the same hospitalization for acute heart failure in patients not on  $\beta$ -blockers at the time of admission. However, prospective studies have shown that the initiation of  $\beta$ -blocker therapy before discharge in patients hospitalized for acute heart failure is safe and associated with higher post-discharge treatment rates.<sup>41</sup> The Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF), a prospective trial powered to assess the effects on outcomes of pre-discharge initiation of  $\beta$ -blocker therapy, has shown a 54% reduction in the risk of subsequent death (95% CI, -70% to -27%;  $P = .0006$ ) and a 29% reduction in the risk of death or re-hospitalization (95% CI, -57% to -6%;  $P = .0175$ ), compared to no  $\beta$ -blocker administration, in patients discharged on  $\beta$ -blocker treatment after a hospitalization for heart failure.<sup>42</sup>

On the basis of these data, it is now recommended that patients hospitalized for acute heart failure and reduced ejection fraction (1) continue  $\beta$ -blockers if they had been taking these agents and have no hemodynamic instability or contraindications; (2) initiate  $\beta$ -blocker treatment if it was not used before; and (3) start  $\beta$ -blocker therapy after discontinuing intravenous furosemide, vasodilators, or inotropic therapy and after volume status is optimized and clinical stability is achieved.<sup>53</sup>

## $\beta$ -BLOCKER THERAPY IN CLINICAL PRACTICE

### $\beta$ -Blocker Use

Studies of the prognostic role of adherence to guidelines,<sup>144,145</sup> as well as studies of prescriptions at discharge of patients hospitalized for heart failure,<sup>146-148</sup> have confirmed the independent role of  $\beta$ -blocker administration for improving patient prognosis.  $\beta$ -Blocker prescription rates have increased since 1990, starting after the publication of the landmark outcomes trials in the late 1980s and of 2001 guidelines, with an increase of about 5% to 10% every year from 2001 to 2005 (Figure 46-9).<sup>142,149-151</sup> This pattern has been observed also in elderly subjects, a population for which  $\beta$ -blockers are underprescribed. An analysis of 741 octogenarians (median age, 83.7 years), assessed in the Euro Heart Failure Survey II, confirmed  $\beta$ -blockers are prescribed less often for these patients than for younger subjects; however, the number of prescriptions was more than twice as high as that in the Euro Heart Failure Survey I, performed in 2000 to 2001 (53% vs. 25%

for  $\beta$ -blocker prescriptions and 12% vs. 5% for high-dose  $\beta$ -blocker prescriptions;  $P < .001$  in both cases).<sup>152</sup>

Despite these improvements,  $\beta$ -blockers remain underprescribed for some patients. These subpopulations include elderly patients, patients with hypotension, patients with severe heart failure, and patients with renal insufficiency.<sup>39,40,150-155</sup> Many of these patients may benefit from  $\beta$ -blockers to a similar, if not greater, extent than do the other patients; their tolerance of  $\beta$ -blockers is often underestimated<sup>33,39-43,118,119</sup> and can be increased by adequate implementation strategies. In the Carvedilol Open-Label Assessment (COLA) II study, Krum and colleagues<sup>40</sup> demonstrated that the tolerance of  $\beta$ -blocker therapy, although reduced by aging (76.8% of patients aged >75 years vs. 84.3% of patients aged 70 to 75 years), remains high among elderly patients with heart failure. The Beta-blockers In Patients with Congestive Heart Failure: Guided Use in Clinical Practice (BRING-UP)-2 study was designed to improve the prescription rate and to assess the tolerability of  $\beta$ -blockers in the elderly patients (aged  $\geq 70$  years), both those with moderate and those with severe heart failure.<sup>39</sup> Among the 1518 elderly patients included in the study, 505 (33.3%) were already taking  $\beta$ -blockers at the time of enrollment, 464 (30.6%) were prescribed a  $\beta$ -blocker for the first time, while the remaining patients had specific contraindications to  $\beta$ -blockade (chronic obstructive pulmonary disease, peripheral vascular disease, long P-R interval, 378 patients, 24.9%) or had not started taking  $\beta$ -blockers without a clear contraindication (real underprescription: 171 patients, 11.3%).<sup>39</sup> These data show that  $\beta$ -blockers can be administered to a high percentage of elderly patients (75.1% in BRING-UP-2) when adequate physician education and disease management programs are provided.

In BRING-UP-2,  $\beta$ -blocker therapy was also implemented in 709 patients with severe heart failure, defined by symptoms at rest or during minimal exercise with LVEF of less than .25. Results were similar to those for the elderly patients. Only 272 (38.4%) of patients were already taking a  $\beta$ -blocker at the start of the study and 220 additional patients (31%) could start taking carvedilol during the study. Two-hundred-twenty patients (31%) could not start because they were either receiving intravenous therapy (58 patients, 8.2%) or had contraindications such as chronic obstructive pulmonary disease or peripheral vascular disease. Only 54 patients (7.6%) never started taking  $\beta$ -blockers despite having no contraindications. After 1-year follow-up, patients taking  $\beta$ -blockers had a lower incidence of death (10.8% among patients already treated and 11.2% among patients newly treated, in contrast to 18% among those not treated).<sup>39</sup> Thus, these data show the potential of an education program to increase prescription rates of

**FIGURE 46-9** Temporal trends in  $\beta$ -blocker use at hospital discharge in 769 patients with heart failure and systolic dysfunction from 1998 to 2004. (From Patel P, White DL, Deswal A. Translation of clinical trial results into practice: temporal patterns of beta-blocker utilization for heart failure at hospital discharge and during ambulatory follow-up. *Am Heart J* 2007;153:515-522.)

$\beta$ -blockers in patients with lower tolerance rates in whom this therapy is usually underprescribed.

In clinical practice,  $\beta$ -blockers are often administered at low dosages, instead of the target dosages indicated in guidelines and shown to be effective by randomized controlled trials.<sup>142,149-151</sup> Although even low doses are considered better than no  $\beta$ -blocker therapy,<sup>134</sup> the effects of  $\beta$ -blockers on outcomes have been shown consistently only at the dosages recommended in guidelines, and multiple studies have demonstrated dose dependency of their beneficial effects.<sup>61,105,115-117</sup> Another cause of underuse of  $\beta$ -blockers in clinical practice is the presence of accepted contraindications: bradycardia, second- or third-degree atrioventricular block, and asthma are the major important contraindications to  $\beta$ -blockade. Only bronchial obstruction with sensitivity to the administration of  $\beta_2$ -agonists should be considered as an absolute contraindication to  $\beta$ -blocker therapy in patients with pulmonary diseases. This limitation may, however, be partially overcome by the use of  $\beta_1$ -selective agents.<sup>65,156</sup>

## Implementation Strategies

Despite the evidence of the benefits of  $\beta$ -blocker therapy, first obtained as early as 1990, perceptions of its benefits and, therefore, its implementation still vary among physicians. Awareness of heart failure management recommendations has been investigated with 2041 cardiologists, 1881 internists and geriatricians, and 2965 primary care physicians in nine European countries.<sup>157</sup> Only 39% of internists or geriatricians would have prescribed a  $\beta$ -blocker for more than 50% of their patients (in contrast to 73% of the cardiologists;  $P < .0001$ ); primary care physicians always or often prescribed  $\beta$ -blockers to only 40% of patients with heart failure. Twenty-six percent of internists or geriatricians and 36% of primary care physicians (in contrast to 11% of cardiologists) answered that they would have never prescribed  $\beta$ -blockers to a patient with mild heart failure who was already taking diuretics and ACE inhibitors (Figure 46-10).<sup>157</sup> Prescription of  $\beta$ -blockers prescription also varied widely in a cohort study of U.S. cardiologists.<sup>158</sup>

Many implementation strategies are currently proposed and adopted to favor prescription of  $\beta$ -blocker therapy to all patients without major contraindications. One of the first studies with this aim was the BRING-UP program.<sup>43</sup> It was based on the organization of regional meetings and on

the development and distribution of the recommendations derived from the available clinical evidence on the proper use of  $\beta$ -blockers. It involved 197 cardiology centers and 3091 patients.  $\beta$ -Blockers were newly prescribed in 32.7% of cases, and prescription rates increased from 24.9% to 49.7% over the year of the study. The average  $\beta$ -blocker dosage was 70% of that administered in controlled trials. The use of  $\beta$ -blockers was independently associated with a better prognosis and a 40% reduction in hospitalizations for heart failure. The major reasons for either lack of prescription or lack of upward titration of  $\beta$ -blocker therapy were advanced age, more severe NYHA class, and the presence of atrial fibrillation.<sup>43</sup> The BRING-UP-2 phase extended this evaluation to include elderly patients and patients with severe heart failure.<sup>39</sup> Strategies based on educational programs for physicians and patients, clinical reminders attached to echocardiography reports, close telephone contacts for advice and consultation, led by cardiologists or heart failure nurses or both, have been widely and successfully developed.<sup>44,159,160</sup> Implementation of  $\beta$ -blocker therapy has been actually one of the major aims of heart failure clinics and disease management programs.<sup>161</sup> The benefits of these interventions are obviously greater in the setting with the worst clinical practice.<sup>162</sup>

In addition to disease management and educational programs for ambulatory patients, predischage initiation of  $\beta$ -blocker therapy in patients hospitalized for heart failure is a safe and effective modality; increasing the proportion of patients on  $\beta$ -blockers after discharge has beneficial effects on subsequent outcomes.<sup>41,42,147,148,163</sup>

## Lack of Evidence in Specific Patients Groups: The Case of Heart Failure with Preserved Ejection Fraction

In some subpopulations of patients with heart failure,  $\beta$ -blocker therapy is also underprescribed because of insufficient or poor evidence of efficacy. Prospective trials<sup>36</sup> and registries<sup>148</sup> have also confirmed improved survival in elderly patients (see Chapter 49) taking  $\beta$ -blockers, although the magnitude of the benefit appears to be lower than in younger patients.  $\beta$ -Blocker therapy has also been prospectively assessed in 161 children and adolescents with symptomatic systolic heart failure.<sup>36</sup> A trend toward better outcomes was found with  $\beta$ -blocker therapy, although these results did not achieve statistical significance, which is probably explained by the lower-than-expected event rates.

Another important group of patients with heart failure for whom evidence of efficacy is lacking is that of patients with heart failure and preserved LVEF (HFPEF). The number of patients hospitalized with this diagnosis is actually increasing and, in contrast to patients with low ejection fraction, no improvement in survival has been observed since the mid-1980s.<sup>164</sup> Effects of  $\beta$ -blocker therapy are likely to be different between patients with preserved ejection fraction and those with reduced ejection fraction. For instance, chronic  $\beta$ -blocker therapy has been associated with lower collagen volume fraction, cardiac myocyte diameter, and stimulatory G-protein expression only in patients with HFPEF, whereas expression of inhibitory G-proteins has been lower in only the patients with reduced ejection fraction.<sup>165</sup> The only prospective outcome  $\beta$ -blocker trial that included patients with preserved ejection fraction was SENIORS.<sup>36</sup> The effect of nebivolol on the primary endpoint was similar in the patients with an ejection fraction of less than .35 (risk reduction, -14%; 95% CI, +4% to -28%) in comparison with the patients whose ejection fraction was .35 or higher (-19%; 95% CI, +4% to -37%). Similar results were also observed with regard to all secondary endpoints.<sup>37</sup>

However, SENIORS was not designed and powered to assess the effects of nebivolol in patients with preserved

**FIGURE 46-10** Proportion of European primary care physicians and specialists who prescribed  $\beta$ -blockers or angiotensin-converting enzyme (ACE) inhibitors to more than 50% of their patients (“>50% of patients” defined as “often” or “always” for primary care physicians). (From Remme WJ, McMurray JJ, Hobbs FD, et al. Awareness and perception of heart failure among European cardiologists, internists, geriatricians, and primary care physicians. *Eur Heart J* 2008;29:1739-1752.)

ejection fraction, assessed separately, and the cutoff of .35 for defining preserved ejection fraction is too low.<sup>52,53</sup> Results from analyses of patient databases are controversial; some studies have revealed no benefit<sup>148,166</sup> and others have revealed a favorable effect of  $\beta$ -blocker therapy on the outcomes of the patients with HFPEF.<sup>167,168</sup> Thus, although there is a rationale for administering  $\beta$ -blockers in patients with HFPEF (benefits of bradycardia, increased duration of LV filling time, blood pressure control), evidence regarding clinical efficacy of  $\beta$ -blockers in these patients is lacking.<sup>52</sup>

## LIMITATIONS OF $\beta$ -BLOCKER THERAPY

Despite its proven effectiveness in the general population of patients with stable, low LVEF and NYHA class II to class III heart failure,  $\beta$ -blockade as a treatment of chronic heart failure has some limitations. The foremost issue is the heterogeneity of response, something shared with all forms of heart failure therapy but perhaps more of an issue with  $\beta$ -blockers because of the magnitude of benefit in patients that do respond, the potential to do harm in a small number (10% to 20%) of patients who either do not respond or who cannot tolerate  $\beta$ -blockade, and the fact that determination of response, as currently performed, can be accomplished only empirically, after several months of slow and often tedious upward titration of the  $\beta$ -blocker. Figure 46-11 emphasizes the heterogeneity of response problem: In the Multicenter Oral Carvedilol Heart failure Assessment (MOCHA) trial,<sup>105</sup> after the placebo response rate was subtracted, only 45% of patients were found to exhibit a positive LVEF response to the highest dosage (25 mg twice a day) dose of carvedilol; with 6.25 mg twice a day, the response rate was even lower (30%).<sup>169</sup> As shown in Figure 46-11, small numbers (<10%) of patients actually experienced worsening of LVEF with carvedilol, and these numbers do not include the 8% of patients who could not tolerate open-label carvedilol challenge.<sup>169</sup>

Another issue is poor tolerance of  $\beta$ -blockers, particularly in patients with the most advanced heart failure. The percentage of such patients ranges from 5% to 20% and is highly dependent on the experience of the treating physician, as well as on the  $\beta$ -blocker being used.<sup>170</sup> Much of the intolerance arises from the negative inotropic properties of  $\beta$ -blockers in very advanced heart failure, in which the concomitant use of non- $\beta$ -agonist-positive inotropic agents may be useful.<sup>79,171</sup> The intolerance issue no doubt influences the underuse of  $\beta$ -blockers in clinical practice.

Finally, clinical data are inadequate for certain important subpopulations of patients with heart failure. HFPEF has been highlighted as such a circumstance, but other examples include minimal asymptomatic reduced LVEF, NYHA class IV heart failure, and race (African American).

## FUTURE DIRECTIONS

### Improvement in the Clinical Pharmacology of $\beta$ -Blocking Agents

Improvements in the clinical pharmacological activity of specific agents could potentially favorably affect both heterogeneity of response and tolerability. For example, the new controlled-release formulation of carvedilol has improved pharmacokinetics, which may mitigate some of the vasodilator side effects of high peak blood levels of immediate-release carvedilol. The pharmacodynamic characteristics of controlled-release carvedilol seem comparable with those of immediate-release carvedilol administered twice daily.<sup>172</sup>

Associated or ancillary properties of  $\beta$ -blockers may also be important. In the COMET trial, the superiority of carvedilol over immediate-release metoprolol could be explained by differences in the degree of  $\beta_1$ -receptor blockade<sup>125</sup>; however, ancillary properties of carvedilol could also have contributed to its superiority.<sup>130,131</sup> New  $\beta$ -blockers with novel ancillary properties are now available. Among them, nebivolol is a highly selective  $\beta_1$ -adrenergic receptor blocker with associated  $\beta_3$ -agonist and nitric oxide-releasing properties.<sup>93,94,173</sup> The clinical relevance of these properties should, however, be shown by direct comparison trials.

The relative importance of different mechanisms of action of  $\beta$ -blockers in patients with heart failure is still a matter of debate. For example, a meta-analysis revealed a correlation between survival benefit from  $\beta$ -blocker treatment and heart rate reduction, with an 18% reduction (95% CI, 6% to 29%) in the risk for death for every heart rate reduction of 5 beats/minute with  $\beta$ -blocker treatment.<sup>174</sup> This effect of heart rate reduction was independent from  $\beta$ -blocker dosing. Another study showed that the change in heart rate after  $\beta$ -blocker therapy is correlated with the change in LVEF as well as with reduction in mortality.<sup>175</sup> Thus, heart rate reduction seems to be an important mechanism of action of  $\beta$ -blockers in heart failure. The hypothesis that pure heart rate reduction may have beneficial effects on outcomes is currently being tested.<sup>176</sup>  $\beta$ -Blockers with positive inotropic activity other than through  $\beta$ -receptors may be developed and could

**FIGURE 46-11** Differences in the response to chronic  $\beta$ -blocker therapy. (From Bristow MR, Gilbert EM, Abraham WT, et al. Carvedilol produces dose-related improvements in left ventricular function and survival in subjects with chronic heart failure. *Circulation* 1996;94:2807-2816.)

someday prove useful in patients with very advanced heart failure. Another possibility, as discussed previously and in the next section, is the development of compounds with greater inverse agonist properties on specific genetic subtypes of  $\beta_1$ - or even  $\beta_2$ -receptors.

### Pharmacogenetic Targeting Based on Genetic Variation in Adrenergic Receptors (see Chapter 42)

As discussed in detail in Chapter 42, the response to drug therapy can be improved by genetic biomarker identification of patients who respond differentially, either better or worse/not at all in comparison with the general population. On the basis of data from the human genome sequencing project, the amount of genetic variation in the form of single-nucleotide polymorphisms (SNPs) is estimated to be 0.1% to 0.2%,<sup>177</sup> but certain genes exhibit more variation than others. The small and intronless  $\beta_1$ - and  $\beta_2$ -adrenergic receptor genes are examples of highly polymorphic genes, exhibiting SNP frequencies of approximately 1%. The  $\beta_1$ -adrenergic receptor gene has 12 nonsynonymous SNPs (which result in a change in coded amino acid) and 3 synonymous SNPs in its coding region; the  $\beta_2$  gene has, respectively, 12 and 5.<sup>178</sup> The  $\beta_1$ -receptor gene product is the primary drug target of  $\beta$ -blockers, and one of its polymorphisms, an SNP at nucleotide position 1165 that produces either an arginine (Arg, major allele, frequency of approximately 0.70) or glycine (Gly, minor allele, frequency of approximately 0.30), is associated with markedly different pharmacological properties.<sup>63</sup> In comparison with the 389 Gly version of the  $\beta_1$ -receptor, the Arg variant has much higher signal transduction capacity, higher affinity for norepinephrine, and a higher fraction of receptors in a constitutively active state.<sup>63,179,180</sup> The  $\beta_2$ -adrenergic receptor also has a polymorphism with a major difference in signal transduction function between the variants, at nucleotide position 491 and amino acid position 164 (Thr164Ile).<sup>181</sup> However, the minor, hypofunctional 164 isoleucine allele has a frequency of less than 2% and is therefore of little pharmacogenetic interest.<sup>182</sup> Several additional polymorphisms of  $\beta_1$ -receptors (Ser49Gly) and  $\beta_2$ -receptors (Gly16Arg and Gln-27Glu) can affect receptor internalization without affecting signal transduction. In addition, the  $\alpha_{2c}$  adrenergic receptor has a large deletion polymorphism of amino acid positions 322 to 325 (allele frequency of 4% among white people but 42% among African Americans) that produces a major loss in signal transduction function.<sup>183</sup> This receptor is present on adrenergic nerve terminals, where the wild-type or insertion version tonically inhibits norepinephrine release.<sup>34,82</sup>

Any of these receptor polymorphisms could theoretically alter the response to  $\beta$ -blocker therapy. Small studies have related changes in LV function after  $\beta$ -blockade of SNPs. A greater increase in the LVEF after chronic  $\beta$ -blocker therapy has been shown in subjects homozygous for the Arg389  $\beta_1$ -receptor, compared with Gly389 carriers, in some<sup>180,184</sup> but not all<sup>185,186</sup> single-center studies and in a meta-analysis.<sup>187</sup> A greater improvement in the LVEF after carvedilol administration has been shown in  $\beta_2$  Glu27 carriers in some studies.<sup>186,188</sup>

No significant interaction between  $\beta_2$ -adrenergic receptor polymorphisms and the effects of  $\beta$ -blockers on clinical outcomes have been described to date. Because the receptor is the primary target of  $\beta$ -blocker treatment and because the polymorphic variants possess major functional differences, the  $\beta_1$  Arg389Gly polymorphism has been related to outcomes in two of the large  $\beta$ -blocker studies, BEST<sup>78,80</sup> and MERIT-HF.<sup>189</sup> In both these trials, DNA data banks were obtained in order to assess the relationship between adrenergic receptor polymorphism and the effects of treatment. The DNA bank population of BEST consisted of 1040 patients<sup>123,179</sup> who were studied to test the hypothesis that

polymorphisms of adrenergic receptors can influence clinical, remodeling, or sympatholytic effects of bucindolol. Two sets of receptor polymorphisms were found to influence outcomes:  $\beta_1$  389 Arg/Gly<sup>179</sup> and  $\alpha_{2c}$  322-325 wild-type/deletion.<sup>123</sup> The  $\beta_1$  389 polymorphism interacts with bucindolol in a manner predicted by its pharmacological action: Bucindolol was associated with greater clinical efficacy in patients who were homozygous for the  $\beta_1$  389 Arg receptor gene than in patients with Gly-containing genotypes.<sup>179</sup> Bucindolol-associated sympatholysis was exaggerated in patients with  $\alpha_{2c}$  deletion genotypes, which compromised efficacy.<sup>123</sup> In contrast, patients with  $\alpha_{2c}$  wild-type genotypes exhibited only mild sympatholysis and substantial clinical efficacy, with a reduction in all-cause mortality of 30% ( $P = .025$ ) and a reduction in cardiovascular mortality of 41% ( $P = .003$ ).<sup>123</sup> The interpretation of these findings was that the  $\alpha_{2c}$  deletion receptor produced adrenergic dysregulation, similar to what has been described in mouse knockout models.<sup>190,191</sup> At any rate, it appears that the norepinephrine-lowering properties of bucindolol are subject to genetic regulation by  $\alpha_{2c}$  genotype, and the undesirable property of exaggerated sympatholysis can be avoided by not giving bucindolol to patients with  $\alpha_{2c}$  deletion genotypes. In the BEST substudy of adrenergic receptor polymorphism, the variants affecting  $\beta$ -receptor internalization did not consistently alter clinical responses or affect norepinephrine release. In BEST, neither the  $\beta_1$  Arg/Gly or  $\alpha_{2c}$  wild-type/deletion polymorphisms affected clinical responses in patients treated with placebo<sup>123,179</sup>; that is, there was no apparent clinical effect of these polymorphisms on the natural history of heart failure over the average 2-year follow-up period in the trial.

In a 600-patient DNA substudy of the MERIT-HF trial, the  $\beta_1$  Arg/Gly polymorphism did not affect clinical response in either the metoprolol or placebo group<sup>189</sup>; in a 637-patient study of the effects of all the  $\beta_1$  389 and 49 polymorphisms,  $\beta_2$  16 and 27 polymorphisms, and  $\alpha_{2c}$  wild-type/deletion polymorphisms, no effect of any variant was found in clinical responses to either metoprolol or carvedilol.<sup>192</sup> There are no data on the interaction of nebivolol with adrenergic receptor polymorphisms.

Thus, the available data indicate that the effects on outcomes of bucindolol, but not metoprolol or carvedilol, can be influenced by  $\beta_1$  389 Arg/Gly and  $\alpha_{2c}$  wild-type/deletion polymorphisms. This is perhaps not surprising inasmuch as in human systems only bucindolol interacts pharmacologically with both sets of polymorphisms<sup>123,179</sup>; that is, in isolated human heart preparations with  $\beta_1$  Arg homozygous genotype, bucindolol has inverse agonist properties, which indicates that it facilitates the inactivation of constitutively active  $\beta_1$  Arg receptors.<sup>179,193,194</sup> Carvedilol and metoprolol do not exhibit this property.<sup>193,194</sup> Carvedilol and metoprolol also are not sympatholytic and so would not be expected to interact pharmacologically with  $\alpha_{2c}$  polymorphisms. The deletion variant of the  $\alpha_{2c}$  receptor results in adrenergic dysregulation in response to agents that affect the release of norepinephrine,<sup>191</sup> which is the probably basis of this receptor variant's strong interaction with the norepinephrine-lowering effects of bucindolol.<sup>193</sup>

Therefore, genetic variation in two adrenergic receptors appears to influence the clinical response to bucindolol. In order to take full advantage of this, both sets of polymorphisms would need to be considered. Only the patients with the hypofunctional 389 Gly version of the  $\beta_1$ -adrenergic receptor are susceptible to the exaggerated sympatholytic effects of bucindolol in association with  $\alpha_{2c}$  deletion genotypes.<sup>195</sup> This creates a situation in which the approximately 50% of patients with the  $\beta_1$  Arg 389 homozygous genotype exhibited the greatest degree of efficacy in response to bucindolol, including a 38% reduction ( $P = .042$ ) in all-cause mortality, a 48% reduction ( $P = .014$ ) in cardiovascular mortality,

**TABLE 46-4** Generational Classification of  $\beta$ -Blockers for the Treatment of Heart Failure

Generation	Definition	Examples
First	Nonselective for $\beta_1$ - and $\beta_2$ -adrenergic receptors	Propranolol, timolol
Second	Selective for $\beta_1$ - versus $\beta_2$ -adrenergic receptors	Metoprolol, bisoprolol
Third	Selective or nonselective, with a favorable ancillary property (e.g., vasodilation)	Carvedilol, nebivolol
Fourth	Selective for specific adrenergic receptor polymorphisms	Bucindolol

and a 36% reduction ( $P = .007$ ) in hospitalizations for heart failure.<sup>179,195</sup> On the other hand, the approximately 10% of patients who have both  $\beta_1$  389 Gly and  $\alpha_{2c}$  deletion genotypes should not be treated with bucindolol, because there is no evidence of efficacy in these patients.<sup>123,179</sup>

Bucindolol is still in development; the final clinical trial to be conducted exclusively in patients who have the  $\beta_1$  389 Arg homozygous genotype, in a 1:1 comparison with metoprolol succinate. If this trial confirms results of the BEST DNA substudy, bucindolol would be approved with pharmacogenetic labeling, indicated for patients with the  $\beta_1$  Arg/Arg genotype, with language warning against administering the drug to patients who have both  $\alpha_{2c}$  deletion and  $\beta_1$  389 Gly genotypes. Obviously, a baseline genetic test would be necessary to optimally administer a drug with a pharmacogenetic indication, and this test is also being developed. Thus,  $\beta$ -blocker drug development has now evolved through four generations (Table 46-4): The first-generation compounds, developed in the late 1960s and early 1970s, could competitively antagonize both  $\beta_1$ - and  $\beta_2$ -receptors; the second generation, developed in the 1970s through the 1990s, consisted of  $\beta_1$ -selective compounds; the third generation, developed in the 1980s through the 2000s, comprised compounds with the ancillary property of vasodilation; and the fourth-generation compounds, currently being developed, act against specific adrenergic receptor polymorphisms. This last approach should improve therapeutic index of this already highly effective therapeutic class and may serve to increase the interest of pharmaceutical companies in this venerable class of compounds.

failure to 10.5% among patients with class III and 18.6% among patients with class IV heart failure. However, the relative percentages of sudden deaths demonstrate the opposite trend: they were highest, at 64%, among patients with class II heart failure and fell as functional class worsened (Figure 47-1). Most commonly, sudden death results from ventricular tachycardia with secondary degeneration into ventricular fibrillation (see Chapter 46). Moreover, although bradyarrhythmia accounts for only 5% to 10% of sudden death among patients with heart failure, this category is perhaps more commonly overlooked by contemporary clinicians, who are focused on tachyarrhythmias.

### THE BASICS OF IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS (ICDs)

A precisely engineered and encased battery, capacitor, lead connectors, computer chip with memory, and software (known as “the can”) are typically implanted in the prepectoral space; a combined insulated pacing and defibrillator lead typically passes through the subclavian vein into the right ventricle. Many implantable cardiovert-defibrillator (ICD) leads also contain a second shocking coil, which is typically located in the superior vena cava or right atrium by virtue of its distance from the lead tip, and it can be readily located under fluoroscopy or routine chest radiography. The lead transmits the local electrographic reading at the myocardial contact site back to the can, where the information is processed. If any tachyarrhythmia is detected, the device can deliver both pacing and shock therapies designed to terminate the arrhythmia in response to a wide array of programmable parameters. If a shock is indicated, the capacitor charges to a prespecified voltage and delivers an electrical shock current by means of a prespecified vector. The shock vector is usually determined at the time of implantation, when the defibrillation threshold is checked. It can be configured between

The goals for device therapy in heart failure are to extend life by detecting and treating arrhythmias, to apply pacing strategies when needed to reduce morbidity and mortality from the disease, and to provide valuable diagnostic information to the managing clinician. The first two goals are the mainstays of current device therapy; the third holds enormous promise as technology advances beyond the devices’ standard reporting of arrhythmia events to the ability to provide additional hemodynamic data.

### SUDDEN CARDIAC DEATH

Progression of disease and the associated clinical complications account for the majority of deaths from heart failure. However, unexpected death from arrhythmia remains an important and treatable cause across the spectrum of heart failure. In the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF),<sup>1</sup> the incidence of sudden death rose incrementally from 6.3% among patients with New York Heart Association (NYHA) class II heart

the right ventricle coil and the superior vena cava coil or between the right ventricle coil and the can, or it can include additional separate implantable shocking coils.

When the device is tested, ventricular fibrillation is most commonly induced in the electrophysiology laboratory by right ventricular pacing, followed by a low-voltage shock administered during cardiac repolarization as timed during the T-wave, or it is induced by application of a 10-V direct current. The device is then given the opportunity to detect fibrillation (which is often of low amplitude) and to deliver the appropriate therapy. The defibrillation threshold (generally 10 to 20 J) is then documented and can be modified by changing the shock vector or ultimately even adding another shocking coil into the coronary sinus, azygous vein, or subcutaneously. Routine defibrillation threshold testing has become somewhat controversial, but it is still practiced by the majority of electrophysiologists.

### Antitachycardia Pacing

In addition to shocks, antitachycardia pacing can be delivered in response to a detected ventricular arrhythmia. Burst pacing is a type of antitachycardia pacing in which the device delivers a ventricular stimulation sequence at a cycle length that is slightly shorter than that of the tachycardia (i.e., a faster heart rate) in an attempt to cause either unidirectional or bidirectional block in the reentry circuit and thus terminate the arrhythmia. The device can also deliver ramp pacing, in which the paced cycle length is incrementally decreased to enable a wider range of paced cycle lengths to break the arrhythmia loop. Multiple algorithms have been developed, stemming historically from a time when diagnostic electrophysiological studies were more commonly performed to induce ventricular arrhythmias to test drug sensitivity or as a criterion for ICD placement. Operators routinely used these pacing strategies in an attempt to reduce the need for shocking the patient during spontaneous tachycardias.

### Device Programming

The contemporary ICD has programmable “tachycardia zones,” which are nothing more than prespecified heart rate ranges to which the device responds with a prespecified

MODE OF DEATH IN THE MERIT-HF TRIAL

**FIGURE 47-1** Severity of heart failure (HF) and mode of death in the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF) trial. NYHA, New York Heart Association (classification); SD, sudden death. (Modified from MERIT-HF Study Group. Effect of metoprolol CR/XL in chronic heart failure: Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF). *Lancet* 1999;353:2001-2007.)

**TABLE 47-1** Detection of Ventricular Tachyarrhythmias and Subsequent Therapy

Detection Zone	Detection Rate (Beats per Minute)	Duration	Response
Very fast	250	30 of 40 beats	High-energy shock
Intermediate	182	30 of 40 beats	Antitachycardia pacing first and, if needed, shock
Slow	167	32 beats	Only record the rhythm

Detection of ventricular tachyarrhythmias and the subsequent therapy is segmented by rate zones, duration of the tachycardia, and appropriate therapy for tachycardia characteristics in a particular zone. Duration is often programmed in seconds faster than a certain rate instead of number of heartbeats in a particular rate zone. The parameters displayed in the table are based on those that were used in the Primary Prevention Parameters Evaluation (PREPARE) study for patients with primary prevention indications for the implantable cardioverter-defibrillator.

From Wilkoff BL, Williamson BD, Stern RS, et al. Strategic programming of detection and therapy parameters in implantable cardioverter-defibrillators reduces shocks in primary prevention patients: results from the PREPARE (Primary Prevention Parameters Evaluation) study. *J Am Coll Cardiol* 2008;52:541-550.

therapy (Table 47-1). This allows the clinician the opportunity to choose less aggressive pacing therapies during slower tachyarrhythmias (typically 170 to 180 beats per minute), which are more likely to be hemodynamically tolerated, and more aggressive pacing therapies plus rapid defibrillation at the highest available shock voltage for more urgently life-threatening ventricular fibrillation or fast ventricular tachycardia. When an atrial lead is present, the device can use the local electrographic reading to compare the atrial rate with the ventricular rate in an effort to discriminate supraventricular arrhythmias, to document atrioventricular dissociation, and to help avoid inappropriate shocks (e.g., when the atrial rate is greater than the ventricular rate, as is the case with atrial flutter with 2:1 block). When the atrial rate is equal to the ventricular rate, or in the case when only a right ventricle lead is present, the device can apply morphological criteria to compare the QRS electrographical reading to a stored “native” QRS electrographical reading when the patient is known to be in normal sinus rhythm. Used in this manner, the atrial lead can help discriminate an atrial arrhythmia with 1:1 conduction from a ventricular arrhythmia with retrograde conduction through the atrioventricular node into the atria. As discussed later in this chapter, increasingly sophisticated methods are under development to prevent inappropriate shocks.

### Primary Prevention of Sudden Cardiac Death

Contemporary ICD indications have evolved historically from the notion that the prophylactic suppression of ventricular ectopy and arrhythmias is insufficient for adequately

managing all at-risk patients.<sup>2</sup> According to the VPC (ventricular premature contraction) *suppression hypothesis*, ectopy in at-risk patients with left ventricular dysfunction triggered lethal arrhythmias, and suppression would lead to improved outcomes. In the Cardiac Arrhythmia Suppression Trial (CAST),<sup>3</sup> however, the class Ic antiarrhythmics flecainide and encainide actually increased mortality in comparison with placebo, and thus this hypothesis was set aside. According to the *electrophysiology-inducible suppression hypothesis*, the induction of ventricular arrhythmias by means of programmed stimulation techniques in the electrophysiology laboratory, and subsequent suppression with antiarrhythmic drugs, could improve outcomes. Problems arose in that a suppressing therapy was found for only approximately half the patients with inducible arrhythmia. Furthermore, electrophysiological testing has limited predictive ability, especially in patients with nonischemic cardiomyopathy. Programmed stimulation is very effective in inducing arrhythmias with a reentrant mechanism created by a focal area of scarring, for example, as is the case in ischemic heart disease, but it is limited in assessing arrhythmias by other mechanisms. In the Multicenter Unsustained Tachycardia Trial (MUSTT),<sup>4</sup> patients with inducible arrhythmia clearly had improved outcomes with ICDs. This led to subsequent ICD trials designed to refine this concept and to create the contemporary guidelines.

The ACC/AHA/ESC 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities<sup>5</sup> for primary prevention ICDs reflect lessons learned from four major trials (Table 47-2). In MUSTT,<sup>4</sup> patients with inducible ventricular tachycardia, left ventricular ejection fraction (LVEF) of 40% or lower, and documented coronary artery disease demonstrated a survival benefit with ICDs. In the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE),<sup>6</sup> patients with NYHA functional class III symptoms, nonischemic cardiomyopathy, nonsustained ventricular tachycardia (NSVT), and LVEF of 35% or lower demonstrated a reduction in sudden deaths from cardiac arrhythmias. In this study, a total of 229 patients were randomly assigned to receive standard medical therapy and 229 to receive standard medical therapy plus a single-chamber ICD. As shown in Figure 47-2, all-cause death was not reduced in DEFINITE (hazard ratio, 0.65; 95% confidence interval [CI], 0.40 to 1.06;  $P = .08$ ), whereas there was a significant ( $P < .006$ ) reduction in sudden deaths from cardiac arrhythmias (hazard ratio, 0.20; 95% CI, 0.06 to 0.71). Thus, in patients with severe nonischemic dilated cardiomyopathy who were treated with angiotensin-converting enzyme (ACE) inhibitors and  $\beta$ -blockers, the implantation of an ICD significantly reduced the risk of sudden death from arrhythmia and was associated with a nonsignificant reduction in the risk of death from any cause.

In the Multicenter Automatic Defibrillator Implantation Trial II (MADIT II),<sup>7</sup> patients with LVEF of 30% or lower 30 days after myocardial infarction demonstrated a 5.6% absolute reduction in mortality (hazard ratio, 0.69; 95% CI, 0.51 to 0.93;  $P = .016$ ) in comparison with routine care over

TABLE 47-2 Summary of Indications for Implantable Cardioverter-Defibrillator in a Population with Heart Failure	
Primary Prevention	Secondary Prevention
Ischemic Cardiomyopathy	
NYHA classes I, II, III 30 days after myocardial infarction, LVEF ≤ 30%	Survival after cardiac arrest or sudden death >5 days after myocardial infarction
Nonischemic Cardiomyopathy	
NYHA class II or III LVEF ≤ 35% and NSVT 3 months on standard medical therapy	Sustained ventricular tachyarrhyth- mia >30 seconds or necessitating therapeutic termination because of hemodynamic compromise*
Both Types of Cardiomyopathies	
NYHA class II or III, LVEF ≤ 35% LVEF 35% to 40%, NSVT, and inducible ventricular tachycardia with programmed stimulation	Unexplained syncope and left ventricular dysfunction†

\*Attributable to a nonreversible condition (i.e., not a transient electrolyte abnormality or a medication or drug effect).  
†See text discussion regarding the need for additional risk stratification.  
LVEF, left ventricular ejection fraction; NSVT, nonsustained ventricular tachycardia;  
NYHA, New York Heart Association.

approximately 2 years (Figure 47-3). The effect of defibrillator therapy on survival was similar in subgroup analyses stratified according to age, sex, ejection fraction, NYHA class, and the QRS interval. In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT),<sup>8</sup> patients with both ischemic and nonischemic cardiomyopathy who were receiving optimal medical therapy (ACE inhibitor/angiotensin receptor blocker,  $\beta$ -blocker, and an aldosterone antagonist), had an LVEF of 35% or lower, and had NYHA class II or III heart failure demonstrated an absolute 7.2% reduction in mortality in comparison with similar patients who received, in addition, amiodarone treatment or placebo over approximately 4 years. As shown in Figure 47-4, amiodarone, in comparison with placebo, was associated with a similar risk of death (hazard ratio, 1.06; 97.5% CI, 0.86 to 1.30;  $P = .53$ ), whereas ICD therapy was associated with a 23% relative decreased risk of death (hazard ratio, 0.77; 97.5% CI, 0.62 to 0.96;  $P = .007$ ). ICD implantation guidelines are summarized in Table 47-2.

Third-party payer reimbursement for ICD implantation is a separate issue. In 2005, the Center for Medicare and Medicaid Services stipulated that it would reimburse ICD implantation for primary prevention in patients who had nonischemic cardiomyopathy and LVEF of 35% or lower, provided that they have carried the diagnosis for 3 months and still meet the criteria for inclusion in the national ICD registry.<sup>9</sup> This waiting period is designed to allow time for myocardial recovery and improvement in LVEF after treatment with ACE inhibitors and  $\beta$ -blockers. Similarly, patients with LVEF of 30% or lower after myocardial infarction are required to wait 40 days after myocardial infarction and 3 months after revascularization. Although ICDs are effective at preventing sudden death, identifying the patients at risk is a major challenge. Current guidelines unquestionably miss the mark.<sup>10</sup> Approximately 66% of sudden deaths occur among patients with significant structural heart disease; however, the sheer size of the population at “low risk” still accounts for the largest absolute number of sudden deaths in the United States annually.<sup>11</sup> Because there is currently no way of identifying them, they are not considered candidates for primary prevention ICDs. Similarly, the current inclusion criteria do not positively and

**FIGURE 47-2** Kaplan-Meier estimates of death from any cause (A) and sudden death from arrhythmia (B) among patients who received standard therapy and those who received an implantable cardioverter-defibrillator (ICD) in the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) trial. **FIGURE 47-4** Kaplan-Meier analysis of the time to death from any cause in patients receiving conventional therapy for heart failure, conventional therapy plus amiodarone, or conventional therapy plus a conservatively programmed, shock-only, single-lead implantable cardioverter-defibrillator (ICD) in the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT). CI, confidence interval. (Modified from Bardy GH, Lee KL, Mark DB, et al. Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure. *N Engl J Med* 2005;352:225-237.)

adequately predict who will have an event; rather, they identify only an approximate population that derive mortality-related benefit overall. Over the years, many risk-stratification modalities have been evaluated, in addition to cause of cardiomyopathy, NYHA classification, LVEF, and inducibility of arrhythmia. Included among the additional modalities listed in Table 47-3 are heart rate variability, signal-averaged electrocardiography, baroreceptor sensitivity, and microvolt T-wave alternans (MTWA) testing. Of these, MTWA testing is the most heavily studied modality and is the only modality besides invasive electrophysiological testing to gain the reimbursement approval from the Center for Medicare and Medicaid Studies. T-wave alternans—microvolt beat-to-beat alterations in the amplitude, duration, or structure of the T-wave—has been clearly associated with ventricular arrhythmias and mortality.<sup>12,13</sup> Cantillon and associates<sup>14</sup> demonstrated that MTWA testing is superior to electrophysiological testing in predicting ventricular arrhythmias among patients with an LVEF of 35% or lower with either NSVT or unexplained syncope. This study also demonstrated that the MTWA result was a robust predictor both in patients with ischemic cardiomyopathy and in those with nonischemic cardiomyopathy but that the 2 year event rate for sustained ventricular tachycardia or death was approximately 10% among the patients with negative MTWA findings (almost twofold higher than in previously published studies with cohorts at lower risk). In addition, presentation of the Microvolt T-Wave Alternans Testing for Risk Stratification of Post-MI Patients (MASTER) I data, in which T-wave alternans was predictive of all-cause mortality but not of the need for appropriate ICD shocks for ventricular tachycardia, has led to some doubt that this modality can sufficiently stand alone to identify patients at risk. Multiple trials are under way to investigate combining some of the previously associated modalities for risk stratification to further refine current indications for primary prevention.

## Secondary Prevention of Sudden Cardiac Death

ICD implantation for secondary prevention involves treating clinically documented ventricular arrhythmias or those that are highly suspected as a cause of hemodynamic compromise.

**TABLE 47-3** Adjunctive Modalities for Stratification of Sudden Death Risk in Patients with Heart Failure

Modality	Pathological Finding
Programmed stimulation (electrophysiological testing)	Sustained VT/VF with double or triple extra stimuli
Microvolt T-wave alternans testing	Positive or indeterminate result
Event or Holter monitoring	Sustained or nonsustained VT or VF
Heart rate variability (turbulence)	Loss of heart rate variability
Baroreceptor sensitivity	Loss of normal vagal response
QRS duration and structure	≥120 msec, left bundle branch block
Exercise stress testing (including metabolic studies)	Drop in blood pressure with exercise, low functional capacity or low peak $\text{VO}_2$ , or ventricular arrhythmias during exercise or recovery
Signal-averaged electrocardiography	Abnormal result

VF, ventricular fibrillation;  $\text{VO}_2$ , ventilatory oxygen uptake; VT, ventricular tachycardia.

Survivors of sudden cardiac death or patients with sustained ventricular arrhythmias and cardiomyopathy with left ventricular dysfunction are solid candidates for secondary ICD implantation under both the 2008 guidelines<sup>5</sup> and the requirements of the Center for Medicare and Medicaid Services.<sup>9</sup> Survivors of sudden cardiac death who, according to echocardiographic testing, have apparently structurally normal hearts need to be examined carefully for an underlying predisposition to ventricular arrhythmias, such as the long QT syndrome, the Brugada syndrome, or arrhythmogenic right ventricular dysplasia (ARVD). Electrolyte disturbances and medication or drug effects are also common causes of ventricular arrhythmias in patients with structurally normal hearts. A careful family history must be obtained for unexplained sudden death among first-degree relatives, especially those who died at a young age. Patients with such familial disorders who have clinical events also qualify solidly for secondary ICD implantation (see Table 47-2). Primary prevention ICDs for these patients are somewhat more intricate, and a discussion of these is beyond the scope of this chapter.

ICD implantation for patients with unexplained syncope and left ventricular dysfunction in the absence of a documented ventricular arrhythmia is a somewhat more controversial topic. As is always the case with syncope, the clinical history and risk factor profile can often strongly suggest what happened in the absence of objective rhythm tracings (i.e., a history consistent with vasovagal syncope in a normal heart versus a history consistent with ventricular tachycardia in a patient with known ischemic heart disease). Such important clinical data cannot be discarded. The decision to implant an ICD in a patient with symptomatic heart failure can be made easier when indications for primary and secondary prevention overlap for unexplained syncope and when the LVEF is lower than 35%, the cutoff used in the SCD-HeFT trial. For unexplained syncope with LVEF higher than 35%, some clinicians explore alternative forms of risk stratification to help guide the decision of whether to implant an ICD. An electrophysiological study may be reasonable for patients with ischemic disease in whom the LVEF ranges from 35% to 40%, according to the MADIT I study,<sup>16</sup> and T-wave alternans testing may be reasonable for deferring ICD implantation on the basis of a negative result in a patient with an LVEF higher than 35%.<sup>17</sup>

A more conservative approach for unexplained syncope with only mild left ventricular dysfunction could include inpatient cardiac telemetry taping, outpatient Holter

monitoring, or event monitoring (wearable or implantable) for a more precise characterization with or without concomitant medical therapy. Other experts favor a “best judgment” empirical decision that is based on the clinical circumstances of the syncope event, the severity of left ventricular dysfunction, and whether the patient has demonstrable myocardial ischemia that can be reversed with revascularization. Furthermore, not all of these strategies are mutually exclusive. The only caveat is that, as highlighted in the previous section, there is some discordance in when it is reasonable to implant an ICD and when a third party will pay for it. Such pragmatic considerations are not completely negligible within these uncertain areas, inasmuch as ICD implantation and follow-up care are costly and have the potential to create a burden for the individual uninsured patient or for the larger health care system beleaguered by rising costs.

## Inappropriate Shocks from Implantable Cardioverter-Defibrillators

Inappropriate shocks are more than just a nuisance to patients and physicians and may actually reduce the benefit from ICDs. An analysis of the MADIT II database demonstrated a hazard ratio of 2.29 for increased all-cause mortality among the 11.5% of ICD recipients who experienced more than one inappropriate shock.<sup>18</sup> The same analysis demonstrated that a history of atrial fibrillation, tobacco use, diastolic hypertension, and a prior inappropriate shock was predictive of future inappropriate shocks. Psychiatric morbidity, including posttraumatic stress disorder, has been associated with multiple ICD shocks over time.<sup>19</sup> Hence, achieving control of supraventricular arrhythmias is crucial, often including catheter ablation procedures. In addition to sustained ventricular tachycardia, abnormal oversensing (in which the device interprets noise or the T-wave as arrhythmia) is a common cause of inappropriate shocks. Adjusting sensing thresholds, modifying detection heart rate zones, and modifying their corresponding therapies are often necessary. In the Primary Prevention Parameters Evaluation (PREPARE) study,<sup>20</sup> such strategic programming reduced appropriate and inappropriate shocks by approximately 66% among primary ICD recipients. In extreme situations, ablation of the atrioventricular node or disablement of the shocking function may become necessary to stop incessant shocks. Distinguishing appropriate from inappropriate therapy can be difficult. According to at least one definition, 66% of the rhythms in patients in the PREPARE trial would have elicited inappropriate therapy, even though at least 50% of the shocks would have been delivered for ventricular tachycardia.

## Complications of and Informed Consent for Implantable Devices

Pooled device complication rates in the heart failure population<sup>21</sup> are summarized in Table 47-4. Patients have a right to accept or refuse any medical intervention, and they need to understand the risks and benefits of what is being offered to them. Both the clinical practice guidelines<sup>5</sup> and Center for Medicare and Medicaid Services guidelines<sup>9</sup> recommend caution in offering ICD therapy to patients with life expectancy of less than 1 year because they are unlikely to derive benefit for a relatively low 1-year event rate, according to the Kaplan-Meier curves in the previously cited major trials; therefore, they incur only the up-front risk associated with implantation, without the counterbalancing clinical benefit. Furthermore, some experts have criticized the electrophysiology community for inappropriately extending ICD indications beyond what was studied in the clinical trials and for not fully explaining how an ICD benefits an individual patient.<sup>22</sup> Defibrillator shocks are intrusive in a patient who

**TABLE 47-4 Pooled Rates of Device Complications Reported from MIRACLE, COMPANION, and CARE-HF Trials**

Complication	Range of Event Rates
Procedure-related death	0.2% to 0.6%
Coronary venous dissection (CRT devices)	0.3% to 4.0%
Lead dislodgment	5.7% to 6.0%
Coronary venous perforation	0.8% to 2.0%
Tamponade	0.3% to 0.5%
Infection or pocket erosion	1.3% to 2.7%

CARE-HF, Cardiac Resynchronization in Heart Failure; COMPANION, Comparison of Medical Therapy, Pacing, AND Defibrillation in Heart Failure; CRT, cardiac resynchronization therapy; MIRACLE, Multicenter InSync Randomized Clinical Evaluation.

chooses not to be resuscitated in the event of a cardiac arrest. Some patients also inappropriately believe the presence of a primary prevention ICD somehow improves their heart's performance on a daily basis. Therefore, patients must be able to repeat back an understanding of the procedure in order to avoid such misunderstanding.

## PACING AND CARDIAC RESYNCHRONIZATION

### Basic Considerations

In a normal heart with a narrow QRS complex, right and left ventricular depolarization is synchronous when an atrial impulse is conducted through the atrioventricular node, down the bundle of His, and through the right and left bundle and their associated subdivisions. *Electrical dyssynchrony* refers to an abnormally widened surface QRS duration exceeding 120 msec in any electrocardiographic limb lead, and it is associated with increased mortality among patients with symptomatic heart failure. A left bundle branch block, for example, is suggestive of delayed electrical activation of the left lateral wall, which impairs left ventricular diastolic filling, increases mitral regurgitation, and reduces cardiac output. *Mechanical dyssynchrony* refers to echocardiographic evidence of abnormal activation timing within or between the ventricles. *Interventricular dyssynchrony* occurs when activating timing between the right and left ventricles is altered. *Intraventricular dyssynchrony* occurs between segments within the left ventricle, such as the septum and lateral wall. *Atrioventricular dyssynchrony* refers to atrial contraction that is out of phase with ventricular filling, as manifested by an abnormal PR interval. The extreme example of this is complete heart block (atrioventricular asynchrony), in which the atria often contract against closed atrioventricular valves, producing the characteristic cannon waves.

### Mechanical Dyssynchrony

Cardiac resynchronization therapy (CRT) aims to restore synchronous biventricular contraction sequence through the normalization of activation timing by pacing both ventricles (i.e., biventricular pacing). In the 2008 consensus statement by the American Society of Echocardiography and the Heart Rhythm Society,<sup>23</sup> echocardiographic criteria used to assess mechanical dyssynchrony were evaluated, and some of these common modalities are summarized in Table 47-5. Interventricular dyssynchrony is currently best assessed by means of the interventricular mechanical delay (IVMD), which is defined

as a 40-msec or longer difference between peak right and left ventricular contraction, measured separately from the onset of the QRS complex with pulsed-wave Doppler imaging of the velocities of the right and left ventricular outflow tracts. This is a simple technique that can be easily applied and does not require advanced equipment. Prolonged IVMD has been associated with an increase in all-cause mortality.<sup>24</sup> The major disadvantage is that IVMD is considered a nonspecific finding, inasmuch as CRT responders and nonresponders have similar rates of IVMD.<sup>25</sup>

Color-coded tissue Doppler imaging is the current favored method of assessment of intraventricular dyssynchrony. In this technique, longitudinal wall delay is evaluated in an apical three-, four-, or five-chamber view at two opposing sites from the QRS onset to peak contraction with a cutoff of 65 msec or longer; this method requires advanced tissue Doppler equipment. Intraventricular radial dyssynchrony can be assessed with M-mode echocardiography in the parasternal short-axis view of the middle of the left ventricle to assess

the septal-to-posterior wall delay, in which 130 msec or longer is considered abnormal. This approach does not require advanced equipment, but it can be confounded by regional akinetic segments. Additional techniques such as speckle-based tracking, in which natural acoustic reflections (speckles) are tracked in a time-velocity plot to allow for the assessment of rotational strain (or torsion), and 3-dimensional echocardiography, in which volume calculations can be applied, are also helpful and appear to be increasingly prevalent in clinical use.

## Candidacy for Cardiac Resynchronization Therapy

Multiple key trials that have validated the benefit of CRT are listed in Table 47-6. In the Multicenter InSync Randomized Clinical Evaluation (MIRACLE) trial,<sup>26</sup> 453 patients with dilated cardiomyopathy (end-diastolic diameter  $\geq 5.5$  cm), LVEF of 35% or less, and QRS interval of 130 msec or longer were randomly assigned to receive CRT or no pacing. The study demonstrated improvements in quality-of-life measures, the 6-minute walk test, and number of hospitalizations for heart failure. In the Comparison of Medical Therapy, Resynchronization, and Defibrillation Therapies in Heart Failure (COMPANION) trial,<sup>27</sup> 1520 patients with an LVEF of 35% or lower, QRS interval of 120 msec or longer, and NYHA class III or IV heart failure were randomly assigned to receive CRT alone, CRT with ICD capability (CRT-D), or no pacing. The patients who received CRT or CRT-D demonstrated relative reductions of 34% (hazard ratio, 0.81;  $P = .014$ ) and 40% (hazard ratio, 0.80;  $P = .01$ ), respectively, in composite all-cause mortality and hospitalization for heart failure in contrast to those who received no pacing (Figure 47-5, A). Only those with CRT-D demonstrated a decrease in all-cause mortality alone (see Figure 47-5, B).

In the Cardiac Resynchronization in Heart Failure (CARE-HF) trial,<sup>28</sup> 819 patients with LVEF of 35% or lower, QRS interval either of 150 msec or longer or of 120 to 150 msec with mechanical dyssynchrony, and NYHA class III or IV heart failure were randomly assigned to receive either CRT or no pacing; thus, this study did not include defibrillator therapy. CRT resulted in a significant 16% absolute risk reduction (hazard ratio, 0.63; 95% CI, 0.51 to 0.77;  $P < .001$ ) in morbidity and mortality during a mean follow-up period of 29.4 months (Figure 47-6, A), as well as a significant 10% absolute risk reduction (hazard ratio, 0.64; 95% CI, 0.48 to 0.85;  $P < .001$ )

**TABLE 47-5** Commonly Applied Methods Used to Assess Mechanical Dyssynchrony

Modality	Criteria
<b>Interventricular Dyssynchrony</b>	
Interventricular mechanical delay (IVMD)	$\geq 40$ -msec difference from QRS onset between peak RV and LV contraction on pulsed-wave Doppler imaging of the velocity of the RV and LV outflow tracts, or aortic pre-ejection period $> 160$ msec
<b>Intraventricular Dyssynchrony*</b>	
Color tissue Doppler imaging (cTDI)	$\geq 65$ -msec segmental opposing wall delay from QRS onset to peak contraction, assessed in apical three-, four-, or five-chamber view for longitudinal axis
M-mode with or without tissue color	$\geq 130$ -msec delay from septal to posterior wall, in parasternal view for radial axis

\*Speckle-based tracking and 3-dimensional echocardiography are also gaining popularity in the assessment of intraventricular mechanical dyssynchrony (see text). LV, left ventricular; RV, right ventricular.

**TABLE 47-6** Designs and Outcomes of Major Trials of Cardiac Resynchronization Therapy

Trial	Inclusion Criteria	Sample Size	Conditions	Result
COMPANION	NYHA classes III to IV LVEF $\leq 35\%$ QRS duration $\geq 120$ msec	1520	CRT vs. CRT-D vs. no pacing	All-cause mortality and hospitalization
MIRACLE	NYHA classes III to IV LVEF $\leq 35\%$ EDD $\geq 5.5$ cm QRS duration $\geq 130$ msec ICD indicated	369	CRT-D vs. ICD alone	Improved quality of life, improved NYHA class
CARE-HF	NYHA classes III to IV LVEF $\leq 35\%$ QRS duration $\geq 150$ msec or 120 to 150 msec with dyssynchrony	819	CRT vs. no pacing	All-cause mortality or unplanned hospitalization
RETHINQ	NYHA classes III to IV LVEF $\leq 35\%$ QRS duration $\leq 130$ msec Mechanical dyssynchrony (TDI)	172	CRT vs. no pacing	No increase in peak $\text{Vo}_2$ at 6 months

of death from any cause (see Figure 47-6, B). Thus, both the primary endpoint of time to death or unplanned hospitalization and the secondary endpoint of all-cause mortality were reduced in the CRT recipients. The benefits of CRT were similar among patients with ischemic heart disease and patients without ischemic heart disease and were in addition to the benefits of pharmacological therapy. In addition, CRT reduced the interventricular mechanical delay, the left ventricular end-systolic volume index, and the area of the mitral regurgitant jet, and it increased the left ventricular ejection fraction.

On the basis of these results, current candidates for CRT include those with LVEF of 35% or lower, a QRS duration of 120 msec or longer on surface electrocardiogram, and NYHA functional class III or IV heart failure despite optimal medical therapy with  $\beta$ -blockers, ACE inhibitors or angiotensin receptor blockers, aldosterone antagonists, and loop diuretics. Because QRS duration is measured from the onset of the Q wave to the termination of the S wave, where it is longest in the electrocardiograph limb leads, accurate measurement

of QRS duration is needed; the automatic computer measurement can fail to include the terminal deflection and thus may underestimate the true value. When a patient is assessed for CRT, it is important to concomitantly consider ICD candidacy; the overwhelming majority of candidates meets criteria for both, and these functions can be coupled into one implanted device (i.e., a CRT-D system, which includes a defibrillator). That said, it is important to recognize that CRT can be offered without the defibrillator for patients who do not want shocks and can still be offered as an excellent palliative therapy for class IV heart failure, for example.

Whereas the original studies with CRT included patients with moderate to advanced heart failure, researchers have more recently begun to examine the role of CRT for patients with less advanced heart failure. In the Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction (REVERSE) study, researchers assessed the effects of CRT in 610 patients with NYHA functional class I and II heart failure who had had previous symptoms of heart failure.<sup>29</sup> These

**FIGURE 47-5** Kaplan-Meier estimates of the time to the primary endpoint of death from or hospitalization for any cause (A), the time to the secondary endpoint of death from any cause (B), the time to death from or hospitalization for cardiovascular causes (C), and the time to death from or hospitalization for heart failure (D) in the Comparison of Medical Therapy, Resynchronization, and Defibrillation Therapies in Heart Failure (COMPANION) trial.  $P$  values are for the comparison with optimal pharmacological therapy. (Modified from Bristow MR, Saxon LA, Boehmer J, et al. Cardiac-resynchronization therapy with or without an implantable defibrillator in advanced chronic heart failure. *N Engl J Med* 2004;350:2140-2150.)

**FIGURE 47-6** Kaplan-Meier analysis of the time to death from any cause or an unplanned hospitalization for a major cardiovascular event (**A**) and death from any cause (**B**) in patients receiving standard pharmacological therapy and cardiac resynchronization therapy (CRT) in the Cardiac Resynchronization in Heart Failure (CARE-HF) trial. (Modified from Cleland JG, Daubert JC, Erdmann E, et al. The effect of cardiac resynchronization on morbidity and mortality in heart failure. *N Engl J Med* 2005;352:1539-1549.)

patients, who also had a QRS interval of 120 msec or longer and an LVEF of 40%, received a CRT device and were randomly assigned (in a ratio of 2:1) to receive active CRT (CRT-ON) or to the control condition (CRT-OFF) for 12 months. The primary endpoint of the study was a composite score (better, worse, or same); 16% of the subjects experienced worsening in CRT-ON, in comparison with 21% in the CRT-OFF condition ( $P = .10$ ). However, patients in the CRT-ON condition experienced a greater improvement in left ventricular end-systolic volume index and other measures of left ventricular remodeling. Although the 12- and 18-month follow-up analyses of REVERSE did not demonstrate improvements in patients' functional status, the prospectively planned 24-month analysis of REVERSE revealed that patients in the CRT-ON condition had less clinical worsening, with a 62% relative risk reduction in time to first hospitalization or death, in comparison with those who did not receive therapy.<sup>30</sup> The Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy (MADIT-CRT trial) was a multicenter, double blind randomized clinical trial designed to address the potential survival and morbidity benefit of CRT in NYHA class I and II heart failure patients. The primary endpoint of the trial was the reduction in the risk of death and non-fatal heart failure events.<sup>31</sup> Prophylactic CRT combined with an ICD was compared to ICD only in 1,820 patients with EF  $\leq 30\%$ , QRS  $\geq 130$  msec, and either an ischemic (class I patients) or any (class II patients) etiology. During the average follow-up of 2.4 years, the primary endpoint of death from any cause or nonfatal heart-failure event occurred in 17.2% of the CRT-ICD group versus 25.2% of the ICD only group, with

a relative risk reduction of 34% (FIR 0.66, 95% confidence interval 0.52 to 0.84,  $p=0.001$ ) (Figure 47-7). This significant benefit was driven by a 41% reduction in heart failure events, (139% vs 22.8%, HR 0.59, 95% confidence interval 0.47 to 0.74,  $p < 0.001$ ). In terms of pre-specified subgroups, both ischemic and non-ischemic groups showed benefit with CRT; however, a greater benefit was noted for women versus men and in patients with QRS  $\geq 150$  msec. Another factor predicting CRT responsiveness in this trial was QRS morphology, as patients benefitting most had left bundle branch block (LBBB).<sup>31a</sup> Together, REVERSE and MADIT-CRT support the expansion of the CRT indication to the population of NYHA class I and II patients.

## Special Considerations

Special considerations in CRT include the presence of a right bundle branch block on surface electrocardiogram, the presence of mechanical dyssynchrony with narrow QRS complex, and the absence of mechanical dyssynchrony with a wide QRS complex. A right bundle branch pattern is suggestive of early activation of the left ventricle and therefore should preclude any benefit from pacing the posterolateral left ventricle with a coronary sinus lead. However, many of the CRT responders in the previously cited trials did indeed have a right bundle branch block. With regard to mechanical dyssynchrony and a narrow QRS complex, the Resynchronization Therapy in Normal QRS (RETHINQ) trial<sup>32</sup> was an evaluation of 172 patients with NYHA class III or IV heart failure, LVEF of 35% or lower, QRS interval of 130 msec or less, and mechanical dyssynchrony demonstrated by tissue Doppler imaging. These patients were randomly assigned to receive CRT or no pacing; at 6 months, there was no reduction in the primary endpoint of peak myocardial oxygen consumption, assessed by metabolic stress test. However, there was a suggestion of benefit among the subgroup of patients with QRS duration between 120 and 130 msec. Most experts would not deny CRT to a patient with a wide QRS complex who otherwise meets current criteria without mechanical dyssynchrony demonstrable by echocardiography, inasmuch as this was not an inclusion criterion in either the COMPANION or MIRACLE study.

## Coronary Sinus or Left Ventricular Epicardial Lead Placement

CRT devices are placed by means of the same fundamental device implant technique described previously, with the addition of a third lead intended for the coronary venous circulation. The coronary sinus is cannulated, usually with a sheath that permits venographic visualization of potential target cardiac vein branches into which the lead is guided. The venous branch with a posterolateral distribution mimicking the posterolateral circumflex artery is typically selected because the classic CRT candidate has activation delay in the left posterolateral wall. Anterior and inferior branches are typically avoided. The coronary sinus can be difficult to cannulate in the case of an atretic vein or, more commonly, valves located over the ostium. Epicardial leads can be placed with a limited thoracotomy approach when the operator is unable to access the coronary sinus or find a suitable branch. Once a suitable anatomical site is localized, pacing is performed to assess thresholds and to rule out diaphragmatic stimulation, which can commonly occur by inadvertent stimulation either of the phrenic nerve or of the diaphragm muscle itself. Low pacing thresholds are desirable, to maximize the device's battery life and minimize the number of invasive procedures required for generator change, and the absence of diaphragm capture is essential for patient comfort. Lead placement is confirmed by a postprocedure chest radiograph (Figure 47-8).

**FIGURE 47-7** Kaplan—Meier Estimates of the Probability of Survival Free of Heart Failure in MADIT-CRT. There was a significant difference in the estimate of survival free of heart failure between the group that received CRT—ICD and the group that received an ICD only (unadjusted  $P < 0.001$  by the log-rank test). (Modified from Moss AJ, Hall WJ, Cannom DS, et al. Cardiac resynchronization therapy for the prevention of heart failure events. *N Engl J Med* 2009; 361:1329-1338).

## Summary of Cardiac Resynchronization Therapy

CRT is an efficacious therapy with morbidity- and mortality-related benefits for patients who meet the inclusion criteria. However, some patients do not respond, and a small number, in fact, paradoxically worsen. The relationship between lead placement and electrical-mechanical activation has not been fully explored. Local myocardial properties at the pacing site (such as infiltration or scar) may also influence outcomes, and variations in cardiac venous anatomy always present a significant challenge and barrier to transvenous CRT. Therefore, the precise mechanism of benefit and even the underlying pathological mechanisms for CRT remain incompletely understood. Much remains to be learned, and technological refinements need to be made, but CRT will remain a standard of care.

## DEVICE DIAGNOSTICS

For decades, devices have provided diagnostic information on cardiac arrhythmias in heart failure to managing clinicians. Such data can be used to guide decisions about antiarrhythmic therapy, may hint at the development of myocardial ischemia or electrolyte imbalances (through a recent increase in ventricular ectopy, for example), and can be used to diagnose occult atrial arrhythmias, such as atrial fibrillation, that can point to the need for anticoagulation for stroke prevention. Furthermore, pacemaker and ICD diagnostics provide data on underlying rhythm, pacemaker dependence, and intrinsic function of the sinus and atrioventricular nodes. In fact, a noninvasive electrophysiological study can be performed in which the atrial and ventricular leads are used to assess inducibility for ventricular arrhythmias—a feature not commonly used.

The technology of device monitoring has also grown tremendously. Originally, patients had to come to clinic in person for device diagnostics and reprogramming. Remote interrogation enabled patients to transmit device diagnostics information over the phone instead. The newest horizon is in remote wireless interrogation. In the PreFER Managed Ventricular Pacing (PreFER) study,<sup>33</sup> 897 patients were randomly assigned to undergo new wireless-capable device monitoring or classic rhythm strip phone monitoring; events were verified by in-person clinic interrogation in both groups. At approximately

**FIGURE 47-8** Typical posteroanterior (left) and lateral (right) chest radiographic views, demonstrating inappropriate coronary sinus lead placement in an anterolateral venous branch (A) and optimal posterolateral venous positioning (B).

1 year, the detection rate for clinically important events (such as atrial or ventricular arrhythmias) was significantly higher with the wireless devices, and a surprisingly high percentage of events was, in fact, missed in the rhythm strip device.

In addition to arrhythmias, device-reported hemodynamic data in patients with heart failure are important. Perhaps the best studied modality is one that records and reports intrathoracic impedance as an index of pulmonary edema and can provide additional clues that the patient may imminently require hospitalization. The newest investigational technology involves optical sensing from the device that can measure pulse oximetry and extrapolate blood pressure. This might be used as an index to assess the hemodynamic stability of a given rhythm and, it is hoped, prevent inappropriate shocks. Within an “intermediate” tachycardia zone (e.g., 150 to 170 beats per minute), the device could potentially incorporate such measurement into its algorithm in determining whether to initiate therapy. Atrial rhythms such as sinus tachycardia, atrial fibrillation, or other supraventricular tachycardias that are hemodynamically tolerated should maintain favorable blood pressure and pulse oximetry recordings, and a shock would not be administered. Hemodynamically intolerable “slow” ventricular arrhythmias would, conversely, trigger therapy.

Implantable loop recorders are yet another modality by which important data can be gleaned about heart failure. A much smaller device with telemetry capability is implanted prepectorally and can record arrhythmia activity extending over a period of several months—far beyond what an event monitor can record. Future implantable loop records will also probably report hemodynamic data.

## FUTURE DIRECTIONS

Device technology for heart failure has undergone extraordinary growth and is increasingly meeting the broad goals outlined in this chapter’s introduction. Current and future research is directed at better identifying patients at risk for

sudden cardiac death and identifying both the underlying mechanisms and application of cardiac resynchronization. Subsequent generations of devices will aim to provide increasingly sophisticated hemodynamic data, monitoring, and modalities to minimize inappropriate shocks. Future development in nanotechnology, stem cell therapy, and biopacemakers will also probably reshape this field.

comparison with heart failure with depressed ejection fraction (commonly referred to as *systolic heart failure*); however, there is consensus that HFPEF is a condition associated with substantial morbidity and mortality, and the frequency of clinical events increases markedly once a patient is hospitalized for heart failure. One review suggested that once hospitalized for heart failure, patients with HFPEF have high rates of rehospitalization; up to a third may be readmitted for exacerbation of heart failure within a year, and 45% to 60% may be rehospitalized for any reason.<sup>1</sup> Similarly, once such patients are hospitalized, the mortality rate may be as high as 22% to 29% at 1 year and approximately 65% at 5 years.<sup>6,11</sup> However, this population has been underrepresented in most randomized clinical trials in heart failure. In fact, researchers examining secular trends of heart failure within Olmsted County found that survival improved significantly over time among patients with heart failure and reduced ejection fraction (probably in relation to use of evidence-driven therapies), but no such trend toward improvement was noted for patients with HFPEF.<sup>6</sup> Therefore, effective treatment strategies for the management of patients with this condition are urgently needed.

## DEVELOPMENT OF TREATMENT STRATEGIES BASED ON PATHOPHYSIOLOGY OF HFPEF

The development of treatment strategies for HFPEF is based on the currently evolving understanding of the pathophysiological processes of this condition (see Chapter 14). HFPEF commonly afflicts elderly patients with such comorbid conditions as hypertension, left ventricular (LV) hypertrophy, diabetes mellitus, myocardial ischemia, and obesity. Of these risk factors, hypertension and subsequent LV hypertrophy are the most prevalent and are highly associated with HFPEF. Less commonly, HFPEF occurs as a result of restrictive and infiltrative cardiomyopathies and transplant rejection.<sup>12</sup> In the presence of the conditions just mentioned, clinical symptoms and signs of heart failure are commonly precipitated by concomitant anemia, pulmonary disease, renal insufficiency, and atrial fibrillation. In patients with HFPEF, in the absence of significant valvular or pericardial disease,

diastolic dysfunction consisting of abnormalities of LV relaxation and increased LV stiffness has long been thought to be the central pathophysiological process contributing to the development of heart failure.<sup>13-15</sup> The term *diastolic heart failure* has been used to describe this condition. Although mechanistic studies have demonstrated that abnormalities of diastolic function are invariably present in HFPEF, there is some disagreement concerning the relative contribution of diastolic dysfunction to clinical heart failure in elderly persons, because diastolic dysfunction is highly prevalent in this population even in the absence of clinical heart failure. However, it is likely that these patients frequently experience clinical decompensation when the aforementioned precipitants occur in the presence of the underlying substrate of diastolic dysfunction. Decompensated heart failure would be unlikely to occur when the same precipitants occur in patients without underlying diastolic dysfunction.

Factors other than diastolic dysfunction have also been suggested to contribute to the development of HFPEF; these include increased vascular and LV systolic stiffness, volume overload secondary to renal disease with abnormal renal sodium handling, atrial dysfunction, neurohumoral activation (specifically of the renin-angiotensin-aldosterone system [RAAS]), reduced vasodilator reserve, and chronotropic incompetence during exercise.<sup>16-19</sup> Aging is associated with a reduction in the elastic properties of the heart and vasculature along with an increase in systolic blood pressure. This probably contributes to the much higher prevalence of HFPEF in elderly persons. In addition, the comorbid conditions described previously are more common among elderly patients, contributing further to the increasing prevalence of this condition with increasing age.

The following sections in this chapter provide an overview of therapeutic modalities that may be effective in patients with HFPEF, with regard to either symptomatic benefit or targeting pathophysiological mechanisms. The clinical approach to management of HFPEF is then summarized on the basis of current evidence and consensus opinion.

## Treatment of Volume Overload and Congestion

Although diuretics may not alter the pathophysiological processes responsible for HFPEF, they do reduce ventricular filling pressures and are therefore very useful in relieving symptoms in patients with pulmonary vascular congestion and peripheral edema (see Chapter 44). Some patients with the classic profile of “diastolic heart failure” with significant left hypertrophy and small LV volumes may exhibit a fall in cardiac output with rapid diuresis, which results in hypotension and prerenal azotemia. This is caused by an LV diastolic pressure-volume curve that is so steep that a small change in diastolic volume causes a large change in pressure and cardiac output.<sup>15</sup> Diuretics may also benefit patients through other potential pathogenic mechanisms. First, it is known that the right ventricle forms the external pressure for approximately one third of the surface area of the left ventricle.<sup>12,20</sup> Therefore, elevation of right-sided diastolic pressures can constrain the filling of the left ventricle. In some patients, reduction of right-sided diastolic pressures by diuretics may unload the interventricular septum, improving LV distensibility,<sup>21</sup> and may therefore help reduce pulmonary venous pressures while maintaining LV filling and cardiac output. Maurer and colleagues<sup>18</sup> demonstrated that in a subgroup of patients with hypertensive HFPEF, the LV end-diastolic pressure-volume relationship may be shifted rightward with somewhat increased end-diastolic volumes (in contrast to the classic paradigm of diastolic heart failure with leftward and upward shifts in the end-diastolic pressure-volume relationship and smaller LV volume). This may be a result of a volume overload state exacerbated by extracardiac factors such as renal dysfunction with abnormal renal sodium handling, obesity, and anemia. This situation could also represent a group of patients who would respond more favorably to diuretic therapy. Last, low-dose diuretics, especially thiazide diuretics, are useful in the treatment of hypertension, which plays a key pathophysiological role in HFPEF.<sup>22,23</sup> Some patients with volume overload that is refractory to increasing doses of diuretics may be candidates for ultrafiltration (Chapter 44).

Furthermore, therapy with nitrates may also provide symptomatic benefit in patients with HFPEF with pulmonary vascular congestion. Nitrates are primarily venodilators with some arterial vasodilating action. They may benefit patients with HFPEF by reducing preload, which leads to reductions in ventricular filling pressures and in pulmonary congestion. In acute decompensated heart failure, they can be used intravenously and may improve symptoms by reducing filling pressures, as well as by controlling systemic hypertension. Theoretically, by releasing nitric oxide, nitrates may improve the diastolic distensibility of the ventricle.<sup>24,25</sup> As with diuretics, caution is required when nitrates are used in patients without hypertension or with severe diastolic dysfunction; they must be monitored for a significant reduction in cardiac output and blood pressure as a result of preload reduction.

## Treatment of Hypertension (see Chapter 28)

Of the various risk factors involved in the development of HFPEF, hypertension and subsequent LV hypertrophy are the most prevalent and most highly associated with the condition. The significant contribution of hypertensive heart disease to the development of diastolic dysfunction and HFPEF (reviewed by Hoit and Walsh<sup>26</sup>) implies that treating hypertension should be beneficial not only for the treatment of HFPEF but also for its prevention (see Chapter 41). For example, the increased afterload imposed by significant arterial hypertension reduces LV relaxation and filling rates.<sup>27</sup> Stiffening of the aorta and

the left ventricle, as occurs in elderly patients with HFPEF, increases the tightness of the coupling of arterial systolic and left atrial pressures, with increases in systolic arterial pressure resulting in elevation of left atrial pressures.<sup>12,16,28</sup> Controlling systolic hypertension could allow the left ventricle to eject to a smaller end-systolic volume, thus allowing the ventricle to operate with a smaller diastolic volume and reduced left atrial pressure. Lowering the systolic pressure allows the left ventricle to relax more rapidly, which enhances early filling.<sup>29</sup>

In addition, concentrically hypertrophied hearts demonstrate increased passive stiffness and impaired relaxation independent of hemodynamic loads, and have limited coronary vascular reserve, which can contribute to myocardial ischemia even in the absence of epicardial coronary artery disease. Adequate control of hypertension should benefit patients with HFPEF by, in the short term, favorably altering loading conditions and, in the long term, by leading to regression of LV hypertrophy. There may be some additional benefits of using one class of drugs versus others,<sup>22</sup> but the most important goal is achieving an adequate reduction in blood pressure. Results of several studies of reduction of blood pressure with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) in comparison with other agents have suggested that ultimately blood pressure control, rather than the specific class of antihypertensive agents used, may be the major determinant of regression of hypertrophy and improvement in diastolic function.<sup>23,30-33</sup> Moreover, trials have definitively demonstrated approximately a 50% reduction in the incidence of heart failure among patients treated for hypertension, especially in the elderly population.<sup>34,35</sup>

Drugs such as  $\beta$ -blockers and calcium channel blockers that reduce blood pressure and heart rate and thus indirectly improve diastolic function, as well as increase diastolic filling time, may be beneficial in patients with HFPEF. On the other hand, the direct myocardial effects of slowing the relaxation rate of the ventricle and the negative inotropic actions of these drugs may be detrimental with regard to diastolic function.<sup>12</sup> In addition, one study demonstrated that during exercise, patients with HFPEF achieved less of an increase in heart rate (inadequate chronotropic response), and thus less of an increase in cardiac output, despite a similar rise in end-diastolic volume, stroke volume, and contractility than did matched subjects with hypertensive cardiac hypertrophy.<sup>17</sup> These data raise questions regarding possible deleterious effects of heart rate-reducing drugs such as  $\beta$ -blockers and certain calcium channel blockers in patients in whom exercise capacity may be reduced partly as a result of reduced chronotropic reserve.

Over the years, a number of small studies of calcium channel blockers,  $\beta$ -blockers, ACE inhibitors, and ARBs have yielded variable results suggestive of modest improvements in exercise capacity, New York Heart Association (NYHA) class, quality of life, and diastolic function in patients with HFPEF.<sup>36-39</sup> However, until recently, none of the studies performed was a large or randomized multicenter trial and thus definitive evidence of benefit on longer-term outcomes was not available.

## $\beta$ -Blockers

In a smaller trial, the Swedish Doppler-Echocardiographic study (SWEDIC), researchers examined the effect of the  $\beta$  blocker carvedilol on diastolic function in patients with HFPEF (left ventricular ejection fraction [LVEF] > 45%) who also met conventional Doppler criteria for diastolic dysfunction.<sup>40</sup> Ninety-five patients completed the 6-month study. There were no significant differences between the patients who received carvedilol and those who received placebo in

the primary endpoint, a composite of improved, unchanged, or worsened diastolic function, or in clinical endpoints. At baseline, the majority of patients had only mild diastolic dysfunction and had NYHA class I or II functional status; this made it more difficult to detect improvement in these parameters.

In another multicenter trial, researchers evaluated the effects of nebivolol in elderly patients with heart failure, irrespective of LVEF. Nebivolol is a  $\beta_1$ -selective blocker that also has vasodilating properties related to nitric oxide modulation and improves arterial distensibility.<sup>41</sup> In the Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalisations in Seniors with Heart Failure (SENIORS), 2128 patients aged 70 years or older with a history of heart failure were randomly assigned to receive nebivolol or placebo.<sup>42</sup> Of these patients, 752 patients (35%) had LVEF exceeding 35%. In the overall study, nebivolol was associated with a modest 14% reduction in the primary composite endpoint of death and cardiovascular hospitalization (hazard ratio [HR], 0.84; 95% confidence interval [CI], 0.74 to 0.99), influenced by a reduction in both mortality and hospitalization for cardiovascular causes. A similar magnitude of reduction was noted in the subgroup with LVEF higher than 35%; however, it did not reach statistical significance, possibly because fewer patients were in the subgroup (HR, 0.82; 95% CI, 0.63 to 1.05). Although considered to have preserved ejection fraction or HFPEF, this subgroup of patients, whose ejection fraction was higher than 35%, was clearly heterogeneous, with both preserved and reduced LVEF. The proportion of patients with truly preserved LVEF ( $\geq 50\%$ ) was small (<15% of all patients in the trial). Also, the effect of nebivolol on hospitalizations for heart failure was not reported.<sup>42</sup> Although the overall results of the trial were suggestive of a modest cardiovascular benefit of the  $\beta$ -blocker nebivolol in elderly patients with heart failure, they did not convincingly demonstrate a benefit in elderly patients with HFPEF.

## Renin-Angiotensin-Aldosterone Blockade

As in systolic heart failure, preclinical and clinical evidence suggests that the activation of the RAAS is a contributing factor in the development of HFPEF, principally through the trophic effects of angiotensin II on the vasculature and myocardium, but perhaps also through myocardial fibrosis mediated by aldosterone.<sup>43,44</sup> In addition, angiotensin II slows LV relaxation, which results in elevation of LV diastolic pressures.<sup>45,46</sup> Therefore, agents such as ACE inhibitors and ARBs, which are antihypertensive agents and attenuate the effects of angiotensin II, appeared to be attractive options in the treatment of HFPEF. Furthermore, clinical trials have shown ACE inhibitors and ARBs to be effective in improving cardiovascular outcomes in populations with diabetes, coronary artery disease, vascular disease, and hypertension<sup>47,48</sup>; these comorbid conditions are frequently present in and contribute to the development of HFPEF.

On the basis of a strong theoretical rationale for RAAS blockade in patients with HFPEF,<sup>39</sup> three large, randomized clinical trials were designed specifically to evaluate ACE inhibitors and ARBs in patients with HFPEF: the Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity–Preserved (CHARM–Preserved) trial, the Perindopril in Elderly People with Chronic Heart Failure (PEP–CHF) trial,<sup>49,50</sup> and the Irbesartan in Heart Failure with Preserved Ejection Fraction (I–PRESERVE) trial.<sup>51</sup> The characteristics of the patient populations evaluated in these three trials are summarized in Table 48-1.

Of the 3023 patients enrolled in the CHARM–Preserved trial, almost 20% were taking ACE inhibitors and 56% were taking  $\beta$ -blockers at the time of random assignment to receive candesartan or placebo. After a median follow-up period of

36.6 months, the primary endpoint of the study (death from cardiovascular causes or hospitalization for heart failure) occurred in 22% of the candesartan recipients and 24% of the placebo recipients (HR, 0.89; 95% CI, 0.77 to 1.03;  $P = .118$ ; covariate-adjusted HR, 0.86; 95% CI, 0.74 to 1.00;  $P = .051$ ) (Figure 48-1). The difference, which was of borderline statistical significance only for the adjusted hazard ratios, was driven mostly by a difference in hospitalizations for heart failure between the candesartan- and placebo-treated subjects (HR, 0.85; 95% CI, 0.72 to 1.01;  $P = .072$ ); the two groups had almost identical rates of mortality from cardiovascular causes (Figure 48-2). In addition, the total number of hospitalizations for heart failure was noted to be significantly lower among the candesartan recipients. Within 6 months after the trial began, the blood pressure was significantly more reduced in the candesartan recipients (6.9 mm Hg systolic and 2.9 mm Hg diastolic) than in the placebo recipients ( $P < .0001$ ). It is therefore difficult to tease out whether the modest 15% relative reduction in hospitalizations for heart failure among candesartan recipients with HFPEF was mostly a result of blood pressure reduction or any other more specific angiotensin-blocking effects of candesartan and whether any other drugs causing similar blood pressure reduction would have led to similar effects. The lack of a greater benefit from the use of the ARB in CHARM–Preserved may also have been influenced by the fact that ACE inhibitors were allowed for patients in the trial—20% of patients were taking ACE inhibitors even at the beginning of the trial—and the fact that annual event rates of the primary composite outcome were relatively lower than expected (9.1%) among the placebo recipients.

In the PEP–CHF trial of perindopril in HFPEF, the patient population was older than that in the CHARM–Preserved trial (see Table 48-1). However, the results of the study were neutral with regard to the primary outcome and demonstrated only a trend toward modest benefit in other endpoints.<sup>50</sup> In comparison with the CHARM–Preserved trial, the PEP–CHF study enrolled only 850 patients with HFPEF, who, in addition to having relatively preserved ejection fraction, also had objective evidence of diastolic dysfunction at enrollment. The mean follow-up period of 26.2 months was shorter than that in the CHARM–Preserved trial. The event rate was much lower than expected, and despite a much longer follow-up period than originally intended, only 46% of the expected events occurred; thus, the study had only 25% power to show a difference in the primary endpoint. Furthermore, a large number of patients stopped their assigned treatment after 1 year, and most of them started taking open-label ACE inhibitors (discontinuation rate of 38% at 18 months;  $\approx 36\%$  of patients were receiving open-label ACE inhibitor treatment by the end of the study).

Over the entire duration of follow-up, perindopril was not associated with an improvement in the primary composite endpoint of death or hospitalization for heart failure (HR, 0.92; 95% CI, 0.70 to 1.21;  $P = .55$ ) (Figure 48-3, A). However, an analysis confined to 1 year of follow-up—at which point most patients were still taking the assigned medication—revealed that perindopril was associated with a 31% relative reduction in the primary endpoint (HR, 0.69; 95% CI, 0.47 to 1.01;  $P = .055$ ), which was of borderline statistical significance. Similarly, although perindopril was not associated with a benefit in hospitalization for heart failure over the entire duration of the trial (see Figure 48-3, B), at 1 year of follow-up, the perindopril recipients had a lower rate of hospitalizations for heart failure (HR, 0.63; 95% CI, 0.41 to 0.97;  $P = .03$ ). Thus, although perindopril did not have a beneficial effect on the overall primary outcome, there was a suggestion of reduction in hospitalizations for heart failure at 1 year when patients were on assigned treatment.<sup>50</sup>

In addition, significant improvements were observed in comparison with the placebo recipients in some other

secondary endpoints, including the proportion of patients with NYHA functional class 1 and change in 6-minute walking distance at 1 year. As observed in the CHARM-Preserved trial, the active drug in PEP-CHF produced a significantly greater reduction in systolic blood pressure (mean difference, 3 mm Hg;  $P = .03$ ) than did placebo. Furthermore, patients with a higher baseline blood pressure appeared to have a greater benefit with perindopril. Therefore, as in the CHARM-Preserved trial, it is not possible to rule out a significant contribution of the blood pressure-lowering effect of the ACE inhibitor, as opposed to other RAAS-blocking actions of perindopril, to the observed beneficial effect on hospitalizations

for heart failure. Also, both trials illustrate the encountered difficulty of lower event rates among patients enrolled in clinical trials than in the general population with the same condition. The switch to open-label ACE inhibitors illustrates the many existing indications for administration of ACE inhibitors or ARBs to patients with vascular disease, diabetes, and hypertension, the same group of comorbid conditions that are frequently encountered in patients with HFPEF, thus potentially limiting the opportunities to add ACE inhibitors or ARBs specifically for HFPEF.

The largest and most recently completed trial, I-PRESERVE, enrolled 4128 patients with HFPEF (see Table 48-1).<sup>51</sup>

The patients were randomly assigned to receive the ARB irbesartan or placebo daily. During a mean follow-up period of 49.5 months, there was no significant difference in the occurrence of the primary outcome of death or hospitalization for heart failure (Figure 48-4) between patients taking irbesartan and those receiving placebo (HR, 0.95; 95% CI, 0.86 to 1.05;  $P = .35$ ). Overall rates of death were also similar (HR, 1.00; 95% CI, 0.88 to 1.14;  $P = .98$ ), as were rates of hospitalization for cardiovascular causes, hospitalization for heart failure, and other secondary outcomes. In comparison with the CHARM-preserved trial, the I-PRESERVE trial involved more patients, slightly better preserved ejection fraction ( $\geq 45\%$  vs.  $>40\%$  in CHARM-Preserved), greater specificity of the substrate for HFPEF, and a higher proportion of older patients and women (i.e., a study cohort more representative of the “real world” HFPEF population); however, the I-PRESERVE trial did not provide any evidence for overall benefit of ARBs with regard to cardiovascular outcomes in this population of patients.

In addition to the larger trials just described, the results of a smaller trial, the Hong Kong Diastolic Heart Failure Study (PROBE), have also been reported (see Table 48-1).<sup>52</sup> Although the drug assignment was open label, there was blind endpoint evaluation. The three treatment arms consisted of diuretics,

diuretics plus ramipril, and diuretics plus irbesartan. At 52 weeks, no differences were noted in quality of life, recurrent hospitalizations, or LV dimensions in the three treatment groups. However, the peak systolic and early diastolic mitral annular velocities viewed on tissue Doppler imaging increased slightly, albeit significantly, and N-terminal pro-B-type natriuretic peptide (NT-proBNP) levels decreased significantly only in patients taking irbesartan and ramipril, but not in those taking only diuretics. This was the first comparative trial of ACE inhibitors with ARB therapy in patients with HFPEF that was treated with a diuretic. However, the sample size was small and powered only to detect a large effect size of 50% improvement in clinical endpoints. Thus, apart from a signal for a modest improvement in diastolic function with the addition of ACE inhibitors or ARB therapy, this smaller trial was also unable to provide clinical evidence of benefit with angiotensin blockade in patients with HFPEF.<sup>53</sup>

Another large multicenter trial with the aldosterone antagonist spironolactone is currently ongoing in patients with HFPEF. This trial, Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT), is designed to examine the effects of the aldosterone antagonist therapy in 4500 patients with HFPEF (LVEF  $\geq 45\%$ ) with a composite morbidity-mortality endpoint (Table 48-2). Study completion is anticipated in 2011. Although ACE inhibitors and ARBs have not proved to have a major beneficial effect on clinical outcomes in HFPEF, it remains to be seen whether aldosterone antagonists have more success; aldosterone plays a major role in stimulating myocardial collagen formation and in inhibiting the turnover of extracellular matrix.

## Digoxin

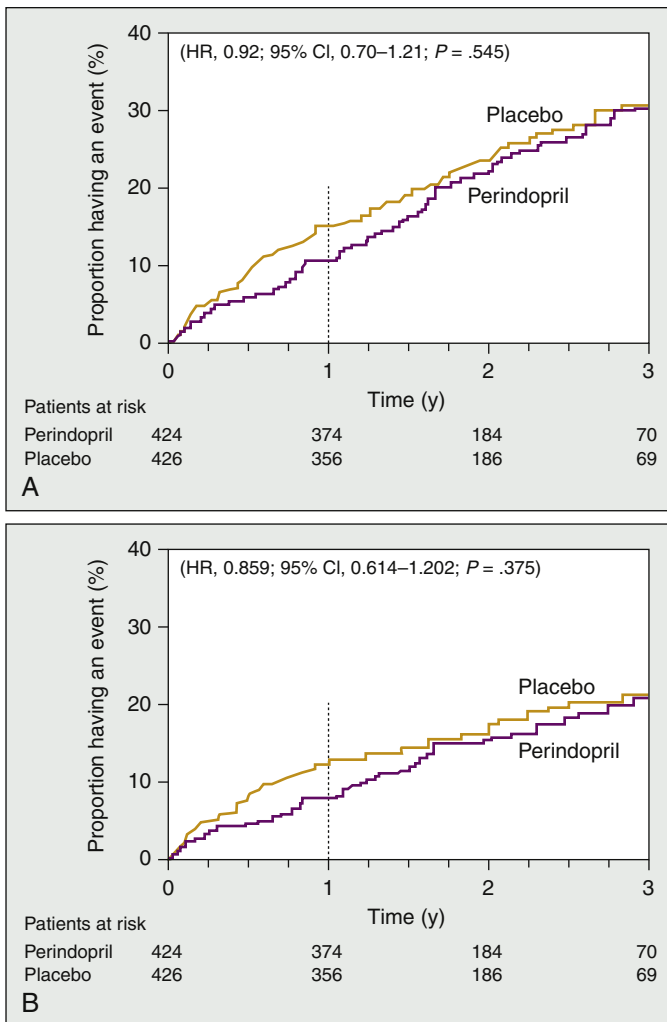

Digoxin is one of the oldest drugs that has been used in the management of heart failure, but it has been historically thought to be contraindicated in HFPEF.<sup>54</sup> Theoretical considerations suggest potential benefit, as well as harm, from digoxin in this group of patients. For example, digoxin may improve the active energy-dependent myocardial early diastolic function and may improve the neurohormonal profile in patients with HFPEF.<sup>54,55</sup> However, it may produce an increase in systolic energy demands, adding to a relative calcium overload in diastole, especially during periods of hemodynamic stress or ischemia, and may thus contribute to diastolic dysfunction.<sup>15</sup> The Digitalis Investigators Group (DIG) investigated the effects of digoxin on morbidity and mortality in patients with heart failure in normal sinus rhythm, the majority of whom had systolic heart failure.<sup>56</sup> However, the trial population also included a small group

The occurrence of the endpoint at 1 year of follow-up is specified on the red dotted line. CI, confidence interval. (From Cleland JG, Tendera M, Adamus J, et al. The Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) study. *Eur Heart J* 2006;27:2338-2345.)

of patients with HFPEF (ejection fraction > 45%). In a post hoc analysis, among the 988 patients with chronic HFPEF, digoxin had no significant effect on the composite primary endpoint of mortality from heart failure and hospitalizations for heart failure (HR, 0.82; 95% CI, 0.63 to 1.07;  $P = .14$ ).<sup>57</sup> Similarly, digoxin produced no benefit in the composite endpoint of mortality from cardiovascular causes and hospitalization for heart failure. Although the use of digoxin was associated with a trend toward a reduction in hospitalizations for worsening heart failure (HR, 0.79; 95% CI, 0.99 to 1.91;  $P = .09$ ), it was also associated with a trend toward an increase in hospitalizations for unstable angina (HR, 1.37; 95% CI, 0.99 to 1.91;  $P = .06$ ). Thus, digoxin was not associated with any overall reduction in hospitalizations for cardiovascular reasons.<sup>57</sup> This post hoc analysis suggests that digoxin should not be recommended as treatment for all patients with HFPEF except, if required, as an agent for rate control in patients with concomitant atrial fibrillation. As noted previously, the DIG trial had enrolled only patients in sinus rhythm.

## Endothelin Antagonists

Experimental studies have suggested that selective antagonists of endothelin type A (ET<sub>A</sub>) may exert beneficial effects in diastolic heart failure by attenuating the progression of LV hypertrophy and fibrosis, which results in improvement in diastolic function.<sup>58</sup> In addition, in patients with moderate to severe heart failure, acute ET<sub>A</sub> receptor blockade with the selective ET<sub>A</sub> antagonist sitaxsentan has caused selective pulmonary vasodilation. Therefore, sitaxsentan may also be of value in the treatment of patients with pulmonary hypertension secondary to chronic heart failure.<sup>59</sup> On the basis of these considerations, a double-blind, placebo-controlled study with sitaxsentan in 192 patients with HFPEF was undertaken. The patients were randomly assigned in a 2:1 ratio to receive either the active drug or placebo for 24 weeks. According to preliminary results, patients treated with sitaxsentan had a significant increase in treadmill exercise time (90 seconds) in comparison with placebo (37 seconds;  $P = .03$ ). No other differences in diastolic parameters, functional status, or clinical outcomes were noted.<sup>60</sup> The details of this study, as well as those of larger future studies, are awaited in order to evaluate whether this benefit will translate into better clinical outcomes in patients with HFPEF.

## CURRENT RECOMMENDATIONS FOR THE MANAGEMENT OF PATIENTS WITH HFPEF

The clinical diagnosis of HFPEF depends on the presence of clinical symptoms and signs of heart failure with preserved LVEF ( $\geq 45\%$  or  $\geq 50\%$ ) measured by any cardiac imaging technique such as echocardiography, radionuclide-enhanced ventriculography, contrast-enhanced ventriculography, or cardiac magnetic resonance imaging. The observation of diastolic abnormalities, elevated LV filling pressures and left atrial enlargement, and substrate for diastolic dysfunction (i.e., LV hypertrophy) on echocardiography may provide supportive evidence. The clinical confirmation of the diagnosis of heart failure, although considered rudimentary, is key especially in ruling out other causes of symptoms such as lung disease and obesity. Several conditions need to be considered in the differential diagnosis before the prototypic “diastolic heart failure” or

HFPEF can be treated. The algorithm suggested in the Heart Failure Society of America Heart Failure Practice Guidelines provides a useful framework for the initial workup of such patients (Figure 48-5).<sup>61</sup> Conditions that necessitate specific intervention—such as valvular heart disease, coronary artery disease, pericardial disease, isolated right-sided heart failure caused by primary pulmonary conditions, or contributing systemic conditions such as anemia and thyrotoxicosis—must be identified. Once these conditions are ruled out or treated, patients with HFPEF should be managed in accordance with general guidelines presented in Table 48-3. Treatment considerations can be broadly grouped in the following categories: treatment of volume overload, aggressive control of hypertension, treatment of factors contributing to decompensation (most commonly atrial fibrillation, ischemia, and anemia), and therapies based on associated cardiovascular diagnoses or risk factors. Although based on practice guidelines published by the American College of Cardiology/American Heart Association (ACC/AHA) and the Heart Failure Society of America, it should be noted that the majority of recommendations (other than the treatment of hypertension) are based on consensus opinion of experts rather than on definitive clinical trial data.

## FUTURE MODALITIES OF THERAPY IN HFPEF

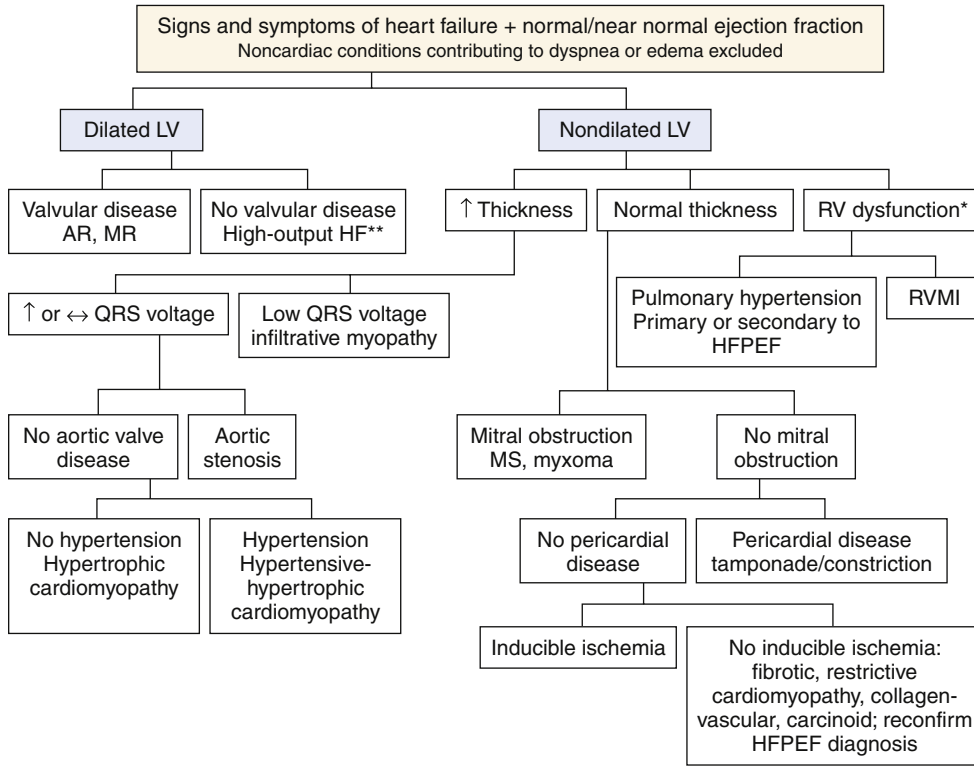

Potential novel modalities of therapy for HFPEF, some of which are under active investigation, are discussed as follows.

### Selective Phosphodiesterase-Type 5 Inhibition

Sildenafil is the one of the best known agents in a class of selective inhibitors of phosphodiesterase-5, which are known to enhance nitric oxide-mediated vasodilation by inhibiting degradation of cyclic guanosine monophosphate, a key intracellular second messenger.<sup>62</sup> Whereas inhibitors of the cyclic adenosine monophosphate (AMP)-specific phosphodiesterase-3 (including inotropic agents such as milrinone and enoximone) augment intracellular levels of cyclic AMP and increase mortality among patients with heart failure,<sup>63</sup> sildenafil is highly selective for human phosphodiesterase-5, does not increase cyclic AMP levels, and lacks inotropic effects. Therefore, it is not thought to share the toxicity associated with phosphodiesterase-3 inhibition.<sup>64</sup>

Several experimental observations suggest that sildenafil may be beneficial in the treatment of patients with HFPEF. In

**FIGURE 48-5** Diagnostic considerations in patients with heart failure with preserved ejection fraction (HFPEF). *Asterisk* indicates that some patients with right ventricular dysfunction have left ventricular dysfunction as a result of ventricular interaction. *Double asterisk* indicates, for example, anemia, thyrotoxicosis, and arteriovenous fistula. Copyright 2006, with permission from the Heart Failure Society of America.)

mice exposed to sustained pressure overload, chronic phosphodiesterase-5 inhibition led to attenuation of cardiac and myocyte hypertrophy, attenuation of interstitial fibrosis, and improvement in cardiac functioning.<sup>65</sup> Sildenafil treatment applied to well-established hypertrophic cardiac disease in mice also prevented further cardiac and myocyte dysfunction, as well as progressive remodeling.<sup>66</sup> These investigators demonstrated that phosphodiesterase-5 is upregulated in the heart in response to pressure overload and that the effects of phosphodiesterase-5 inhibition are not mediated by an effect on blood pressure. In addition, phosphodiesterase-5 inhibition has been associated with improvement in flow-mediated vasodilation in patients with systolic heart failure and an improvement in large artery stiffness in hypertensive men.<sup>67,68</sup> Beneficial effects on pulmonary vasculature with reduction in pulmonary pressures, as well as reduction in right ventricular hypertrophy, have been demonstrated in patients with pulmonary hypertension.<sup>69</sup> Furthermore, phosphodiesterase-5 inhibition may restore renal responsiveness to natriuretic peptides in several states of abnormal sodium handling, including heart failure.<sup>70</sup> Because phosphodiesterase-5 is upregulated in cardiovascular disease states such as heart failure, with resultant greater susceptibility to phosphodiesterase-5 inhibition in these disease states—along with the potential beneficial effects on LV hypertrophy, endothelial function, arterial stiffness, pulmonary hypertension and renal responsiveness to natriuretic peptides just summarized—the use of selective phosphodiesterase-5 inhibitors as therapeutic agents is being evaluated in the treatment of patients with HFPEF. As an initial step, the Phosphodiesterase-5 Inhibition to Improve Clinical Status and Exercise Capacity in Diastolic Heart Failure (RELAX) study, sponsored by the National Institutes of Health, is currently enrolling patients with HFPEF. Patients are randomly assigned to receive either sildenafil or placebo for 24 weeks in order to evaluate the effect of sildenafil on a number of intermediate outcomes, including exercise capacity, quality of life, diastolic function, LV mass, and peripheral vascular function (see Table 48-2).<sup>71</sup>

## Advanced Glycation End Products

Increased LV and arterial stiffness, which may be involved in the pathophysiology of HFPEF, especially in elderly subjects,<sup>16,72</sup> is at least partially contributed to by nonenzymatic crosslinks that develop between advanced glycation end products on long-lived proteins such as collagen and elastin. Alagebrium chloride nonenzymatically breaks these cross-links and has been shown to improve LV distensibility and arterial compliance in experimental animals.<sup>73</sup> Initial clinical experience with this agent also showed increased arterial compliance in elderly subjects with systolic hypertension.<sup>74</sup> These data suggest that alagebrium chloride may be beneficial in the treatment of HFPEF, especially in the setting of hypertension, diabetes, and aging. An initial open-label study evaluated the use of alagebrium chloride for 16 weeks in 23 elderly patients with stable heart failure and LVEF higher than 50%.<sup>75</sup> Alagebrium chloride was associated with a reduction of LV mass, improvement in tissue Doppler indices of diastolic function, and improvement in quality of life. However, there was no change in blood pressure, pulse pressure, peak oxygen consumption, or aortic distensibility. At this point, it remains to be seen whether the initial modest benefits observed with this agent will translate into reduction in clinical endpoints such as hospitalization for heart failure or in improvement of exercise capacity. A phase II, placebo-controlled, double-blind, randomized clinical trial, Beginning a Randomized Evaluation of the AGE [advanced glycation end] Product Breaker Alagebrium in Diastolic Heart Failure (BREAK) was intended to assess the effect of 6 months of oral treatment with alagebrium chloride versus placebo in 80 patients with HFPEF; however, it was halted for administrative reasons.<sup>71</sup>

## Lusitropic Agents

Another promising agent appeared to be MCC-135, an oral drug that improves lusitropy by enhancing calcium uptake by the sarcoplasmic reticulum and inhibiting the reverse mode of the sodium-calcium exchanger.<sup>76</sup> A double-blind,

**TABLE 48–3 Recommendations for the Treatment of HFPEF**

Recommendations	Strength of Recommendation*	Level of Evidence†
Control of systolic and diastolic hypertension as per published guidelines.	I	A
Control of ventricular rate in atrial fibrillation.	I	C
Diuretics to control pulmonary congestion and peripheral edema. (Treatment may be started with a thiazide or loop diuretic. Excessive diuresis may lead to orthostatic changes in blood pressure and worsening renal function. Counseling on the use of a low-sodium diet is recommended.)	I	C
Possible revascularization in patients with significant coronary artery disease and symptoms or demonstrable ischemia, in which ischemia may be regarded as a contributor to abnormal cardiac function.	IIa	C
Restoration and maintenance of sinus rhythm in certain patients with atrial fibrillation, which may be useful to control symptoms.	IIb	C
ACE inhibitors and ARBs in patients with controlled hypertension, which might be useful in minimizing symptoms of heart failure.	IIb	C
β-blockers, which might be effective in control of symptoms. They should be given greater consideration for patients with HFPEF and	IIb	C
• Prior myocardial infarction		A
• Hypertension		B
• Atrial fibrillation		B
Calcium channel blockers, for control of symptoms. They should be given greater consideration for patients with HFPEF and	IIb	C
• Atrial fibrillation necessitating control of ventricular rate when blockers have proven inadequate; diltiazem or verapamil should be considered		C
• Symptom-limiting angina		A
• Hypertension; amlodipine should be considered		C
Possibly digitalis, to minimize symptoms of heart failure	IIb	C

\*Strength of recommendations: I indicates a recommendation that treatment is useful or effective; IIa indicates a recommendation in favor of treatment's being useful or effective; IIb indicates greater conflicting evidence from multiple randomized trials or meta-analyses.

†Level of evidence: A indicates that data were derived from multiple randomized clinical trials or meta-analyses; B indicates that data were derived from a single randomized clinical trial or nonrandomized studies; C indicates only consensus opinion of experts, case studies, or standard of care.

randomized, placebo-controlled phase II trial of MCC-135 was completed in 2003 with 500 patients who had heart failure, 230 of whom had HFPEF.<sup>77</sup> However, the results have not been published to date, which suggests that beneficial effects may not have been noted.

## Treatment of Obstructive Sleep Apnea

Obstructive sleep apnea (OSA) has been detected in 11% to 37% of patients with heart failure with systolic dysfunction.<sup>78-80</sup> In a small study of HFPEF, sleep-disordered breathing was reported in more than 50% of patients with HFPEF; the majority of these patients had obstructive sleep apnea.<sup>81</sup> Patients with HFPEF and sleep-disordered breathing had worse diastolic dysfunction than did patients without sleep-disordered breathing. Unlike systolic heart failure, for which a number of studies have shown an increased prevalence of central sleep apnea, HFPEF may be more often associated with OSA. Several theoretical mechanisms may explain how OSA contributes to the development of diastolic dysfunction and heart failure.<sup>82</sup> The most direct mechanism may be through long-standing OSA, which induces LV dysfunction by raising blood pressure, a major risk factor for the development and progression of HFPEF.<sup>83</sup> It has been suggested that LV hypertrophy is linked to hypertension more closely during sleep than during wakefulness.<sup>84</sup> Thus, because hypertensive patients with OSA have higher nocturnal blood pressure than do those without OSA, they may be at greater risk in the long term for LV hypertrophy and heart failure. In patients with heart failure, the coexistence of OSA may also be associated with higher sympathetic nerve activity and higher systolic blood pressure during wakefulness, despite more intense antihypertensive therapy.<sup>85</sup>

Responses to cytokines, catecholamines, endothelin, and other growth factors produced in OSA may contribute to ventricular hypertrophy independently of hypertension, as suggested by the fact that LV wall thickness has been shown to be increased in normotensive patients with OSA, in comparison with normotensive control subjects. In addition, nocturnal oxygen desaturation is an independent predictor of impaired ventricular relaxation during diastole.<sup>86</sup> Increased negative intrathoracic pressure during obstructive apneas may also lead to increased LV wall tension and afterload, which may contribute to low stroke volume and cardiac output during OSA. Long-term recurrent exposure of the heart to markedly subatmospheric pressure during OSA could promote hypertrophy and diastolic dysfunction, in addition to the long-term effects of systemic hypertension. Furthermore, a leftward shift of the interventricular septum, which results from overdistention of the right ventricle during obstructive apneas, may also limit LV filling and thus decrease cardiac output. Some of the cardiovascular changes may be reversible with effective continuous positive airway pressure (CPAP) treatment.<sup>82,87</sup> However, at this time, little evidence is available regarding the benefit of CPAP on patients with HFPEF. In one small group of patients who had OSA but did not have hypertension, diabetes, or other factors that could contribute to diastolic dysfunction, 12 weeks of CPAP reportedly attenuated abnormalities in diastolic function.<sup>88</sup> Further studies are, however, needed to examine the clinical benefit of CPAP in patients with HFPEF.

## Potential Device Use in HFPEF

### Pacemakers

Patients with HFPEF have been reported to have chronotropic incompetence in response to exercise, and this may contribute to significant limitation of their physical activity. Borlaug and associates<sup>17</sup> showed that at matched low-level

workload, as well as at peak workload, patients with HFPEF had less of an increase in heart rate and in cardiac output and less systemic vasodilation than did control subjects, despite similar rises in end-diastolic volume, stroke volume, and contractility. Although these findings first raise questions about the conventional wisdom of using  $\beta$ -blockers (which are negative chronotropic agents) in patients with HFPEF, especially elderly patients, they also reveal a potential modality for treatment of HFPEF. The Restoration of Chronotropic Competence in Heart Failure Patients with Normal Ejection Fraction (RESET) trial (see Table 48-2) is intended to evaluate the effect of atrial rate-responsive pacing on exercise capacity and quality of life in patients with HFPEF.

#### Device-Based Treatment of Resistant Hypertension

A number of patients with HFPEF have uncontrolled hypertension that is resistant to a combination of multiple antihypertensive agents. The importance of the carotid sinus baroreceptors in modulating autonomic tone and regulating blood pressure (baroreflex mechanism) has long been recognized. It is also well established that the arterial baroreflex buffers short-term fluctuations in blood pressure. Although there has been some debate regarding its role in long-term blood pressure control, study results have suggested that the baroreflex system is important in chronic hypertension, and that renal sympathetic inhibition with a resultant increase in natriuresis may be one of the mechanisms by which the baroreflex participates in long-term blood pressure control.

Animal and human studies have demonstrated a safe and effective lowering of blood pressure with chronic electrical stimulation of the carotid sinus. The postulated mechanism is that activation of the baroreceptors is interpreted by the brain as elevation in blood pressure; as a result, cardiac parasympathetic tone is activated, and sympathetic outflow to the heart, kidneys, and peripheral vasculature is diminished.<sup>89-95</sup> The most recent studies have been performed with the Rheos System (CVRx, Inc.). The system consists of an implantable pulse generator, the energy from which is conducted through leads to the left and right carotid sinuses, resulting in carotid sinus stimulation. Use of the device has been associated with significant improvement in blood pressure sustained over 2 to 3 years (reduction of  $\approx 30/20$  mm Hg) along with improvement in LV mass in patients with resistant hypertension. No significant side effects of bradycardia or orthostatic hypotension were noted.<sup>96,97</sup> A phase II study with this system has been initiated to examine the safety and efficacy of baroreceptor activation on LV mass in patients with HFPEF (see Table 48-2).<sup>71</sup> A different approach involving catheter-based renal sympathetic denervation has also been reported to show similar significant and sustained improvement in blood pressure in patients with resistant hypertension.<sup>98</sup> A sustained improvement of blood pressure in patients with HFPEF and resistant hypertension will probably translate into improvement in cardiovascular outcomes.

#### Targeting Diastolic Suction

Another pathological mechanism being targeted is a proposed abnormality of early diastolic suction of the left ventricle in patients with diastolic heart failure. The elastic recoil of the ventricle during early diastole contributes significantly to an early diastolic pressure gradient from the left atrium to the LV apex and allows the left ventricle to actively suction blood from the left atrium during early diastole, thus contributing to early LV filling.<sup>99-102</sup> Diastolic suction allows the left ventricle to decrease its pressure despite its filling during early diastole. A major determinant of diastolic suction is the potential energy stored as myocytes are compressed and the elastic elements in the LV wall are compressed and twisted during systole. This energy is released as the elastic elements recoil during relaxation. With diastolic dysfunction (slowed

relaxation and reduced elastic recoil), this diastolic suction is reduced, and LV early filling is probably impaired.

A series of passive diastolic assist devices (manufactured by CorAssist Cardiovascular Limited) are being developed and studied.<sup>103</sup> The initial device, ImCardia, is attached to the epimyocardial surface of the left ventricle. The design is based on the principle of restoring normal balance of myocardial dynamic energy by the transfer of energy from preserved systole to underfunctioning diastole in a stiff ventricle. Potential energy produced by the left ventricle during systole is stored in the device—in essence, being loaded like a spring—and is released during diastole, providing a recoiling force to restore the myocardium to its resting length. Initial feasibility and proof-of-concept studies have been performed in animals, and initial small studies are under way with human subjects.<sup>104,105</sup> A newer generation of the device that is implanted into the inner ventricular cavity is also being tested. The device is yet to be tested in larger clinical trials in patients with HFPEF.

## CONCLUSIONS

The high prevalence of HFPEF with its associated substantial morbidity and mortality has been recognized, and as a result, a quest for effective therapy for the condition has been initiated. In contrast to systolic heart failure, in which RAAS blockers have been proved to have beneficial effects on mortality and morbidity (see Chapter 45), none of the clinical trials to date with ACE inhibitors or ARBs has demonstrated definitive benefit in clinical outcomes in patients with HFPEF. A number of novel therapies that are being currently tested for HFPEF are targeting alternative pathophysiological mechanisms. At present, recommended therapy is aimed at relief of symptoms, control of hypertension, and management of other contributory comorbid conditions. Although RAAS blockers and  $\beta$ -blockers are not currently recommended specifically for the treatment of HFPEF, their use in the treatment of other conditions that frequently coexist in affected patients remains important. Researchers may need to reconsider traditional endpoints such as mortality for the evaluation of efficacy of therapies in patients with HFPEF, a population with many comorbid conditions and many competing risks for mortality. Researchers also need to consider whether hospitalization and exercise capacity are more meaningful endpoints in this patient population. In addition, because of the heterogeneity of patients with HFPEF, it may be difficult to prove that a particular therapeutic agent is efficacious in all patients; therefore, relevant interventions in more homogeneous subgroups of patients may need to be studied.

## Heart Failure in Special Populations

Mathew Maurer, Eileen M. Hsich, Ileana L. Piña, and  
Anne L. Taylor

Population variables of race or ethnicity, gender, and age significantly influence the expression of heart failure. Prevalence, incidence, risk profile, causes, and outcomes of heart failure are all affected by these variables. Registries, longitudinal cohort studies, and administrative databases are increasingly important sources of insights about the effects of these variables. Potential differences in response to therapies in

these groups, in contrast, are not well characterized because of poor representation in randomized clinical trials. Thus, therapeutic recommendations are, with rare exceptions, not specific to these categories, and therapies are applied universally.

### RACE OR ETHNICITY AND HEART FAILURE

In considering the effects of race or ethnicity on heart failure, it is important to keep in mind several key concepts. Race, ethnicity, and geographical descent may include some clustering of common genetic characteristics, but they also include social, environmental, and lifestyle factors that may have a huge effect on cardiovascular health.<sup>1</sup> In some instances, ethnicity is determined only by a commonality of language (e.g., Spanish), in which population origin varies significantly within the group (e.g., Afro-Caribbean descent for northeastern Hispanic people, Native American descent for Central and South American Hispanic people, and European descent for Hispanic people from Argentina). Asian populations are similarly very diverse, and the health status of Hispanic and Asian populations may vary according to time of immigration and racial mixing. Thus, although disease patterns within racial/ethnic population groupings should be investigated, these are not simple variables.<sup>1</sup> More data concerning comparisons of heart failure in African American and white populations have been collected than for other racial or ethnic groups. Cohort studies and databases are including a broader range of subjects by race and ethnicity, but ethnic subgroups are rarely included or analyzed even post hoc in randomized clinical trials, and so treatment-specific data are largely absent. Thus, understanding the true role that race and ethnicity play in heart failure requires greater study and better inclusion in clinical trials.

#### Clinical Features by Race or Ethnicity

The major risk factors for heart failure are listed in [Table 49-1](#),<sup>2</sup> and the prevalence of heart failure according to sex and race or ethnicity is listed in [Table 49-2](#).<sup>2</sup> Annual rates of new heart failure events per 1000 persons by age groups are listed in [Table 49-3](#) (see also Chapter 22).

Heart failure occurs at earlier ages in African American populations than in white populations<sup>3,4</sup> and is associated more frequently with hypertension and diabetes than with ischemic heart disease.<sup>5-8</sup> African American patients have also been noted to have more advanced disease at first evaluation, lower norepinephrine levels, and a trend toward lower plasma renin activity than do other racial groups.<sup>9</sup> Hispanic patients with heart failure are also younger than other racial groups and have higher rates of diabetes and renal disease; rates of ischemic cardiomyopathy are intermediate between non-Hispanic white populations and African American populations.<sup>10</sup>

The incidence of heart failure by race or ethnicity and by associated risk factors was examined in the Multi-Ethnic Study of Atherosclerosis (MESA), which included 6814 participants, of whom 38.5% were white, 27.8% were African American, 21.9% were Hispanic, and 11.8% were Chinese American.<sup>11</sup> The incidence was highest among African American patients, second highest among Hispanic patients, followed by non-Hispanic white patients, and lowest among Chinese American patients over a 5-year follow-up period ([Figure 49-1](#)).

Observed racial differences in morbidity from heart failure may be related to differences in comorbid conditions (hypertension, diabetes, or renal disease), effectiveness of treatment, socioeconomic factors (access to insurance and specialty care), lifestyle, and health care-seeking behaviors (i.e., time between symptom onset and presentation for care).<sup>5,10-12</sup>

Data from analysis of Medicare enrollees revealed that hospitalization for heart failure was 1.5 times higher among African American patients, 1.2 times higher among Hispanic patients, but 0.5 less likely among Asian patients<sup>13</sup> than among white American patients. African American patients with heart failure have a higher risk for hospitalization and readmission than do white patients.<sup>10,14-19</sup> Hispanic patients have higher hospitalization rates and readmission rates than do non-Hispanic white patients<sup>10</sup>; length of stay is intermediate among non-Hispanic white patients and African American patients ([Figure 49-2](#)).<sup>10</sup>

African American patients with heart failure have been reported to have similar,<sup>19</sup> higher,<sup>20</sup> and lower rates of mortality than do white patients.<sup>17,21</sup> Data may conflict partly because of differences in study period, method (registries, observational databases, administrative databases, or randomized clinical trials), pathophysiological characteristics (heart failure with preserved or decreased left ventricular [LV] function), and age of patients studied. Hispanic patients have been reported to have lower rates of in-hospital and short-term mortality.<sup>10</sup> The lower rate of mortality with similar incidence has been termed the “Hispanic paradox.”

## Racial Differences in Response to Drug Treatment for Heart Failure

The efficacy of pharmacological treatments in racial or ethnic subgroups is controversial, in part, because there have been few randomized clinical trials of heart failure treatment that have *prespecified* a subgroup analysis of outcomes by race or ethnicity and also included sufficient numbers of subjects for meaningful statistical analysis. However, findings of retrospective analyses suggest that there may be differences between African American and white populations in response to some pharmacotherapy for heart failure, but few data exist for Hispanic and Asian populations in comparisons of outcomes by specific treatments.

### Angiotensin-Converting Enzyme Inhibitors

Pooled data from the Studies of Left Ventricular Dysfunction (SOLVD) prevention and treatment trials<sup>22</sup> revealed that enalapril therapy was associated with a significant reduction in the risk of hospitalization for heart failure among white patients but not among African American patients (see Chapter 45). African American patients randomly assigned to receive enalapril had 7.9 more hospitalizations per 100 persons per years of follow-up than did matched white patients.<sup>23</sup> Analysis of the database from both the SOLVD prevention and treatment study revealed no significant difference in the risk of death associated with enalapril treatment in African

**TABLE 49–2 Prevalence of Heart Failure, by Sex and by Race or Ethnicity**

American and matched white patients,<sup>22</sup> although African American patients overall had higher rates of all-cause mortality and higher rates of mortality from pump failure.<sup>22</sup> In white patients treated with enalapril, significant reductions in both systolic blood pressure ( $5 \pm 17.1$  mm Hg) and diastolic blood pressure ( $3.6 \pm 10.6$  mm Hg) were observed, but no reduction in blood pressure was shown in African American subjects similarly treated. However, in both SOLVD

From Rosamond W, Flegal K, Furie K, et al. Heart disease and stroke statistics—2008 update: a report from the American Heart Association Statistics Committee and Stroke Statistics Subcommittee. *Circulation* 2008;117(4):e25-e146.

**FIGURE 49-1** Nelson-Aahlen plots of cumulative hazard ratios for the development of congestive heart failure (CHF), by racial or ethnic group, in the Multi-Ethnic Study of Atherosclerosis (MESA) study. (From Bahrami H, Kronmal R, Bluemke DA, et al. Difference in the incidence of congestive heart failure by ethnicity: the Multi-Ethnic Study of Atherosclerosis. *Arch Intern Med* 2008;168:2138-2145.)

to symptomatic heart failure in both African American and white subjects. However, despite the fact that enalapril produced comparable relative reductions in risk for the development of symptomatic heart failure, the differences in the baseline magnitude of risk were such that African American subjects randomly assigned to receive enalapril remained at higher risk for the progression to clinical heart failure than did white subjects randomly assigned to receive placebo. The differences between African American and white subjects in the risk of progression of asymptomatic LV dysfunction remained after adjustments for potential confounders, including ejection fraction, New York Heart Association (NYHA) class, serum sodium level, and origin of LV dysfunction (Figure 49-3).<sup>24</sup>

**β-Blockers (see Chapter 46)**

Several large multicenter trials have proved the beneficial effects of β-blockers in heart failure<sup>25</sup>; however, all have included only small numbers of African American subjects, and the analyses by ethnicity were post hoc.<sup>26-28</sup> Nonetheless, these post hoc analyses revealed a trend for carvedilol and metoprolol to have a beneficial effect in African American patients. Therefore, despite the small numbers of African American subjects in the trials and failure of hazard ratios to reach statistical significance, these β-blockers are recommended for all patients without distinction by race.

In the Beta-Blocker Evaluation of Survival Trial (BEST), the only trial prospectively stratified by race (African American or white), the β-blocker bucindolol significantly reduced the risk of death or hospitalization among white patients but was associated with a nonsignificant increase in the risk of serious clinical events in African American patients<sup>29</sup> (Figure 49-4). Therefore, the benefits in African-American patients may be specific to some β-blockers but not to others.

**Isosorbide Dinitrate Plus Hydralazine**

Retrospective analyses of the first and second Vasodilator Heart Failure Trials (V-HeFT I and II)<sup>30,31</sup> (in which 28% to 30% of subjects were African American) suggested racial differences between African American and white subjects in response to treatment.<sup>32</sup> In V-HeFT I comparisons of a combination of isosorbide dinitrate plus hydralazine, prazosin, and placebo, a mortality-related benefit was observed in African American subjects but not in white patients treated with isosorbide dinitrate plus hydralazine. In V-HeFT II comparisons of enalapril

**FIGURE 49-2** Age-specific prevalence of hospitalization with a first-listed diagnosis of heart failure among Medicare enrollees aged 65 years or older, by sex and by race and ethnicity. (Modified from Brown D, Haldeman G, Croft J, et al. Racial or ethnic differences in hospitalization for heart failure among elderly adults: Medicare, 1990-2000. *Am Heart J* 2005;150:448-454.)

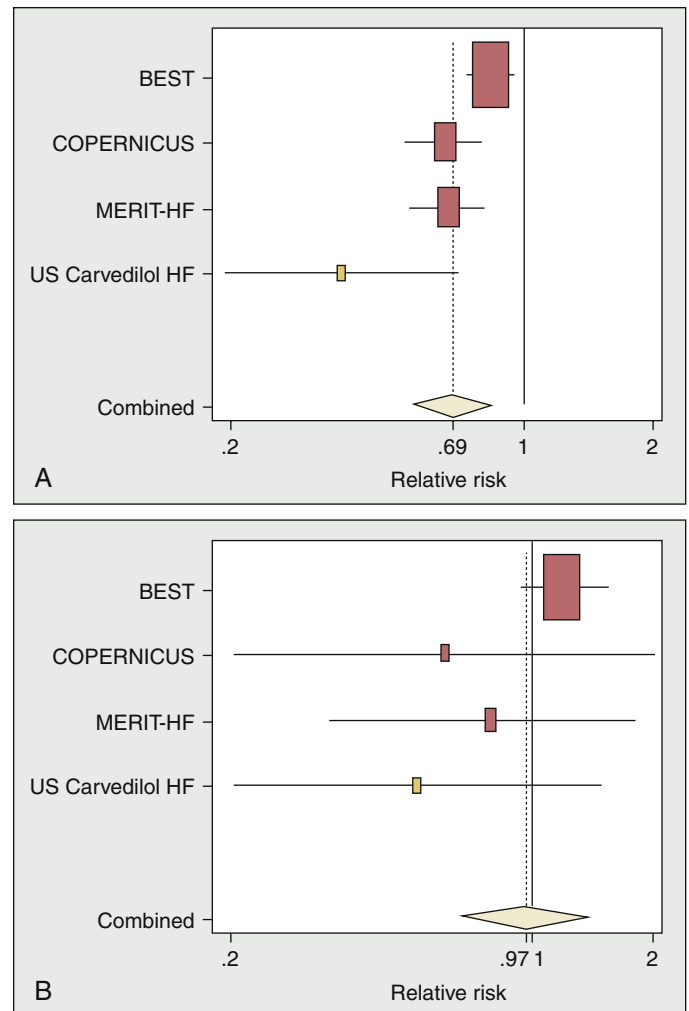

**FIGURE 49-3** Effect of angiotensin-converting enzyme inhibition on preventing the development of symptomatic heart failure in African American and white patients with asymptomatic left ventricular dysfunction. (Adapted from Dries D, Strong M, Cooper R, et al. Efficacy of angiotensin-converting enzyme inhibition in reducing progression from asymptomatic left ventricular dysfunction to symptomatic heart failure in black and white patients. *J Am Coll Cardiol* 2002;40:311-317.)

and the combination isosorbide dinitrate plus hydralazine, a survival advantage of enalapril was observed only in white patients; no survival advantage of enalapril over isosorbide dinitrate plus hydralazine was observed in African American patients. Although these were retrospective analyses of small numbers of subjects and the interaction among race and treatment was not significant, these findings suggested there might be differences in response between the two groups.

The African-American Heart Failure Trial (A-HeFT) tested the hypothesis derived from the retrospective analyses of the V-HeFT trials: that addition of combined isosorbide dinitrate plus hydralazine to background neurohormonal blockade would improve heart failure outcomes in African American patients with low ejection fractions and advanced symptoms.<sup>8</sup> Of importance was that 40% of the trial cohort were women; the results provided the only clinical trial data of this treatment strategy in women.<sup>33</sup> Although patients in both conditions of the trial were well treated with background neurohormonal blockade and there were some baseline clinical differences between men and women, there were no differences in baseline medications for heart failure.<sup>33</sup> In this trial, the addition of isosorbide dinitrate plus hydralazine to neurohormonal blockade significantly improved survival and reduced hospitalizations in self-identified African American men and women with advanced heart failure<sup>8,10,13</sup> (Figure 49-5). How this therapy affects other populations requires further testing.

Review of clinical trials of other pharmacotherapy for differences in outcomes by race or ethnicity reveals that only extremely small numbers of racial or ethnic minorities were included and does not permit conclusions to be drawn with regard to treatment by race. In trials of angiotensin receptor blockers (ARBs), African American patients represented 2% of subjects in the Evaluation of Losartan In The Elderly (ELITE)<sup>34</sup>; 4% in the Candesartan in Heart Failure Assessment in Reduction of Mortality (CHARM), in which 6.9% were identified as “other” without further specification<sup>35-38</sup>; and 7.0% in the Valsartan in Heart Failure Trial (Val-HeFT), in which 2.6% were identified as “other.”<sup>39</sup> In trials of aldosterone antagonists, African American patients represented

(Adapted from Shekelle PG, Rich M, Morton S, et al. Efficacy of angiotensin-converting enzyme inhibitors and beta-blockers in the management of left ventricular systolic dysfunction according to race, gender, and diabetic status. *J Am Coll Cardiol* 2003;41:1529-1538).

1% of subjects in Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS)<sup>40</sup> and 14% of nonwhite subjects (but not further characterized) in the Randomized Aldactone Evaluation Study (RALES).<sup>41</sup> Similar low numbers of minorities have been included in trials testing the utility of implantable cardioverter-defibrillators (ICDs)<sup>42,43</sup> and pacemakers for cardiac resynchronization therapy (CRT),<sup>44</sup> as well as in registries tracking the use of these devices.<sup>45</sup>

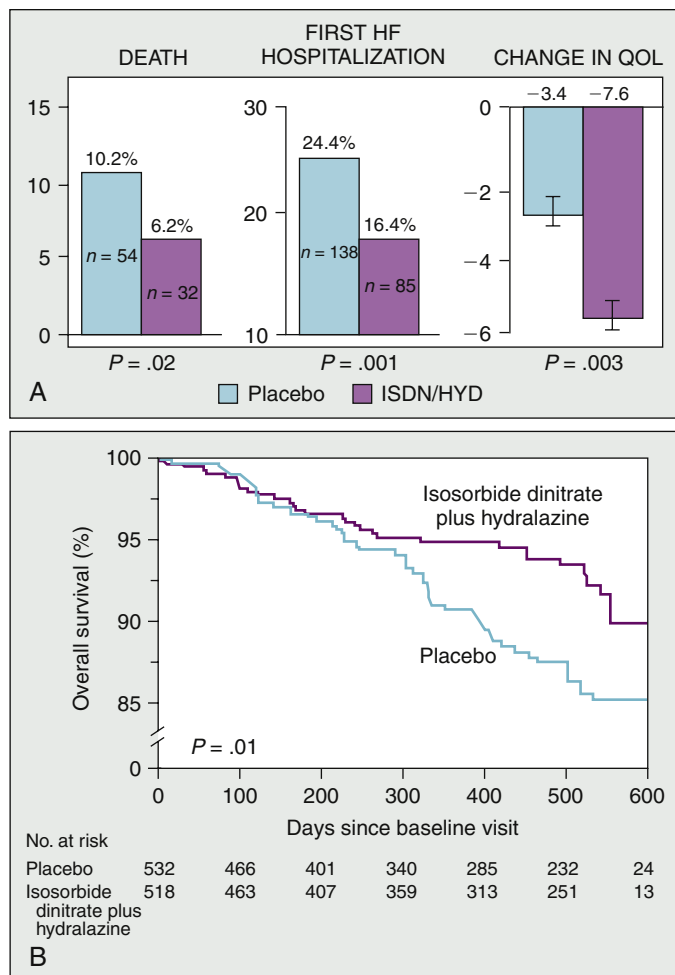

At present, with the exception of a positive recommendation for use of nitrates and hydralazine in African American patients,<sup>46</sup> there are no data supporting differences in use of heart failure therapies by racial or ethnic groupings.

## HEART FAILURE IN ELDERLY POPULATIONS

### Clinical Features

Heart failure is principally a disorder of older adults; the prevalence and incidence rates increase dramatically with age. Of the more than 5 million adults with heart failure in

**FIGURE 49-5** Clinical outcomes in the African American Heart Failure Trial (A-HeFT). **A**, Components of composite score in A-HeFT. **B**, Effect of fixed-dose isosorbide dinitrate plus hydralazine on mortality in A-HeFT. HF, heart failure; ISDN/HYD, isosorbide dinitrate plus hydralazine; QOL, quality of life. (Modified from Taylor AL, Ziesche S, Yancy C, et al. Combination of isosorbide dinitrate and hydralazine in blacks with heart failure. *N Engl J Med* 2004;351:2049-2057.)

the United States, 50% are at least 75 years of age. Heart failure is the leading cause of hospital admissions among older adults and the leading cause of readmission within 30 days of discharge.<sup>47</sup> In the Framingham Heart Study, the incidence of heart failure increased from a rate of 2 to 3 per 1000 in the population younger than 65 years to 9 to 12 per 1000 of those aged 65 years or older. The incidence rate in the “oldest old” population (those  $\geq 85$  years of age) was more than twentyfold higher among women and more than tenfold higher in men than in those younger than 55 years.<sup>48</sup> In the Cardiovascular Health Study, the prevalence of heart failure among women increased from 4.1% at age 70 to 14.3% at age 85; among men at the same ages, it increased from 7.8% to 18.4%.<sup>49</sup> The prevalence and incidence of heart failure are similar in older white and African American populations.

Important risk factors for the development of heart failure in the older population include age; male gender; and the presence of ischemic heart disease, systolic hypertension, widened pulse pressure, diabetes, chronic lung disease, renal dysfunction, atrial fibrillation, LV hypertrophy, and obesity.<sup>49,50</sup> Among these, systolic hypertension has the greatest population attributable risk, especially among women, for the development of heart failure.<sup>49</sup>

Older patients show a particular propensity for developing heart failure with preserved LV systolic function, or normal

ejection fraction (HFNEF). Population-based reports from several studies suggest that 50% or more of elderly patients with heart failure have HFNEF and that the proportion increases with advancing age. Thus, the profile of the typical older person with heart failure in the general population contrasts with that of middle-aged patients enrolled in heart failure trials or in specialty heart failure referral clinics.

## Pathophysiology

The pathophysiological characteristics of heart failure differ between older and younger adults, because the cardiovascular reserve declines with normative aging.<sup>51,52</sup> Age-related changes in other organ systems can impair the ability of older adults to compensate for heart failure and can alter the response to pharmacological agents. The cause of heart failure with reduced ejection fraction (HFREF) is related to ischemic heart disease more often in older adults than in younger patients. In addition, older adults have greater systemic vascular resistance, higher norepinephrine concentrations, higher urea nitrogen and creatinine levels, and lower glomerular filtration rates than do younger adults.<sup>53</sup> Thus, older adults with HFREF have greater vasoconstriction and blunted heart rate response with circulating norepinephrine. The superimposition of normal aging changes on the heart failure process suggests that at equivalent levels of clinical severity, heart failure is more advanced from a pathophysiological perspective in older patients.

Diabetes, chronic kidney disease, anemia, and obesity, which are common comorbid conditions in older individuals with HFNEF, are associated with impaired relaxation, alterations in *ventricular-vascular coupling* with age, and a remodeled ventricle that is more sensitive to volume overload and the effects of increasing heart rate. Severe systolic hypertension is often present during acute exacerbations of pulmonary edema.<sup>54-56</sup>

Rates of mortality from heart failure increase with age and are threefold higher in patients aged 65 to 74 than in those aged 25 to 54 years. Among community-dwelling persons with heart failure who are 65 to 74 years old, the 10-year mortality rates are 50% among women and more than 70% among men. Elderly patients who have been hospitalized with heart failure have even higher mortality rates, estimated at 33% at 1 year and 70% at 5 years.<sup>57</sup> Mortality rates are slightly lower among African American patients than among white patients and slightly lower among women than among men. Predictors of mortality in older patients with heart failure include age, gender (worse in men), recent hospitalization, diabetes, LV dilation and systolic dysfunction, ischemic heart disease, renal insufficiency, hyponatremia, reduced peak oxygen consumption, and increased slope of minute ventilation/carbon dioxide production during exercise.<sup>58,59</sup>

Data from community-dwelling elderly subjects with heart failure suggest that the cause of mortality differs between subjects with a preserved ejection fraction and subjects with a reduced ejection fraction. Of persons with heart failure and a preserved ejection fraction, 45% survived, and 43% of the deaths had noncardiovascular causes. The leading cause of death in subjects with preserved ejection fraction was noncardiovascular (49%), whereas coronary heart disease was the leading cause of death (43%) in subjects with reduced ejection fraction. After adjustment, preserved ejection fraction was associated with a lower risk of cardiovascular death but not all-cause death.<sup>60</sup> Thus, older adult subjects with heart failure and a preserved ejection fraction have less cardiovascular disease before death and are less likely to die of cardiovascular disorders than are subjects with reduced ejection fraction.

Elderly patients with heart failure have chronic exercise intolerance, reduced quality of life, frequent hospitalizations,

**TABLE 49–4 Comorbid Conditions in Older Patients with Heart Failure**

Condition	Prevalence	Potential Consequences
Renal dysfunction	16%: GFR $\leq$ 30 mL/min 40%: GFR 30–59 mL/min*	Worsens symptoms, prognosis; exacerbated by diuretics, ACE inhibitors and ARBs.
Chronic lung disease	20%–32%†	Worsens symptoms and prognosis; contributes to uncertainty about diagnosis; exacerbates right-sided heart function
Dementia or delirium	Dementia: 8.5%‡ Delirium: <ul style="list-style-type: none"> <li>• 30%–50% of hospitalized patients</li> <li>• 36.8% (range, 0%–73.5% of postoperative patients)</li> <li>• &gt;70% of patients in ICU</li> </ul>	Increases chance of nonadherence with medications, diet, and nonpharmacological interventions
Diabetes	30%–50%	Worsens prognosis and increases risk associated with polypharmacy Increases risk of vascular disease, dementia, chronic renal dysfunction, and anemia
Depression	8%§	Worsens prognosis, exacerbates symptoms, and increases chance of noncompliance
Falls, difficulties with mobility	30%–50%	Exacerbated by diuretics and vasodilators, impairs mobility in the community, and interferes with ability to attend follow-up visits routinely
Postural or postprandial hypotension	Postural: 10%–30% Postprandial: 10%–20%	Worsened by diuretics, vasodilators
Anemia	Inpatient: 70% Outpatient: 10%–20%	Worsens symptoms, increases risk of hospitalization
Urinary incontinence	Women: 35% Men: 22%¶	Aggravated by medical therapy, including diuretics, ACE inhibitors (secondary to cough, thereby worsening stress incontinence)
Sensory impairments	Ocular disorders: 24%	Interferes with compliance, increases chance of medication error
Frailty	30%–50%	Worsens symptoms, prognosis, reduces quality of life
Fatigue or anergia	Mild to moderate: 70% Severe: 20%	Worsens symptoms, complicates diagnosis
Nutritional deficiencies	>30%	Exacerbated by dietary restrictions imposed by heart failure state
Polypharmacy	Almost all	Increases risk of nonadherence, medication interaction, and adverse drug reaction

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; GFR, glomerular filtration rate; ICU, intensive care unit.

and high health care costs. Older patients with heart failure also have a high rate of other morbid outcomes (Table 49–4), including stroke and myocardial infarction. Of importance is that morbidity is similar in patients with either HFREF or HFNEF (see Chapter 48). Exercise intolerance in older patients with HFNEF is as severe as in those with HFREF, and reductions in quality of life are comparable.<sup>61</sup> Peak oxygen uptake, as measured by expired gas analysis during cycle ergometry, was similar in patients with HFNEF and HFREF and markedly reduced in comparison with healthy control subjects.<sup>62</sup>

The diagnosis of heart failure is challenging in older adults, who are more likely than younger adults to have other conditions that mimic the symptoms and signs of heart failure. A reliable history may be more difficult to

obtain because of cognitive dysfunction or sensory impairment; a family member, caregiver, or witness may be very helpful in corroborating the patient's history. Atypical presentations are more common in older adults, in whom heart failure may manifest as somnolence, confusion, disorientation, weakness, fatigue, gastrointestinal disturbances, or failure to thrive. Other potential causes of the signs and symptoms of heart failure must be confirmed or ruled out.<sup>63,64</sup> Both chest radiography and echocardiography have lower specificity for diagnosing heart failure in the elderly because of chronic parenchymal changes and because of comorbid lung disease and the presence of normal ejection fraction, respectively, which may contribute to diagnostic uncertainty.<sup>65</sup>

Goals of therapy in older adult patients with heart failure include relief of symptoms, improvement in functional capacity and quality of life, reduction in hospital admissions, and lengthening survival. In older patients, preservation of independence and maintenance of a satisfactory quality of life may be more important than length of survival.

Several studies have confirmed the efficacy of a multidisciplinary approach to care in reducing hospitalizations, improving quality of life, reducing total costs, and, in one study, increasing length of survival. Many of these studies included older patients, who are ideal candidates for multidisciplinary care. One randomized controlled trial involving patients aged 70 and older demonstrated a 56% reduction in 90-day rehospitalizations for heart failure.<sup>66</sup> Of note was that this study included patients with either HFREF or HFNEF.

The Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) trial was a randomized, double-blind study in which placebo was compared with perindopril in patients aged 70 years or older with a diagnosis of heart failure, who were treated with diuretics and had echocardiographic evidence of diastolic dysfunction (see Chapter 48).<sup>67</sup> Perindopril did not improve rates of long-term morbidity and mortality; however, it improved symptoms and exercise capacity and reduced hospitalizations for heart failure in the first year.<sup>67</sup> In the Candesartan in Heart Failure Assessment in Reduction of Mortality (CHARM)—Preserved trial, candesartan also reduced hospital admissions but not mortality among patients with HFNEF.<sup>68</sup> In a clinical trial involving older adults with diastolic dysfunction and an exaggerated blood pressure response to exercise, losartan, in comparison with hydrochlorothiazide, substantially reduced systolic blood pressure and pulse pressure during exercise and improved exercise capacity and quality of life.<sup>69</sup> In the largest placebo-controlled, morbidity-mortality trial to date in patients with HFNEF—the Irbesartan in Heart Failure with Preserved Systolic Function (I-PRESERVE) trial—4133 patients aged 60 years or older (mean, 72 years; 60% women) were randomly assigned to receive irbesartan or placebo. The patient characteristics closely reflected those of population-based and community samples. During 5-year follow-up, this large study revealed no significant effect of irbesartan on the primary endpoint of death and cardiovascular hospitalizations, on heart failure hospitalizations alone, or on secondary endpoints such as quality of life (see Chapter 46).<sup>70</sup>

$\beta$ -Adrenergic antagonists reduce blood pressure, promote regression of ventricular hypertrophy, and increase the ischemic threshold, all of theoretical importance in HFNEF. In the Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalisation in Seniors with Heart Failure (SENIORS), 35% of the subjects (mean age, 76 years) had an ejection fraction of more than 35%. Among those with an ejection fraction of less than 35 or more than 35%, there was no difference in the observed beneficial effects of  $\beta$ -blocker therapy.<sup>71</sup>

The Digitalis Investigation Group (DIG) ancillary study included 988 patients with preserved systolic function, most of whom were elderly. In patients with chronic mild to moderate heart failure, an ejection fraction exceeding 45%, and normal sinus rhythm who were receiving angiotensin-converting enzyme (ACE) inhibitor and diuretics, digoxin had no net overall effect on natural history endpoints such as mortality and hospitalizations for all causes or cardiovascular causes.<sup>72</sup>

## HEART FAILURE IN WOMEN

### Clinical Features

More than 40% of patients with heart failure are women.<sup>73</sup> The prevalence of heart failure increases with age in both sexes.<sup>73</sup> Women with heart failure are twice as likely to have HFNEF

than are men,<sup>74,75</sup> and women with HFREF tend to present with a higher LV ejection fraction (LVEF) than do men.<sup>74,75</sup> Comorbid conditions also differ between men and women. Women with heart failure tend to have more hypertension, whereas smoking and coronary artery disease are more prevalent among men.<sup>76</sup> In the A-HeFT trial,<sup>8</sup> African American women were more likely to have lower hemoglobin and to have diabetes, but less likely to have renal insufficiency, than were men. Although coronary artery disease is less common, it is such a significant risk factor that women are more likely to develop heart failure with coronary artery disease than with hypertension. For example, in the National Health and Nutrition Examination Survey (NHANES) I epidemiological follow-up study, which included 8098 women without heart failure, 27% had hypertension and only 3% had coronary artery disease, but the relative risk of developing heart failure for women was significantly higher if they had coronary artery disease (relative risk, 8.16; 95% confidence interval [CI], 6.79 to 9.8;  $P < .001$ ) than if they had hypertension (relative risk, 1.51; 95% CI, 1.29 to 1.77;  $P < .001$ ).<sup>77</sup> Diabetes mellitus is common in both genders (i.e., 44%)<sup>74</sup> and is one of the strongest additional risk factors for the development of heart failure in women with coronary artery disease.<sup>78</sup> Thyroid disease is more frequent in women with acute decompensated heart failure, whereas chronic obstructive lung disease, peripheral vascular disease, and renal insufficiency are more common in men.<sup>74,75</sup>

The age-adjusted incidence of heart failure is higher among men than among women; however, men with heart failure have shorter survival than do women.<sup>79,80</sup> Adams and associates<sup>81</sup> found that the female survival advantage occurred only when the cause of heart failure was nonischemic. Between 1979 and 2000, the incidence of heart failure rose 8% (95% CI, -5 to -23) among women and 3% (95% CI, -11 to -20) among men, according to the data from Olmsted County, Minnesota,<sup>79</sup> and the Framingham Heart Study investigators reported an increase in the incidence of heart failure for both women and men between 1980 and 1999.<sup>80</sup> Both of these population cohorts were almost exclusively non-Hispanic white; thus, comparable detailed data about minority women for these time periods are not available. During those time periods, age-adjusted rates of 5-year mortality improved for both sexes.<sup>79,80</sup>

Significant morbidity is associated with heart failure, and women have been shown to have a lower quality of life than do men, with more impairment in functional capacity,<sup>33,82</sup> more hospitalizations for heart failure,<sup>73,74,82</sup> and more depression.<sup>83</sup> Although women are more likely than men to have heart failure with preserved LV systolic function, two observational studies demonstrated similar mortality rates for patients with heart failure and preserved or impaired systolic function.<sup>84,85</sup> Women have less ischemic cardiomyopathy. The CHARM study investigators noted that sex differences in survival were not entirely explained by LV systolic function or by cause of heart failure; however, for both sexes, ischemic cardiomyopathy conferred a worse prognosis.<sup>76</sup>

Peripartum cardiomyopathy is a uniquely gender-specific cardiomyopathy defined as the development of heart failure with impaired systolic function in the last month of pregnancy or within 5 months post partum with no preexisting cardiac disease or identifiable cause (see Chapter 24).<sup>86</sup> The incidence varies based on population studied with an estimated occurrence of 1:4000 pregnancies in the United States.<sup>86</sup> Risk factors include advanced maternal age, African descent, high parity, twin pregnancy, usage of tocolytic agents, and lower socioeconomic status.<sup>87</sup> Approximately half of patients with peripartum cardiomyopathy recover normal systolic function within 6 months.<sup>88</sup> Another 20% deteriorate and either die or require heart transplantation.<sup>89</sup> The degree of LV systolic dysfunction at presentation may be predictive of recovery: Those who recover LV systolic function have higher LVEF at

presentation.<sup>90,91</sup> Data for guiding treatment choice are limited with regard to the risk of heart failure with subsequent pregnancies, and no specific recommendations about therapy exist at present.<sup>92</sup>

In the SOLVD database, of the patients with impaired systolic LV function, women were more likely than men to have dependent edema, jugular venous distention, and an S3 gallop.<sup>93</sup> However, women ( $n = 54,674$ ) in the Acute Decompensated Heart Failure National Registry (ADHERE) with impaired and preserved systolic function did not differ from men ( $n = 50,713$ ) with regard to the frequency of heart failure symptoms and signs.<sup>74</sup> However, ADHERE included patients hospitalized for acute decompensation, whereas SOLVD involved patients with chronic symptoms. In ADHERE, the patients with heart failure and preserved systolic function were more likely to be women, older, and hypertensives. According to both the Framingham and the Olmsted County databases, more women than men have heart failure with preserved LV function.<sup>94,95</sup>

## Therapy

Women hospitalized with heart failure generally receive heart failure medications at similar rates as do men, but elderly patients are less likely to receive guideline-recommended therapy.<sup>96-98</sup> Although women have been included in randomized clinical trials in greater numbers than minorities in general, they have, nonetheless, been significantly underrepresented, and no sex-specific trials have been conducted, except for ischemic disease; thus, evidence-based treatment guidelines for heart failure therapy<sup>46,99</sup> are not sex specific. Post hoc analyses and meta-analyses of randomized clinical trials of women in heart failure studies are reviewed as follows.

### Angiotensin-Converting Enzyme Inhibitors (see Chapter 45)

A meta-analysis of 30 studies of ACE inhibitors, which included a total of 1587 women with heart failure, demonstrated a trend toward improved survival among the subjects taking ACE inhibitors in comparison with those not taking the drug (13.4% vs. 20.1%) and a favorable trend in the combined endpoint of survival and hospitalization in the group of women taking an ACE inhibitor (20.2% vs. 29.5%).<sup>100</sup> Another meta-analysis involving 2373 women demonstrated similar trends<sup>29</sup> (Figure 49-6, Table 49-5). However, both meta-analyses had wide confidence intervals that crossed the line of identity.

### Angiotensin Receptor Blockers (see Chapter 45)

Sex-specific data for ARBs are limited. The CHARM-Alternative trial (ARB for patients intolerant of an ACE inhibitor) and the CHARM-Added trial (ARB added to an ACE inhibitor) included 1188 women with functional NYHA class II to class IV heart failure with LVEF of 40% or lower; pooled data showed that candesartan reduced the combined endpoint of cardiovascular death or hospitalization for heart failure in women.<sup>38</sup> In CHARM-Overall,<sup>101</sup> the reductions in the combined endpoint were the same for men and women (Figure 49-7).

### $\beta$ -Blockers (see Chapter 46)

Post hoc meta-analyses of  $\beta$ -blocker therapy have suggested that these agents are as beneficial in women with heart failure as in men, despite the small number of female participants in each study (Table 49-6).

In both the U.S. Carvedilol Heart Failure Study<sup>102</sup> and the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) study, carvedilol reduced the combined endpoint of death and hospitalization in women in the study.

Similarly, in the second European Cardiac Insufficiency Bisoprolol Study (CIBIS II), bisoprolol improved survival in the 515 women.<sup>103</sup> In contrast, in the Metoprolol Extended-Release Randomized Intervention Trial in Heart Failure (MERIT-HF), metoprolol succinate produced no survival

**FIGURE 49-6** Effect of angiotensin-converting enzyme inhibitors and  $\beta$ -blockers in the management of left ventricular systolic dysfunction according to race, gender, and diabetic status. CONSENSUS, Cooperative North Scandinavian Enalapril Survival Study; SAVE, Survival And Ventricular Enlargement; SMILE, Survival of Myocardial Infarction Long-term Evaluation; SOLVD, Studies of Left Ventricular Dysfunction (Prev, Prevention; Tx, Treatment); TRACE, Trandolapril Cardiac Evaluation. (From Shekelle P, Rich M, Morton S, et al. Efficacy of angiotensin-converting enzyme inhibitors and beta-blockers in the management of left ventricular systolic dysfunction according to race, gender, and diabetic status. *J Am Coll Cardiol* 2003;41:1529-1538.)

benefit in women (6.9% vs. 7.5%, nonsignificant) but did reduce hospitalizations for heart failure by 42% ( $P = .021$ ).<sup>104</sup> It produced an even more dramatic (72%) reduction in hospitalizations for heart failure (0.54 vs. 0.15;  $P = .0004$ ) in the subgroup of women with LVEF of lower than 25%.<sup>104</sup>

### Aldosterone Antagonists

Subgroup post hoc analysis of the two aldosterone antagonists revealed a similar mortality-related benefit for men and women with systolic heart failure in both the Randomized Aldactone Evaluation Study (RALES) and the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS).<sup>40,41</sup>

### Isosorbide Dinitrate Plus Hydralazine

The original data supporting the use of this combination were obtained from studies that included only men.<sup>30,31</sup> In A-HeFT, the combination of isosorbide dinitrate and hydralazine was added to a regimen of ACE inhibitors or ARBs and  $\beta$ -blockers

From Shekelle P, Rich M, Morton S, et al. Efficacy of angiotensin-converting enzyme inhibitors and beta-blockers in the management of left ventricular systolic dysfunction according to race, gender, and diabetic status. *J Am Coll Cardiol* 2003;41:1529-1538.

in 1050 self-identified African American patients (420 of whom were women) who had functional NYHA class III or IV heart failure. Significant survival benefits were noted both for women (hazard ratio, 0.33; 95% CI, 0.16 to 0.71;  $P = .003$ ) and for men (hazard ratio, 0.79; 95% CI, 0.46 to 1.35;  $P = .385$ ), with no significant interaction of treatment by sex. A significant and similar reduction in heart failure hospitalizations was also observed in both men and women.<sup>33</sup>

### Digoxin

On the basis of a post hoc subgroup analysis of the DIG trial,<sup>105,106</sup> there was an initial concern of increased mortality (adjusted hazard ratio, 1.23; 95% CI, 1.02 to 1.47) in women with impaired systolic function that was not observed in men (adjusted hazard ratio, 0.93; 95% CI, 0.85 to 1.02). The increase in mortality was presumed attributable to digoxin

toxicity, inasmuch as the risk of death increased at higher serum drug levels. Drug levels between 1.2 and 2.0 ng/mL were associated with increased mortality (hazard ratio, 1.33; 95% CI, 1.001 to 1.76;  $P = .049$ ); levels between 0.5 and 0.9 ng/mL were considered safe for both women and men (hazard ratio, 0.8), on the basis of results of a retrospective analysis.<sup>107</sup> In current trials, digoxin is used less in patients with stable chronic heart failure than in previous trials.

### Cardiac Resynchronization (see Chapter 47)

Few studies have reported sex-specific data, but it appears that CRT is beneficial for both women and men. In the Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION) study, which included 299 women, women with CRT had a greater reduction in the combined endpoint of total mortality or hospitalization for any cause

than did women who were given only medical therapy.<sup>108</sup> Retrospective analysis of the Cardiac Resynchronization in Heart Failure (CARE-HF) data, which included statistics from 215 women, suggested that CRT was preferable to medical therapy alone in women for the combined endpoint of total mortality and hospitalization for major cardiovascular events. In the Heart Failure and A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION) study, more women had a left bundle branch block but were less likely to have a biventricular pacer at baseline.<sup>109</sup>

#### Implantable Cardioverter-Defibrillator (see Chapter 47)

The recommendations for ICDs to prevent sudden death are based on results of many multicenter studies, but few studies have provided adequate sex-specific data.<sup>108,110</sup> The limited post hoc analyses available for women with an ICD do not clearly demonstrate a mortality-related benefit.<sup>107,108,110</sup> In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), which included 382 women functional NYHA class II or III heart failure with LVEF of 35% or lower (ischemic and nonischemic cardiomyopathy), the benefits of an ICD were not clear, although the trial was not powered to detect sex differences (for women: hazard ratio, 0.96; 95% CI, 0.58 to 1.61). In the Multicenter Automatic Defibrillator Implantation Trial II (MADIT II), which included 119 women with an ischemic cardiomyopathy and LVEF of 30% or lower, there was a nonsignificant trend toward lower rates of mortality among women with an ICD (adjusted hazard ratio, 0.57;  $P = .132$ ), which suggests that this subgroup (patients with ischemic cardiomyopathy) may benefit. However, this analysis was limited by insufficient numbers of female participants.<sup>111</sup> A meta-analysis of outcomes of ICD therapy in women<sup>112</sup> suggested that there was no benefit for women with this therapy. It is notable, however, that women who met criteria for ICD implantation were significantly less likely to receive ICD than were men.<sup>45,112</sup> Because of the low numbers of women in clinical trials and the lower rates of usage of ICDs among women, data do not support sex-specific usage of this device.

#### Ventricular Assist Device (see Chapter 56)

The surgical technique for implanting ventricular assist devices (VADs) does not differ between male and female patients; however, small women have limited VAD options because these devices require a minimum body surface in order to fit properly. The relatively new HeartMate II (Thoratec Corp., Pleasanton, CA), a continuous-flow device, is smaller and may be more easily implanted in women.

VAD outcome data regarding difference between women and men remain limited.<sup>113,114</sup> One study revealed that women were more likely than men to require a right-sided VAD after implantation of a left-sided VAD, but the study included few female participants, and pre-VAD implantation data were not analyzed.<sup>113</sup> In another study in which women had a worse prognosis, women were clinically more unstable than men before VAD implantation. Survival after VAD implantation was best correlated with the degree of medical severity before VAD implantation and not with gender.<sup>114</sup> The HeartMate II allows the implantation of more VADs in women and will enable data analysis in a more consistent prospective manner, because it will be added to the National Heart, Lung, and Blood Institute's Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) for VADs. However, a higher risk of bleeding has also been described in women with the HeartMate II. Women had a 31% greater chance of 1-year mortality, in addition.

#### Heart Transplantation (see Chapter 54)

In the United States in 2007, women donated 28% of the available hearts and received 26% of heart transplants. According to data from the United Network of Organ Sharing (UNOS)

**TABLE 49-7 Risk Factors for Mortality Within 10 Years of Transplantation (July 1994 through June 1998)**

Variable	N	Relative Risk	P	95% Confidence Interval
Female recipient/ male donor	936	1.27	.0001	1.13-1.43
Female recipient/ female donor	936	1.24	.0001	1.11-1.39
Male recipient/ female donor	1817	1.1	.0290	1.01-1.21

Adapted from Taylor DO, Stehlik J, Edwards LB, et al. Registry of the International Society for Heart and Lung Transplantation: twenty-sixth official adult heart transplant report—2009. *J Heart Lung Transplant* 2009;28:1007-1022.)

**FIGURE 49-8** Relative risk of developing cardiac allograft vasculopathy (CAV) after 5 years, according to donor age, donor gender, and recipient gender. (From Hertz MI, Aurora P, Christie JD, et al. Registry of the International Society for Heart and Lung Transplantation: a quarter century of thoracic transplantation. *J Heart Lung Transplant* 2008;27:937-942.)

from 1997 to 2004, the overall rates of survival after transplantation were slightly worse for women (86% at 1 year, 76% at 3 years, 68% at 5 years) than for men (88%, 79%, and 72%, respectively).<sup>115</sup> The most recent available data (2009) from the International Society for Heart and Lung Transplantation revealed that during the period 2002 to 2007, a female recipient of a heart from a male donor had a relative risk of mortality at 1 year of 1.75, in comparison with a male recipient of a heart from a male donor (95% CI, 1.15 to 2.66;  $P = .0095$ ) (Table 49-7). With regard to coronary allograft vasculopathy, the relative risk within 5 years was highest for recipients who received hearts from male donors and lowest for female recipients who received hearts from female donors (Figure 49-8).<sup>116</sup>

Failure, 738

Peripartum Cardiomyopathy, 738

### Summary, 739

Thus far, all attempts to develop a unifying hypothesis that explains the clinical syndrome of heart failure have not met with success when tested in large-scale clinical trials. As a result, combinations of pharmaceutical approaches have been used in the treatment of heart failure. Current therapeutic strategies rely on treating patients' symptoms with diuretics and digitalis, as well as on neurohormonal antagonism with pharmacological agents, such as angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, aldosterone receptor antagonists (see Chapters 45 and 46), and  $\beta$ -blockers (see Chapters 45 and 46), in order to antagonize the effects of the renin-angiotensin-aldosterone system and the adrenergic system, respectively. Despite these pharmacological interventions, heart failure remains a progressive disease with unacceptably high rates of morbidity and mortality. Thus, new and improved therapeutic approaches are needed in the treatment of heart failure.

This chapter is a review of some of the new therapeutic approaches that are being tested in heart failure. This chapter focuses first on new medications that have been explored in patients with heart failure. This is followed by a discussion of novel approaches in heart failure of various causes.

failure.<sup>2</sup> Similarly, tolvaptan, a selective V1a receptor antagonist, was demonstrated to increase urine output and decrease body weight without causing significant decline in renal function.<sup>3,4</sup> In the largest vasopressin antagonist trial to date, the Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST) trial, 4133 patients hospitalized for worsening heart failure and depressed left ventricular (LV) function (ejection fraction < 40%) were randomly assigned to receive either oral tolvaptan or placebo. After a median follow-up period of 9.9 months, there was no difference in the dual primary endpoints of all-cause mortality and mortality from cardiovascular causes or hospitalization for heart failure. However, there were improvements in patient-assessed dyspnea, body weight, and edema. A significant increase in sodium levels was also noted in patients with hyponatremia.<sup>5,6</sup> On the basis of the data available, vasopressin antagonists appear to be safe in patients with heart failure, and they appear to improve volume overload, symptoms of heart failure, and hyponatremia without an impact on long-term clinical outcomes. The U.S. Food and Drug Administration has approved in-hospital oral tolvaptan initiation for the treatment of hypervolemic and euvolemic hyponatremia in the setting of heart failure, liver cirrhosis, and the syndrome of inappropriate antidiuretic hormone secretion.

## NEUROHORMONAL ANTAGONISM

Various neurohormones are activated in heart failure as a compensatory mechanism. Over the long term, the suppression of such neurohormones (renin-angiotensin-aldosterone system and adrenergic system) has resulted in the attenuation of their deleterious effects on the cardiovascular system and also on clinical endpoints, including mortality. More recently, two more neurohormones that are activated in heart failure have been targeted: vasopressin antagonists and endothelin antagonists.

### Vasopressin Antagonists

Vasopressin is a peptide hormone secreted by the posterior pituitary gland in response to a reduction in plasma volume and an increase in plasma osmolality. Through vasopressin 1a (V1a) receptors (in vascular smooth muscle cells) and vasopressin 2 (V2) receptors (in the renal collecting ducts), vasopressin elicits vasoconstriction and water reabsorption with resultant hyponatremia.<sup>1</sup> Conivaptan, a dual vasopressin receptor antagonist, has been shown to significantly increase urine output, decrease pulmonary capillary wedge pressure, and lower right atrial pressure in comparison with placebo in patients with systolic heart

### Endothelin Antagonists

Endothelin is a peptide hormone that is produced in cardiac tissue and exerts its effects through endothelin A and endothelin B receptors. Despite a good scientific rationale and promising initial results with these agents in acute decompensated heart failure (ADHF), the definitive larger clinical trial, Value of Endothelin Receptor Inhibition With Tezosentan in Acute Heart Failure Study (VERITAS)—in which 1760 patients with ADHF were randomly assigned to receive tezosentan or placebo—was prematurely terminated because of a low probability of achieving a significant treatment benefit.<sup>7</sup> Thus, at present, there is no indication for the use of endothelin antagonists in ADHF.

## DIURESIS AND NATRIURESIS

Two novel pharmacological approaches to fluid removal in patients with heart failure have been investigated: adenosine antagonists and ularitide. These new concepts are important in the setting of a greater awareness and possibly a greater incidence of the cardiorenal syndrome, as well as resistance to conventional loop and thiazide diuretics.

### Adenosine Antagonists

Adenosine is a purine nucleoside that is found ubiquitously in various cells. Adenosine exerts its effects through four receptors ( $A_1$ ,  $A_{2a}$ ,  $A_{2b}$ , and  $A_3$ ) located in the kidney, heart, and vasculature.<sup>8</sup> In heart failure, special attention has been given to  $A_1$  receptors, which are located in the afferent arteriole and proximal tubule in the kidneys and are involved in afferent arteriolar vasoconstriction and tubuloglomerular feedback.<sup>8,9</sup> Adenosine levels have been demonstrated to be elevated in the setting of heart failure.<sup>10</sup> In heart failure, elevation of the sodium concentration in the distal tubule stimulates a feedback mechanism to the macula densa, resulting in release of adenosine, which in turn leads to an increase in sodium resorption by the proximal tubule and afferent arteriolar vasoconstriction and a resultant decrease in the glomerular filtration rate (GFR).

Thus,  $A_1$  receptor blockade, which results in afferent arteriolar vasodilation, leads to improved GFR and enhanced diuresis and natriuresis without activation of the tubuloglomerular feedback. Several small clinical trials with  $A_1$ -antagonists in humans with ADHF and chronic heart failure have confirmed this mechanism of action.<sup>11,12</sup> These effects were observed even in patients with more severe renal dysfunction and diuretic resistance.<sup>11</sup> Moreover, whereas GFR declined by 25% during treatment with furosemide, GFR was preserved in patients treated with the  $A_1$ -antagonist. In a different study, the GFR decline caused by furosemide was balanced out by the addition of the  $A_1$ -antagonist BG-9719.<sup>13</sup> Similarly, other  $A_1$  antagonists have been shown to significantly increase natriuresis in patients with heart failure and systolic dysfunction without a decline in renal function.<sup>14</sup>

In a larger study, the pilot phase of the Placebo-controlled, Randomized study of the selective  $A_1$  adenosine receptor antagonist rolofylline for patients hospitalized with acute heart failure and volume Overload to assess Treatment Effect on Congestion and renal function Trial (PROTECT), 301 patients hospitalized with ADHF were randomly assigned to receive one of three doses of rolofylline or placebo. The primary endpoint was a composite of treatment success (improvement in dyspnea), treatment failure (defined as early readmission for heart failure, worsening heart failure, or persistent renal impairment), and unchanged status. Treatment with rolofylline was associated with a higher likelihood of achieving success, as evidenced by improved dyspnea (52.7% vs. 37.2%) and a lower likelihood of experiencing failure (16.2% vs. 28.2%) in comparison with placebo. These findings reached statistical significance only for the highest dose of rolofylline.<sup>15</sup> Rolofoylline recipients exhibited a trend toward a reduction in the composite secondary endpoint of 60-day mortality and readmission for cardiovascular or renal cause and also a trend toward a lesser increase in serum creatinine level. Worsening renal function occurred in 18% of the placebo recipients and only 8% of the patients receiving the 30-mg dosage of rolofylline. Although there is some concern that rolofylline decreases the seizure threshold, it was found to be safe in this trial without an increase in adverse events in comparison to placebo. Of note, patients at high risk for seizures were excluded from this trial, and those with intermediate risk were given prophylactic lorazepam.

In the second phase of the PROTECT study, 2033 patients admitted with heart failure were randomly assigned to receive rolofylline or placebo. The primary endpoint—which included symptoms of heart failure, readmissions for heart failure, survival, and renal impairment—was considered treatment success, treatment failure, or unchanged. The primary endpoint was not significantly different between the two groups.<sup>16</sup> Thus, the results of the pilot PROTECT study were not confirmed in the larger trial. Another trial in subjects hospitalized with worsening renal function and heart failure that necessitated intravenous therapy, the Placebo-Controlled Randomized Study of KW-3902 for Subjects Hospitalized With Worsening Renal Function and Heart Failure (REACH UP) trial, which is evaluating the effect of rolofylline on worsening heart failure, deaths from heart failure, hospitalizations for heart failure, and renal function, is still ongoing.<sup>17</sup>

### Ularitide

Ularitide is a synthetic form of urodilatin, a natriuretic peptide, which is produced in the distal renal tubules. Ularitide binds to natriuretic peptide receptors located on medullary collecting duct cells and vascular smooth muscle cells, which leads to increased diuresis, natriuresis, and arterial and venous vasodilation.<sup>18</sup> Clinically, ularitide has been shown to induce natriuresis and, at the same time, decrease plasma concentrations of renin, aldosterone, and angiotensin II, contrary to findings with conventional diuretics.<sup>19,20</sup> In the Safety and Efficacy of an Intravenous Placebo-Controlled Randomised Infusion of Ularitide II (SIRIUS II) trial, 221 patients with ADHF were randomly assigned to receive one of three doses of ularitide or placebo, in addition to baseline loop and thiazide diuretics. Subjects treated with ularitide exhibited an improvement in dyspnea and hemodynamic parameters (decrease in pulmonary capillary wedge pressure, reduction in systemic vascular resistance, decrease in right atrial pressure, and increase in cardiac index without significant change in heart rate). No difference in urine output was noted between subjects treated with ularitide and those given placebo, which suggests that the predominant mechanism for the hemodynamic changes is vasodilation. A trend toward improved rates of 30-day mortality was noted in the ularitide recipients. The most common side effect of ularitide was hypotension, which was most prominent with the highest dose. No significant worsening of renal function was noted.<sup>21</sup> The Ularitide Global Evaluation in Acute Decompensated Heart Failure (URGENT) trial, a prospective, randomized, placebo-controlled trial, is in the planning phases and is directed toward evaluating the effect of ularitide in 3000 patients with ADHF on dyspnea, safety, and morbidity and mortality both during and after hospitalization.

## INOTROPES

Conventional inotropes, such as dobutamine and milrinone, have been shown to improve hemodynamic status in patients with systolic heart failure, but they do not appear to improve clinical outcomes; in fact, they have been demonstrated to be detrimental in these patients.<sup>22</sup> The negative clinical effects have been attributed to the fact that these inotropes increase intracellular calcium and can thereby cause myocardial cell death and ventricular arrhythmias.<sup>23</sup> Therefore, development of other agents that may not have the detrimental effects observed with conventional inotropes has been an area of considerable interest (Figure 50-1).

### Calcium Sensitizer (Levosimendan)

More recently, there has been a focus on calcium sensitizers as contractility-enhancing agents. In contrast to conventional inotropes, calcium sensitizers enhance contractility by increasing

**FIGURE 50-1** Mechanism of action of novel contractility-enhancing medications. Levosimendan enhances contractility by increasing responsiveness of myofilaments to calcium. The cardiac myosin activator CK 1827-452 stimulates myosin adenosine triphosphatase (ATPase), thereby increasing force generation. Istaroxime inhibits activity of plasma membrane sodium-potassium ATPase and increases the activity of sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA). ADP, adenosine diphosphate; ATP, adenosine triphosphate; I-1, protein phosphatase inhibitor-1; P, phosphate; PLB, phospholamban; PP1, protein phosphatase; RyR2, ryanodine receptor; TnC, troponin C; TnI, troponin I; TnT, troponin T. (Modified from Tavares M, Rezlan E, Vostroknoutova I, et al. New pharmacologic therapies for acute heart failure. *Crit Care Med* 2008; 36[Suppl]:S112-S120.)

responsiveness of myofilaments to calcium while maintaining intracellular calcium concentration. Thus, theoretically, calcium sensitizers should not have the same adverse effects as do conventional inotropes. The best-studied calcium sensitizer is levosimendan, which appears to exert its action through various mechanisms: inhibiting phosphodiesterase III, increasing the calcium sensitivity of cardiac troponin C, and stimulating the opening of potassium-adenosine triphosphate (ATP) channels, which lead to its vasodilatory effects.<sup>24-26</sup> Hemodynamically, levosimendan has been demonstrated to increase cardiac output and stroke volume and to decrease pulmonary capillary wedge pressure in a dose-dependent manner. Other effects include an increase in heart rate at higher doses and a decrease in systemic arterial pressure.<sup>27</sup>

Levosimendan has been evaluated in patients with heart failure in two large trials. In the second Randomized Multicenter Evaluation of Intravenous Levosimendan Efficacy (REVIVE II), study, 600 patients with ADHF were randomly assigned to receive either levosimendan or placebo. The composite endpoint, which included symptoms, clinical status, and major clinical events, was significantly improved in patients treated with levosimendan. However, the use of levosimendan was associated with increased episodes of hypotension, ventricular tachycardia, ventricular extrasystoles, atrial fibrillation, and a higher rate of early mortality. However, at 31 and 90 days, rates of mortality were not significantly different between the treatment and placebo recipients.<sup>28</sup> In the Randomized study on Safety and effectiveness of Levosimendan in patients with LV failure due to an Acute myocardial Infarct (RUSSLAN), 504 patients with recent myocardial infarction and heart failure who were in need of inotropes were randomly assigned to receive four different doses of levosimendan or placebo for 6 hours. The primary endpoint, which was a safety endpoint of the incidence of clinically significant hypotension or myocardial ischemia, was not significantly different between the levosimendan- and placebo-treated subjects. Among the secondary endpoints, levosimendan administration was associated with a significantly decreased risk of death or worsening heart failure at 6 and 24 hours after the infusion and a significant decrease in mortality at 14 days. This mortality benefit that persisted at 180 days of follow-up was, however, not statistically significant.<sup>29</sup>

Additional prospective randomized clinical trials were conducted to assess the efficacy and safety of levosimendan in comparison with placebo in patients with heart failure. In the Levosimendan Infusion versus Dobutamine (LIDO) trial, 203 patients with low output heart failure were randomly assigned to receive levosimendan or dobutamine. Treatment

with levosimendan resulted in a significant improvement in the primary endpoint of hemodynamic status, measured by an increase in cardiac output and a decrease in pulmonary capillary wedge pressure. Moreover, patients treated with levosimendan demonstrated better survival rates at 31 days than did patients treated with dobutamine.<sup>30</sup>

The Calcium Sensitizer or Inotrope or None in Low-Output Heart Failure (CASINO) trial, in which 299 patients with low output heart failure were randomly assigned to receive levosimendan or dobutamine, was terminated prematurely because of a significant survival benefit in patients treated with levosimendan.<sup>31</sup> In the Survival of Patients with Acute Heart Failure in Need of Intravenous Inotropic Support (SURVIVE) trial, 1327 patients with ADHF were randomly assigned to receive levosimendan or dobutamine. The primary endpoint was mortality at 180 days, and results were not different between the two treatment groups. With regard to adverse effects, there was no significant increase in hypotension, heart failure, atrial fibrillation, or ventricular tachycardia in the levosimendan recipients in comparison with the dobutamine recipients.<sup>32</sup>

In summary, treatment with levosimendan results in significant hemodynamic and symptom improvement in patients with decompensated heart failure. Although no significant effect on long-term survival has been noted with levosimendan, studies demonstrated a trend toward decreased survival in comparison to placebo and a trend toward improved survival in comparison to dobutamine.<sup>32</sup> Currently, levosimendan is approved for use in the treatment of ADHF in Europe but not in the United States.

### Cardiac Myosin Activators

Hydrolysis of ATP by myosin adenosine triphosphatase (ATPase) leads to flexion of the myosin head with displacement of myosin in relation to actin, which results in muscle contraction. Cardiac myosin activators stimulate myosin ATPase, thereby increasing force generation. In animal studies, cardiac myosin activators were shown to increase fractional shortening of myocytes, improve cardiac function, and improve hemodynamics without increasing the intracellular calcium concentration, thereby theoretically attenuating myocardial oxygen consumption and the development of arrhythmias.<sup>33,34</sup> Interestingly, the mechanism of improving systolic function appears to be related to an increase in LV systolic ejection time rather than an increase in peak rate of pressure change with time ( $\Delta P/\Delta T$ ) as seen with other inotropes. A phase I study in 34 healthy men

randomly assigned to receive one of four doses of a cardiac myosin activator, CK-1827452, or placebo demonstrated a dose-related increase in systolic function and an increase in systolic ejection time. Although CK-1827452 was well tolerated, it did lead to a significant drop in mean standing systolic blood pressure by 13 mm Hg ( $P < .0001$ ) and in mean supine systolic blood pressure by 7 mm Hg ( $P < .05$ ) in comparison to placebo.<sup>35</sup> In a phase II trial, two cohorts each of 8 patients with stable heart failure (left ventricular ejection fraction [LVEF]  $< 40\%$ ) were treated with placebo and three escalating doses of CK-1827452. Treatment with CK-1827452 was associated with an increase in systolic ejection time and improvement in LV function, as assessed by echocardiography. The drug was well tolerated, with a decrease in heart rate at higher doses but no change in blood pressure.<sup>36</sup> Although the results of these small preliminary studies are promising, the clinical efficacy and safety of cardiac myosin activators in patients with heart failure remain to be determined.

### Istaroxime

Istaroxime, another novel contractility-enhancing agent, inhibits sodium-potassium ATPase and increases the activity of sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA). Increased SERCA activity results in accumulation of calcium within the myocyte during systole and rapid extrusion of calcium in diastole, which lead to an improvement in both inotropic and lusitropic function. Animal studies with istaroxime have demonstrated an improvement in systolic and diastolic function with little change in myocardial oxygen consumption.<sup>37</sup> In the first larger clinical trial in humans, which was a phase II study, Hemodynamic Effects of Istaroxime in Patients With Worsening Heart Failure and Reduced LV Systolic Function (HORIZON-HF), 120 patients who were hospitalized for systolic heart failure were randomly assigned to receive one of three doses of istaroxime or placebo. All istaroxime doses resulted in a significant decrease in pulmonary capillary wedge pressure in comparison to placebo. Moreover, treatment with istaroxime was associated with a significant decrease in heart rate and an increase in systolic blood pressure. Patients treated with the highest dose showed an increase in cardiac index, a decrease in left ventricular end-diastolic volume, and improvement in diastolic parameters on echocardiography without a significant change in left ventricular ejection fraction. No major adverse effects were noted.<sup>38</sup> Although these results are encouraging, istaroxime's effect on short- and long-term clinical and safety outcomes remains to be determined.

## METABOLIC MODULATORS

In the healthy human heart, ATP is produced from free fatty acids (FFA) 70% of the time and from glucose and other carbohydrates 30% of the time.<sup>39</sup> The metabolism of FFAs results in more ATP production, albeit at a greater cost of oxygen use, than of glucose. Moreover, during ischemia, FFA metabolism is altered, resulting in a greater production of lactate, which in turn can lead to tissue acidosis and decreased myocyte contractility<sup>40,41</sup> (Figure 50-2). Thus, under hypoxic or ischemic conditions, a shift from FFA to glucose use would be more metabolically efficient for the heart.<sup>42</sup> However, in situations of cardiac ischemia, as well as heart failure, FFA oxidation is increased and glucose use is decreased, which result in a metabolically inefficient milieu, which can further promote ischemia and worsen myocardial function.<sup>43</sup> Metabolic modulators are agents that create a more efficient milieu of energy metabolism by increasing glucose and decreasing FFA use.

### Perhexiline

The best-studied metabolic modulator to date is perhexiline. Through inhibition of the enzyme carnitine palmitoyl transferase-1, perhexiline reduces mitochondrial FFA transport,<sup>44</sup> which results in increased glucose metabolism. In the 1970s, perhexiline was successfully used for the treatment of angina. However, its use soon plummeted after reports of hepatotoxicity and neurotoxicity in patients who metabolized perhexiline slowly.<sup>45</sup> The metabolic derangement noted in heart failure raised the possibility that perhexiline may theoretically benefit patients with heart failure by directing energy production toward a more metabolically efficient substrate: glucose. In a small trial, 56 patients with chronic New York Heart Association (NYHA) functional class II or III systolic heart failure were randomly assigned to receive perhexiline or placebo. After 8 weeks, perhexiline-treated patients demonstrated a significant increase in LV function and peak exercise oxygen consumption in comparison with the placebo recipients. There was no evidence of hepatotoxicity or neurotoxicity in this small group of patients.<sup>46</sup>

### Trimetazidine

A second drug, trimetazidine, inhibits long-chain 3-ketoacyl coenzyme A thiolase, which is involved in the oxidation of FFA and thereby increases myocardial glucose use.<sup>47</sup> It has been used as an antianginal and, more recently, investigated in patients with heart failure. Results of several small studies of patients with ischemic cardiomyopathy suggested that trimetazidine may have a beneficial effect on preservation or improvement of LV function. Fragasso and associates<sup>48</sup> randomly assigned 55 patients with ischemic and nonischemic cardiomyopathy (NYHA functional classes II to IV) to receive trimetazidine or placebo in addition to conventional heart failure treatment. After a mean follow-up period of 13 months, the trimetazidine-treated patients demonstrated significant improvements in exercise capacity, NYHA functional class, and LVEF and a decrease in LV end-systolic volume in comparison with placebo recipients. No increase in adverse events was noted among the trimetazidine-treated patients.

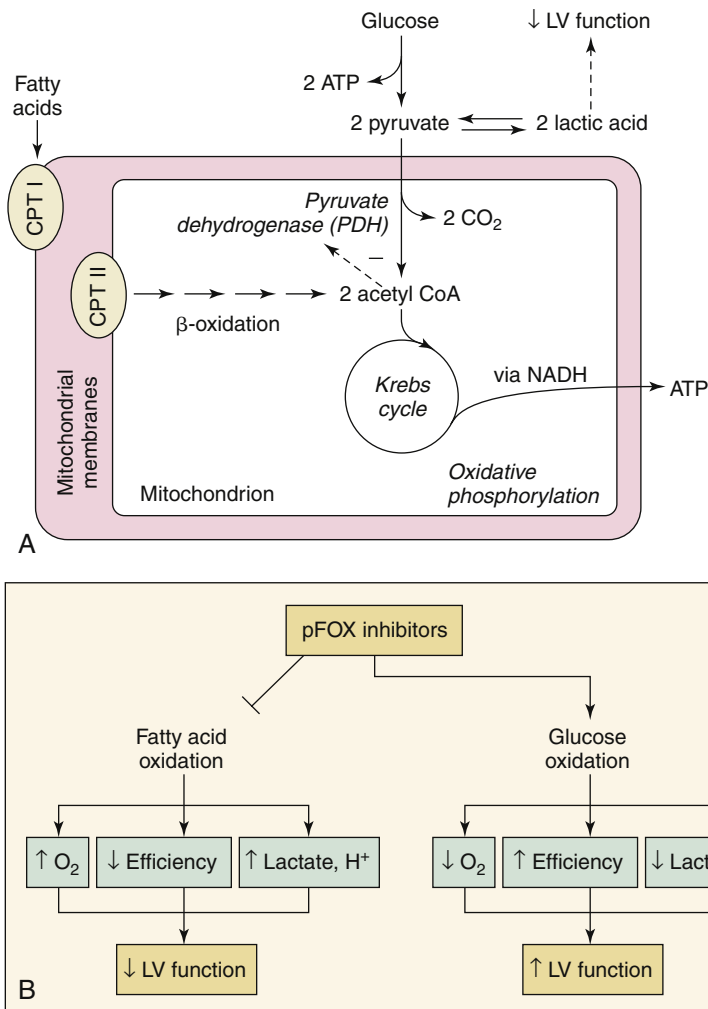

### Ranolazine

A third antianginal agent, ranolazine, alters the transcellular late sodium current, which leads to a decrease in intracellular calcium overload.<sup>49</sup> Ranolazine also appears to promote an increase in glucose oxidation and a reduction in FFA oxidation,<sup>50</sup> with a significant decrease in ischemia and angina.<sup>51</sup> In systolic heart failure, animal experiments have demonstrated that treatment with ranolazine is associated with an improvement in the mechanical efficiency of the left ventricle and in LV function.<sup>52,53</sup> Studies in humans are still lacking. In patients with heart failure and preserved ejection fraction, the effect of ranolazine on echocardiographic parameters of diastolic dysfunction is being investigated in a small clinical trial.<sup>17</sup>

### L-Carnitine

L-Carnitine is an essential cofactor in the metabolism of FFAs. It prevents the accumulation of FFA, prevents lactic acid production, and appears to enhance glucose use.<sup>54</sup> L-Carnitine deficiency has been associated with the development of cardiomyopathy.<sup>55</sup> Supplementation with L-carnitine has been shown to improve exercise capacity in patients with coronary artery disease and angina.<sup>56</sup> In patients with heart failure, administration of propionyl L-carnitine has been demonstrated to acutely decrease pulmonary artery and pulmonary capillary wedge pressure.<sup>57</sup> In small prospective, randomized

**FIGURE 50-2** Metabolism of free fatty acids and glucose. **A**, Metabolic pathway for glucose metabolism and fatty acid oxidation. **B**, Effects switching metabolism from fatty acid  $\beta$ -oxidation to glucose oxidation (under conditions in which oxygen supply is rate limiting) by means of partial inhibitors of fatty acid oxidation (pFOX). ATP, adenosine triphosphate; CoA, coenzyme A; CPT, carnitine-palmitoyl transferase; LV, left ventricular; NADH, nicotinamide adenine dinucleotide (reduced form). (From Dimmeler S, Mann D, Zeiher AM, et al. Emerging therapies and strategies in the treatment of heart failure. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier, pp 697-715.)

trials in patients with heart failure, chronic supplementation with L-carnitine was associated with an increase in exercise capacity and peak oxygen consumption. Echocardiography demonstrated a significant reduction in LV dimensions and improvement in LV function.<sup>57-59</sup>

In summary, although the concept of metabolic modulation for the treatment of heart failure appears promising, the efficacy and safety of this approach need confirmation in larger trials.

## IMMUNOMODULATORY AGENTS

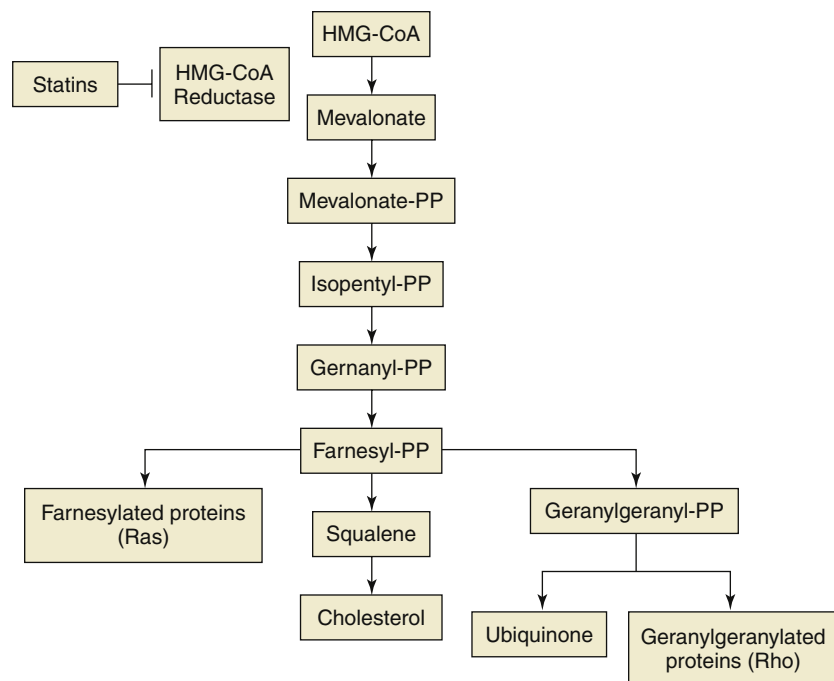

### Statins (see Chapters 11 and 24)

Statins lower cholesterol levels by inhibiting 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in the cholesterol synthesis pathway (Figure 50-3). In addition to their lipid-lowering properties, statins have been reported to have non-lipid-lowering or pleiotropic effects that may have beneficial effects on neuro-hormonal activation and cardiac remodeling in patients with heart failure. Numerous retrospective analyses of data from clinical trials and of observational data revealed a significant mortality-related benefit in patients with heart failure who were treated with statins. Moreover, smaller prospective trials in which the effects of statins on mortality were assessed, as well as nonmortality clinical endpoints (echocardiographic parameters and biomarkers of inflammation), also illustrated beneficial effects of statins in heart failure.<sup>60</sup>

However, two large prospective trials of statin treatment in patients with systolic heart failure have challenged these findings. In the Controlled Rosuvastatin Multinational Trial in Heart Failure (CORONA), 5011 patients with NYHA functional classes II to IV heart failure of ischemic origin were randomly assigned to receive 10 mg of rosuvastatin daily or placebo. Over a median follow-up period of 32.8 months, treatment with rosuvastatin did not confer a significant benefit with regard to the primary endpoint, a composite of death from cardiovascular causes, nonfatal myocardial infarction, and nonfatal stroke, or with regard to several secondary endpoints, including all-cause mortality and coronary events. There was a significant but modest reduction in hospital admissions for cardiovascular events and, according to a post hoc analysis, in nonfatal ischemic events.<sup>61</sup>

In the second trial, Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico-Heart Failure (GISSI-HF), 4574 patients with NYHA functional classes II to IV chronic heart failure were randomly assigned to receive rosuvastatin, 10 mg, or placebo. In contrast to CORONA, 60% of the patients in GISSI-HF had nonischemic cardiomyopathy. At 3.9 years, the two coprimary endpoints, time to death and time to death or hospitalization for cardiovascular reasons, were not significantly different between patients who took rosuvastatin and those who took placebo.<sup>62</sup>

Statins may have a neutral effect in patients with heart failure because they may not alter the pathomechanisms of heart failure, their unfavorable effects may neutralize their beneficial effects, and statin-specific effects may

**FIGURE 50-3** The mevalonate pathway leads to the synthesis of cholesterol. Important intermediate products in the mevalonate pathway include isoprenoids such as farnesyl pyrophosphate and geranylgeranyl pyrophosphate, which have been linked to activation *Ras*- and *Rho*-mediated signaling. 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors decrease the synthesis of isoprenoids as well as cholesterol, by blocking HMG-CoA reductase. PP, pyrophosphate. (From Ramasubbu K, Mann DL: The emerging role of statins in the treatment of heart failure. *J Am Coll Cardiol* 2006;47:342-344; and Dimmeler S, Mann D, Zeiher AM, et al. Emerging therapies and strategies in the treatment of heart failure. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier, pp 697-715.)

be variable. According to the results of CORONA and GISSI-HF, statins should not be initiated in patients with nonischemic cardiomyopathy unless this is indicated by their lipid profile. In patients with chronic heart failure resulting from ischemic cardiomyopathy, the evidence does not support initiating statins for heart failure except in the setting of ischemia or when indicated by the current lipid guidelines.

### Polyunsaturated Fatty Acids (see Chapters 11 and 24)

Small trials have revealed beneficial effects of n-3 polyunsaturated fatty acids (PUFA) in cardiovascular disease, apart from their favorable effects on the lipid profile. These benefits were ascribed to their salutary effects on inflammation, endothelial function, blood pressure, heart rate, autonomic tone, and ventricular function. In patients with cardiovascular disease and at high risk for ventricular arrhythmias, supplementation with PUFA has been shown to result in a decrease in ventricular arrhythmias.<sup>63</sup> In a larger trial, Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico (GISSI)-Prevenzione trial, patients who had suffered myocardial infarction were randomly assigned to receive PUFA; they demonstrated a 20% reduction in mortality, largely attributed to a decrease in sudden death.<sup>64</sup>

On the basis of these findings, the researchers in the GISSI-HF trial randomly assigned 6975 patients with NYHA functional class II to IV heart failure to receive PUFA or placebo (mean LVEF = 33%). After a mean follow-up period of 3.9 years, patients taking PUFA showed a small but significant improvement in rates of mortality (adjusted hazard ratio, 0.91; 95.5% confidence interval, 0.833 to 0.998;  $P = .041$ ) and in rates of mortality or admissions for cardiovascular disorders. Of interest was that mortality reduction was driven largely by a reduction in presumed death from arrhythmia. Moreover, the investigators demonstrated that the administration of PUFA to patients with heart failure did not cause an increase in adverse events.<sup>65</sup> Thus, the administration of PUFA to patients with heart failure is reasonable, with modest efficacy and a good safety profile.

### GENE THERAPY

Gene therapy represents yet another potential novel therapeutic approach for the treatment of heart failure. Gene therapy involves the manipulation of gene expression or function for the purpose of treatment of a specific disease. Gene transfer can result either in the expression and replacement of a missing gene product or in the overexpression of a native or foreign gene whose product can prevent or reverse a disease process. This genetic manipulation may be achieved either by the introduction of foreign DNA that encodes a biologically active transgene into cells or by transfection of short chains of nucleic acids, known as "deoxynucleotides", that modify endogenous gene expression in target cells.<sup>66</sup> Improvements in both gene transfer vectors and in vivo gene delivery techniques have facilitated genetic manipulation of myocardial function and enabled targeted therapy for heart failure.

For any application of gene therapy to be clinically successful, three elements are essential<sup>66</sup>: First, a vector or packaging system to deliver the genetic material is required. Vectors can be distinguished as viral and nonviral vectors. Thus far, for cardiac diseases, viral vectors appear to be the most efficient in achieving high levels of trans-gene expression in postmitotic cells such as cardiomyocytes. These vectors include recombinant adenoviruses and adeno-associated viruses.<sup>67,68</sup> Second, it is important that the vector is adequately delivered to the affected tissues. Numerous techniques have been described for in vivo cardiac gene transfer, including intracoronary catheter delivery, intramyocardial delivery, pericardial injection techniques, and injections by catheters introduced through the left ventricular apex while the aorta and pulmonary arteries are cross-clamped. Each technique has advantages and disadvantages<sup>66</sup> (Figure 50-4). Third, appropriate target gene identification is crucial. For the treatment of heart failure, promising targets that have been the focus of gene transfer research have included genes involved in the myocardial calcium-handling system, the  $\beta$ -adrenergic signaling system, and pathways that affect cardiomyocyte apoptosis, as summarized in the paragraphs that follow.

**FIGURE 50-4** Different techniques for in vivo cardiac gene transfer. **A**, Coronary perfusion. **B**, Intramyocardial injection. **C**, Pericardial injection. **D**, Aortic clamping. **E**, Cross-clamping of the aorta and pulmonary artery. Prospects for gene therapy for heart failure. *Circ Res* 2000;86:616-621; and Dimmeler S, Mann D, Zeiher AM, et al. Emerging therapies and strategies in the treatment of heart failure. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier, pp 697-715.)

### $\beta$ -Adrenergic Signaling System (see Chapter 10)

The  $\beta$ -adrenergic receptor ( $\beta$ -AR) is known to play a critical role in mediating the inotropic state of the heart. Alterations in the myocardial  $\beta$ -AR system both precede and accompany the development of heart failure in humans. These alterations include downregulation of  $\beta$ -ARs, functional uncoupling of remaining  $\beta$ -ARs from second-messenger systems, increased levels of inhibitory G-proteins that blunt  $\beta$ -AR signaling, and upregulation of  $\beta$ -AR kinase 1 ( $\beta$ -ARK1), which appears to play an important role in the downregulation of  $\beta$ -ARs in the failing heart.<sup>69,70</sup> Transgenic mice that overexpressed the  $\beta_2$ -AR in the myocardium demonstrated highly enhanced contractility without overt pathological conditions.<sup>71</sup> This genetic manipulation has created considerable interest in the transfer of the  $\beta$ -AR gene into the failing myocardium as a therapeutic intervention. Adenoviral gene transfer of the human  $\beta_2$ -AR and inhibitor of  $\beta$ -ARK1 has been shown to result in improved  $\beta$ -AR signaling in myocytes in a rabbit heart failure model.<sup>72,73</sup> Moreover, in a mouse heart failure model, overexpression of a  $\beta$ -ARK1 inhibitor appeared to prevent the development of cardiomyopathy.<sup>74</sup> Similarly, adenovirus-mediated delivery of a peptide inhibitor of  $\beta$ -ARK1 in rabbit heart failure models has resulted in restoration of  $\beta$ -AR signaling, as well as reversal of ventricular dysfunction.<sup>75</sup> Of note, excessive stimulation of the  $\beta$ -AR ( $\beta_1$  and  $\beta_2$ ) signaling can also lead to activation of maladaptive signaling pathways in the heart, as well as myocyte death and heart failure.<sup>76,77</sup> Thus, caution must be exercised in promoting the  $\beta$ -AR signaling pathway.

### Calcium-Handling System (see Chapter 4)

Enhancement of myocardial contractility through the manipulation of intracellular calcium levels has also been a target of gene therapy research (Figure 50-5). In failing hearts,

suppression of sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA) activity, or a reduction in the SERCA protein, appears to contribute to the abnormalities in calcium handling and myocardial contraction.<sup>78</sup> Using adenovirus-mediated gene transfer that resulted in an overexpression of SERCA protein in rat cardiomyocytes and rat heart failure models, researchers achieved an improved handling of intracellular calcium that was accompanied by an improvement in myocardial systolic and diastolic function.<sup>79-82</sup> Furthermore, gene transfer of SERCA in rats with heart failure resulted in improved survival, as well as improved energy potential of the failing hearts.<sup>83</sup> In vitro gene transfer of SERCA into human cardiomyocytes from patients with end-stage heart failure resulted in an increase in protein expression, an increase in pump activity, and faster contraction and relaxation velocities.<sup>79</sup>

Phospholamban is a sarcomeric protein that regulates SERCA activity.<sup>84</sup> Results of several studies suggested that an abnormal ratio of phospholamban to SERCA contributes significantly to abnormalities in calcium handling and contraction observed in the failing ventricular myocardium.<sup>66,85</sup> Overexpression of an antisense phospholamban construct or a dominant-negative mutation of phospholamban has been shown to enhance SERCA activity.<sup>86</sup> Moreover, after gene transfer of S100A1 (a calcium-binding protein), beneficial effects on cardiac contractility, including normalized calcium handling and enhanced SERCA activity, were observed in experimental and human models of heart failure.<sup>87</sup>

### Cardiomyocyte Survival (see Chapter 6)

Morphological and biological markers of programmed cell death (apoptosis) have been identified in human heart failure, which suggests that these pathways may contribute to cardiomyocyte loss and cardiac dysfunction in heart failure.<sup>88</sup> The ability to block cardiomyocyte apoptosis through

**FIGURE 50-5** Myocyte calcium handling. Calcium uptake through the L-type calcium channel (LTCC) activates calcium release from the sarcoplasmic reticulum (SR) through the ryanodine receptor (RyR). This increase in intracellular calcium results in myocyte contraction. Reuptake of calcium into the SR by sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA) and extrusion of calcium through membrane sodium-calcium exchanger (NCX) and calcium ATPase result in a decrease in intracellular calcium concentration and myocyte relaxation. ATPase, adenosine triphosphatase; PLB, phospholamban. (From Kawase Y, Hajjar RJ. The cardiac sarcoplasmic/endoplasmic reticulum calcium ATPase: a potent target for cardiovascular diseases. *Nature Reviews Cardiology* 5, 554–565, September 2008).

somatic gene transfer is, therefore, another area of ongoing investigation.<sup>89,90</sup> Gene transfer that leads to overexpression of *Bcl-2*, an antiapoptotic gene, has been shown to inhibit p53-induced apoptosis of cardiomyocytes.<sup>91</sup> Similarly, gene transfer of phosphoinositide 3-kinase and protein kinase B, both antiapoptotic enzymes, has been demonstrated to block cardiomyocyte apoptosis in vitro.<sup>92</sup> In a rabbit model, transduction of cells with the gene for p35, a caspase-3 inhibitor, attenuated the development of heart failure.<sup>90</sup> The development of heart failure after myocardial infarction is associated with the loss of functional cardiomyocytes and replacement with a fibroblast-rich scar tissue. This has led to the attempt of genetically converting cardiac fibroblasts into functional cardiomyocytes.<sup>93</sup>

Thus, using gene therapy for the prevention and treatment of heart failure holds tremendous promise. However, much work remains to be done before the results of these basic investigative studies can be applied to clinical gene therapy in humans with heart failure.

Two clinical trials are currently under way in which researchers are evaluating the gene transfer of SERCA in patients with heart failure. The results are highly anticipated. Hajjar and colleagues<sup>94</sup> designed a phase I/II trial of intracoronary administration of adeno-associated virus serotype 1 (AAV1) and SERCA2a in patients with heart failure, in which the patients will initially undergo open-label administration of various doses of AAV1/SERCA2a. In a second stage, patients will be randomly assigned to receive various doses of AAV1/SERCA2a or placebo in a double-blind manner. In a second study,<sup>17</sup> researchers are evaluating the safety and efficacy of AAV6/SERCA2a administration in patients with nonischemic cardiomyopathy who are undergoing placement of left ventricular assist devices.

## OTHER NOVEL THERAPIES

### Sildenafil

Sildenafil is a selective phosphodiesterase type 5 inhibitor. It therefore increases levels of cyclic guanosine monophosphate (cGMP), which leads to the activation of cGMP-dependent protein kinases that mediate vascular smooth muscle relaxation and thus vasodilation.<sup>95</sup> Newer data implicate the role of cGMP-dependent protein kinases in the reversal of

ventricular hypertrophy by inhibiting downstream hypertrophy signaling<sup>96</sup> (Figure 50-6).

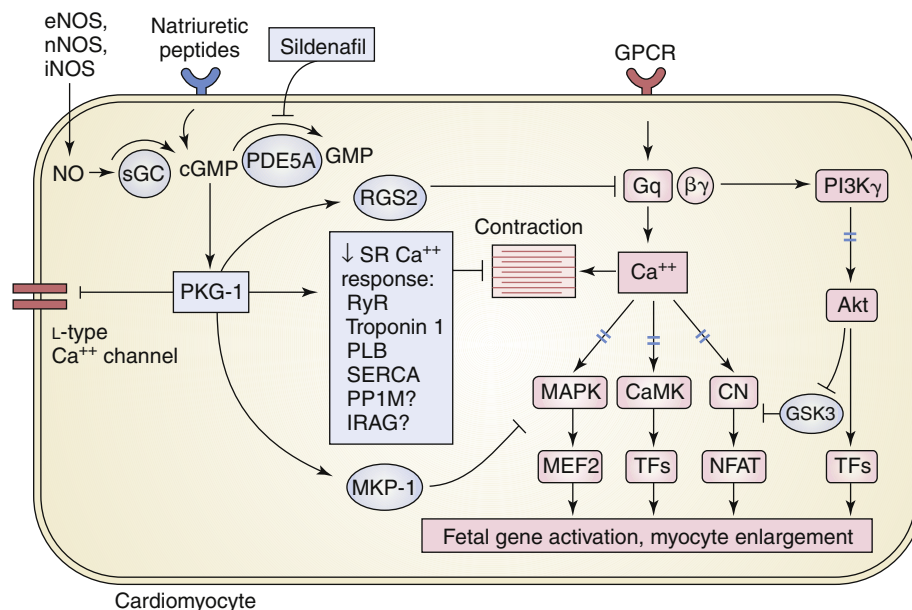

Sildenafil has been shown to be beneficial in the treatment of patients with pulmonary hypertension by decreasing pulmonary artery pressures without having a significant effect on systemic pressures. The development of pulmonary hypertension in patients with heart failure portends worse outcomes and can be a contraindication to therapies such as cardiac transplantation.<sup>97</sup>

Sildenafil has been evaluated for the treatment of systolic heart failure in small clinical trials. Lewis and associates<sup>98</sup> evaluated the acute effect of sildenafil on invasive cardiac hemodynamics, gas exchange, and first-pass radionuclide ventriculography at rest and during exercise in 13 patients with NYHA class III heart failure. Sildenafil administration was associated with reductions in resting pulmonary arterial pressure, systemic vascular resistance, and pulmonary vascular resistance and with an increase in resting cardiac index, without altering mean arterial pressure, heart rate, or pulmonary capillary wedge pressure. During exercise, sildenafil reduced pulmonary arterial pressure and pulmonary vascular resistance. Moreover, peak oxygen consumption ( $\text{VO}_{2\text{max}}$ ) increased, ventilatory response to carbon dioxide output ( $\text{VE}/\text{VCO}_2$  slope) decreased, and right ventricular ejection fraction increased after sildenafil administration. Thus, the investigators were able to demonstrate that sildenafil has a selective pulmonary vasodilator effect with little effect on systemic blood pressure, heart rate, and pulmonary capillary wedge pressure. The pulmonary vasodilator effect leads to an increase in right ventricular function and, possibly as a result, an increase in cardiac output.<sup>98</sup> The increase in cardiac output, together with other mechanisms, may have contributed to improvements in exercise capacity. Of note, the one other selective pulmonary vasodilator, inhaled nitric oxide, has the disadvantage of increasing pulmonary capillary wedge pressure and inducing pulmonary edema in patients with heart failure.<sup>99</sup>

In another trial, Bussotti and colleagues<sup>100</sup> evaluated the acute effects of sildenafil on pulmonary mechanics at rest and with exercise by administering 25-mg and 100-mg doses of sildenafil to 22 male patients with systolic heart failure (NYHA class II or III). Sildenafil administration was associated with enhancements in pulmonary perfusion, gas diffusion, and lung mechanics.

Subsequent studies have been performed to examine the chronic efficacy of sildenafil in patients with heart failure.

**FIGURE 50-6** Sildenafil and hypertrophy. Sildenafil increases intracellular cyclic guanosine monophosphate (cGMP) by inhibiting phosphodiesterase 5 (PDE5A). Then cGMP activates cGMP-dependent protein kinase type 1 (PKG-1). PKG-1, in turn, inhibits several downstream signaling pathways that promote hypertrophy. Akt, Protein kinase B; CaMK, calcium/calmodulin-dependent protein kinases; CN, calcineurin; eNOS, endothelial nitric oxide synthase; GPCR, G-protein-coupled receptor; Gq, heterotrimeric G-protein; GSK3, glycogen synthase kinase 3; iNOS, inducible nitric oxide synthase; IRAG, inositol 1,4,5-trisphosphate receptor I-associated protein; nNOS, neuronal nitric oxide synthase; MAPK, mitogen-activated protein kinase; MEF<sub>2</sub>, myocyte enhancer factor 2; MKP-1, mitogen-activated protein kinase phosphatase-1; NFAT, nuclear factor of activated T cells; NO, nitric oxide; PI3K $\gamma$ , phosphoinositide 3-kinase  $\gamma$ ; PLB, phospholamban; PP1M, myosin phosphatase; RGS2, regulator of G-protein signaling 2; RyR, ryanodine receptor; SERCA, sarcoplasmic/endoplasmic reticulum calcium adenosine triphosphatase; sGC, soluble guanylate cyclase; SR, sarcoplasmic reticulum; TFs, transcription factors. (From Mendelsohn, ME: *Viagra: now mending hearts*. *Nat Med* 2005;11[2]:115-116.)

Lewis and associates<sup>98</sup> randomly assigned 34 patients with NYHA functional class II or III heart failure (LVEF < 40%) and pulmonary hypertension (mean pulmonary arterial pressure > 25 mm Hg) to receive 12 weeks of treatment with sildenafil or placebo. Sildenafil-treated patients demonstrated a significantly greater increase in  $VO_{2max}$  and significantly lower resting pulmonary vascular resistance. The remaining resting hemodynamic parameters did not differ significantly between sildenafil- and placebo-treated patients. With exercise, sildenafil-treated patients exhibited a significant decrease in pulmonary vascular resistance and increases in stroke volume and cardiac output in comparison to placebo recipients. Moreover, sildenafil-treated patients demonstrated a significant increase in right ventricular ejection fraction at rest and with exercise but no change in LV size or LVEF. With regard to symptoms, the Minnesota Living with Heart Failure score and the NYHA functional class improved significantly in the sildenafil-treated patients. Rates of adverse events were similar in the two groups except for headaches, which were more frequent in sildenafil-treated patients. Lewis and associates concluded that in patients with systolic heart failure with pulmonary hypertension, prolonged administration of sildenafil safely decreased pulmonary vascular resistance, improved right ventricular function, and, possibly as a result of these occurrences, led to an increase in stroke volume and cardiac output. In addition, sildenafil significantly improved  $VO_{2max}$ .<sup>98</sup> These findings by themselves are very valuable but are also important in the context of safety: Sildenafil can be safely used in patients with heart failure and pulmonary hypertension, in contrast to other pulmonary vasodilators. In contrast, the endothelin antagonist bosentan has been associated with fluid retention and failure to improve symptoms of heart failure,<sup>101</sup> and the prostacyclin analogue epoprostenol has been associated with increased mortality, especially in patients with coronary artery disease.<sup>102</sup>

Researchers in a second trial also evaluated the chronic effect of sildenafil on hemodynamics, as well as exercise dynamics. Guazzi and coworkers<sup>103</sup> randomly assigned 46 male patients with NYHA functional class II or III heart failure (the presence of pulmonary hypertension was not necessary for inclusion) to receive sildenafil or placebo. At 3 and 6 months, the sildenafil-treated patients demonstrated a reduction in systolic pulmonary artery pressure, a reduction in ergoreflex effect on ventilation, an improvement in  $V_{CO_2}$

production slope and  $VO_{2max}$ , and improvements in breathlessness score and flow-mediated vasodilation. The improvement in exercise efficiency was attributed to improved cardiopulmonary hemodynamics and improved sensitivity of the ergoventilatory reflex (a reflex that couples mechanoreceptors or chemoreceptors, or both, in exercising skeletal muscle to the control of ventilation), which, in turn, was possibly a result of improved skeletal muscle perfusion.

The increase in cardiac output with sildenafil treatment has been attributed largely to an improvement in right ventricular function (which results from a decrease in pulmonary artery pressures) and to a decrease in systemic vascular resistance. Several observations support the concept that sildenafil has positive inotropic properties. In patients given inhaled nitric oxide with comparable reductions in the pulmonary vascular resistance, an increase in cardiac output was not noted in comparison to sildenafil.<sup>104</sup> Moreover, Nagenbran and associates<sup>105</sup> confirmed a lack of phosphodiesterase type 5 in normal human right ventricular myocardium but were able to demonstrate its presence in hypertrophied right ventricular myocardium. In addition, they were able to show a positive inotropic effect with phosphodiesterase type 5 inhibition in this tissue. The mechanism of positive inotropy remains to be elucidated.

Moreover, novel exciting data suggest that cGMP-dependent protein kinases are involved in the reversal of myocardial hypertrophy and subsequent improvement in ventricular function; thus, phosphodiesterase type 5 inhibitors may have a role in the treatment of ventricular hypertrophy and reverse remodeling. In an animal model of ventricular hypertrophy induced by pressure overload, sildenafil administration prevented the development of ventricular hypertrophy and, in animals with established hypertrophy, reversed the hypertrophy. The postulated mechanisms are improved calcium handling, sildenafil-induced increase in cGMP concentration, and thus increase in cGMP-dependent protein kinase activity, which in turn appears to lead to a decrease in downstream hypertrophy signaling. At the same time, animals treated with sildenafil showed an improvement in ventricular systolic function.<sup>96,106</sup>

These findings are very encouraging and suggest that sildenafil may successfully and safely decrease pulmonary artery pressures in patients with systolic heart failure and improve symptoms and exercise capacity even in patients with heart

failure but without significant pulmonary hypertension.<sup>103</sup> Larger prospective clinical trials are needed to confirm these findings and to evaluate the benefit of this agent on morbidity and mortality outcomes in patients with systolic heart failure. Moreover, the evidence that sildenafil may reverse hypertrophy suggests that it may have a role in the treatment of diastolic heart failure, as reviewed in detail in Chapter 48.

### Inhibitor of $I_f$ Current in Sinoatrial Node (Ivabradine)

Ivabradine is a novel agent that selectively decreases heart rate by altering electrical currents in the sinus node. It is an inhibitor of the  $I_f$  current in the sinoatrial node, leading to a decrease in heart rate without affecting blood pressure, contractility, and other aspects of intracardiac conduction.<sup>107-110</sup> The use of ivabradine in patients with coronary artery disease and LV systolic dysfunction is based on the experience that a high heart rate is associated with increased mortality in patients with coronary artery disease and that significant mortality-related benefit is conferred on patients with LV systolic heart failure who are treated with  $\beta$ -blockers.<sup>111,112</sup> Moreover, retrospective analyses of several  $\beta$ -blocker trials in patients with heart failure have demonstrated that heart rate reduction was predictive of survival. This outcome is attributed in part to decreased myocardial oxygen demand with lower heart rates.<sup>113</sup>

In the “morbidity-mortality Evaluation of the  $I_f$  inhibitor ivabradine in patients with coronary disease and left ventricular dysfunction” (BEAUTIFUL) trial, 10,917 patients with coronary artery disease and LVEF of 40% or lower ( $\approx 60\%$  were categorized as NYHA functional class II) were randomly assigned to receive ivabradine or placebo. At 12 months, ivabradine reduced heart rate by 6 beats/minute, in comparison with placebo. However, ivabradine had no effect on the primary endpoint (a composite endpoint of cardiovascular death, hospitalization for acute myocardial infarction, and hospitalization for new-onset or worsening heart failure) or on any of the secondary endpoints (including all-cause mortality and admissions for worsening heart failure). Of note, subgroup analysis did not demonstrate any difference between subjects with NYHA functional classes I and II and those with class III heart failure or in patients with LVEF of 35% or higher versus LVEF lower than 35%. Furthermore, a prespecified subgroup analysis of patients with hearts of 75 bpm or higher did not reveal any significant difference in the primary endpoint; however, it did demonstrate a decrease in hospitalizations for fatal and nonfatal myocardial infarction and coronary revascularization.<sup>114</sup> With regard to heart failure, neutral effects of ivabradine in this trial could potentially be explained by a potential benefit in more symptomatic patients (the majority of patients in the trial had NYHA classes I and II heart failure) and the fact that inherent qualities of  $\beta$ -blockers not necessarily related to heart rate lowering may be responsible for the mortality- and morbidity-related benefits observed with these agents. The SHIFT (Systolic Heart Failure Treatment with the  $I_f$  Inhibitor Ivabradine Trial) trial randomized 6558 patients with NYHA class II-IV heart failure, an LVEF  $<35\%$ , a resting heart rate  $>70$  bpm, and a heart-failure hospitalization within the previous year to receive either placebo or ivabradine at a starting dose of 5 mg twice daily, with adjustments to a maximum dose of 7.5 mg twice daily to achieve a resting heart rate of 50 to 60 bpm.<sup>114a</sup> All patients were receiving standard heart-failure medications, including ACE inhibitors or angiotensin-receptor blockers, beta blockers, aldosterone antagonists, and diuretics. The primary endpoint for the trial was a composite of cardiovascular death or hospital admission for worsening heart failure. Over a mean followup of 23 months, patients taking ivabradine showed a significant ( $p < 0.001$ ) reduction

in cardiovascular death or hospitalization for worsening heart failure when compared with the control group (HR 0.82, 95% CI 0.75-0.90). The effects were driven primarily by a reduction in hospitalizations for worsening heart failure (21% placebo versus 16% ivabradine; HR 0.74, 0.66-0.83;  $p < 0.0001$ ), whereas the overall impact on cardiovascular death was less robust (5% placebo versus 3% ivabradine; HR 0.74, 0.58-0.94,  $p = 0.014$ ). Interestingly, the HR for the primary endpoint was 0.93 (95% CI 0.80-1.08) for patients who had a heart rate  $<77$  bpm at baseline, but was 0.75 (95% CI 0.67-0.85) among those with rates of  $>77$  bpm at baseline. The difference between these subgroups was significant statistically ( $p = 0.029$ ).

### Vagal Stimulation

With regard to the autonomic nervous system, an increased sympathetic and a decreased vagal tone has been demonstrated in heart failure. This constellation has been associated with worse long-term outcome in patients with heart failure.<sup>115</sup> Attempts to block the effects of the sympathetic nervous system with the use of  $\beta$ -blockers has resulted in significant morbidity- and mortality-related benefits in patients with heart failure. The focus of research is directed toward the effects of enhancing vagal tone in patients with heart failure.

In animal studies, rats that underwent vagal stimulation demonstrated a significant decrease in LV end-diastolic pressure and an increase in LV contractility in comparison with sham-treated rats. Moreover, vagal stimulation significantly increased survival rates at 140 days.<sup>116</sup> Similarly, Zucker and colleagues<sup>117</sup> studied vagal stimulation in 15 dogs with pacing-induced heart failure: 7 dogs with baroreceptor stimulation were compared to 8 dogs without baroreceptor stimulation. Dogs that underwent baroreceptor stimulation demonstrated significantly improved survival rates and lower plasma norepinephrine levels, with less of an increase in plasma angiotensin II levels. Interestingly, arterial pressure, resting heart rate, and LV pressure were not different between the two groups. The investigators concluded that vagal stimulation led to the suppression of neurohormonal activation, which was associated with improved survival.

In initial human studies, Schwartz and associates<sup>118</sup> evaluated eight patients with heart failure who underwent implantation of a vagal stimulator. At the 6-month follow-up evaluation, improvements in NYHA functional class, quality-of-life score, and LV end-systolic volume were noted. De Ferrari<sup>119</sup> presented the results of vagal stimulation in 32 patients with NYHA functional class II to IV systolic heart failure. At 6 months, patients demonstrated significant increases in LV function, 6-minute walk distance, and quality-of-life score. Vagal stimulation thus appears to be an exciting new avenue in the treatment of heart failure that could be added to the current treatment armamentarium. However, to date, human studies have been small and non-randomized, and larger, randomized data are necessary in order to definitively assess the efficacy and safety of this treatment strategy.

### Testosterone

The heart failure syndrome is a multisystem disorder in which the main abnormality, LV systolic dysfunction, is not always predictive of long-term outcome and functional capacity. One of the factors contributing to decreased functional capacity is the loss of skeletal muscle strength and muscle fatigue.<sup>120</sup> The underlying mechanism of muscle fatigue is probably multifactorial and includes chronic  $\beta$ -adrenergic stimulation, systemic inflammation, reactive oxygen species, and insulin resistance.<sup>120,121</sup>

Testosterone deficiency has also been implicated as a causative factor in muscle fatigue in patients with heart

failure, especially in patients with cardiac cachexia.<sup>122</sup> Few small studies in male patients with heart failure demonstrated an improvement in functional capacity with testosterone supplementation.<sup>123,124</sup> In a 2009 study by Caminiti and coworkers,<sup>125</sup> 70 elderly men with NYHA functional class II or III systolic heart failure were randomly assigned to receive 3-month treatment with testosterone or placebo, in addition to standard heart failure therapy. At follow-up, patients receiving testosterone showed a significant increase in  $\text{VO}_{2\text{max}}$ , improvement in leg muscle strength, improvement in insulin sensitivity, and an increase in baroreceptor sensitivity. Testosterone-treated patients also gained weight and exhibited a significant increase in hematocrit. No significant difference in LV function was noted between the two groups, which suggests that the increase in functional capacity may have resulted from other factors, including improved peripheral muscle strength, improved insulin sensitivity, and increased hematocrit. Interestingly, the beneficial testosterone effects were seen in patients whose baseline testosterone levels were low or normal, but patients with testosterone deficiency showed a more notable response. Several important issues—including the selection of patients and safety issues of long-term treatment—must be resolved before testosterone supplementation becomes an accepted treatment strategy.

## NOVEL TREATMENT STRATEGIES FOR HEART FAILURE OF SPECIFIC ETIOLOGIES

### Insulin Resistance and Heart Failure (see Chapter 20)

As discussed earlier, cardiac metabolism switches from predominantly FFA to glucose metabolism in the setting of tissue hypoxia/ischemia. However, if insulin resistance is present, an increase in FFA utilization has been observed, leading to a less efficient energy metabolism.<sup>126-128</sup> Moreover, patients with heart failure with diabetes mellitus demonstrate myocardial insulin resistance with reduced myocardial glucose uptake, partly attributed to elevated levels of circulating FFA.<sup>129,130</sup> Furthermore, there is evidence that increased myocardial FFA uptake can lead to lipotoxicity and the development of a cardiomyopathy.<sup>131,132</sup>

Administration of peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ) agonists such as thiazolidinediones, which increase glucose and decrease FFA use, has been shown to prevent the development of cardiomyopathy.<sup>133,134</sup> However, the use of thiazolidinediones in patients with heart failure has been limited because they carry a risk of fluid retention and myocardial infarction.<sup>135,136</sup> Several other agents, such as dichloroacetate<sup>137</sup> and etomoxir,<sup>138</sup> that promote glucose metabolism and decrease FFA metabolism have also been shown to protect against the development of cardiomyopathy.

Glucagon-like peptide-1 (GLP-1), an antidiabetic agent, increases postprandial insulin secretion and improves insulin sensitivity. Apart from its effects on glucose metabolism, GLP-1 receptors can be found on vascular smooth muscle cells, cardiomyocytes, and coronary endothelium and smooth muscle, which implies its role in the cardiovascular system.<sup>139</sup> In fact, in vitro studies indicate that GLP-1 has vasodilatory properties,<sup>140</sup> and in human diabetic and non-diabetic subjects, administration of GLP-1 was associated with an improvement in forearm flow-mediated vasodilation.<sup>141</sup> Moreover, results of preliminary animal and human studies suggest that GLP-1 may be involved in myocardial protection during ischemia with a decrease in infarct size and improvement in regional wall motion and global LV function.<sup>142-144</sup>

In chronic heart failure, the administration of GLP-1 has been associated with an improvement in LV function. In a dog model of pacing-induced cardiomyopathy, the administration of GLP-1 resulted in significant increases in LV  $\Delta P/\Delta T$  and stroke volume and decreases in LV end-diastolic pressure, heart rate, and systemic vascular resistance.<sup>145</sup> Poornima and colleagues<sup>146</sup> investigated the effect of long-term administration of GLP-1 to spontaneously hypertensive, heart failure-prone rats. Fifty rats were randomly assigned to receive a 3-month infusion of GLP-1 or placebo. Those treated with GLP-1 demonstrated improved survival and preserved LV function in comparison with those given placebo. Moreover, GLP-1 treatment was associated with increased myocardial glucose uptake and decreased myocyte apoptosis.

Several small human studies have also suggested a benefit of GLP-1 in patients with systolic heart failure. In a study of 12 patients with NYHA functional class III or IV heart failure, a continuous infusion of GLP-1 for 12 weeks improved LVEF (by 21% to 27%) and functional capacity, even in patients without diabetes.<sup>147</sup> Similarly, in a study of 10 patients with acute myocardial infarction and LV systolic dysfunction (LVEF < 40%), a 72-hour continuous infusion of GLP-1 produced significant improvements in LVEF and both global and regional wall motion.<sup>144</sup> In a small study of 15 patients with heart failure who received a 48-hour infusion of GLP-1, however, there was no improvement in cardiac index or LVEF, and there was a worrisome small but significant rise in heart rate and diastolic blood pressure.<sup>148</sup>

The underlying mechanisms of the vasodilatory effects, protection against ischemia, and improvement in LV function are unclear. Although the findings in these small studies are for the most part promising, similar results must be reproduced in larger, randomized trials with closer scrutiny of safety and feasibility when GLP-1 is added to already established treatment of heart failure. Moreover, GLP-1 must be given as an infusion and has a very short half-life; therefore, alternative GLP-1 agonists may need to be studied.

### Peripartum Cardiomyopathy

Peripartum cardiomyopathy is a rare but potentially lethal condition for which the cause and pathophysiological mechanisms are unknown. Potential mechanisms include inflammatory, autoimmune, and oxidative stress-mediated myocardial changes. Recommended treatment is essentially standard medical therapy for heart failure with attention to safety of the agents during pregnancy and the postpartum period. The use of bromocriptine, a dopamine  $D_2$  receptor agonist, has been investigated in the treatment of peripartum cardiomyopathy. Oxidative stress in the setting of pregnancy or in the postpartum period can lead to the cleavage of the conventional prolactin molecule into a prolactin molecule that appears to have a detrimental effect on the myocardium by promoting apoptosis, vasoconstriction, and inflammation.<sup>149,150</sup> Bromocriptine inhibits the secretion of prolactin; when it was administered in a mouse model of peripartum cardiomyopathy, the development of peripartum cardiomyopathy was prevented.<sup>150</sup> In several human case reports of peripartum cardiomyopathy, treatment with bromocriptine resulted in improvement in clinical status and LV function. However, affected patients were also treated with standard heart failure medications (ACE inhibitors and  $\beta$ -blockers). Thus, improvement may be attributed to natural recovery, treatment with recommended heart failure medications, or treatment with bromocriptine or to a combination of these.<sup>151,152</sup> In a small nonrandomized human study of 12 pregnant patients with a history of peripartum cardiomyopathy during a previous pregnancy, 6 patients were treated with bromocriptine, whereas the remaining 6 patients received standard therapy. All bromocriptine-treated patients had an

uneventful pregnancy, delivery, and postpartum period without recurrence of cardiomyopathy. In contrast, all 6 patients receiving the standard therapy developed recurrent peripartum cardiomyopathy, of which 3 patients died.<sup>153</sup> Although development of this treatment approach seems promising, these findings are restricted to small, nonrandomized case series. Moreover, several reports have indicated serious side effects of bromocriptine, including myocardial infarction and the development of a cardiomyopathy.<sup>154,155</sup> Thus, safety issues, patient selection, and dose issues may need to be clarified before embarking on larger prospective, randomized trials of bromocriptine in peripartum cardiomyopathy.

## SUMMARY

Current neurohormonal strategies do not completely prevent disease progression in heart failure. Thus, current therapy for heart failure should be viewed as a “work in progress.” Although it is not known why heart failure progresses in patients who are receiving optimal therapy with ACE inhibitors and  $\beta$ -blockers, one explanation that has been alluded to in this chapter is that these agents do not directly or sufficiently antagonize all of the biological systems that become activated in the setting of heart failure. Accordingly, one logical direction for future heart failure therapies is the development of therapeutic strategies that more effectively antagonize the neurohormonal systems that are believed to be deleterious. These new neurohormonal treatment strategies will probably be adjunctive to existing clinical strategies for relieving symptoms and preventing disease progression. However, it may not be feasible to antagonize all of the systems that are activated in the setting of heart failure, and such antagonism may even be detrimental, inasmuch as neurohormonal activation is primarily a compensatory mechanism and vital for survival in the acute setting. Accordingly, future therapeutic targets in heart failure will probably need to extend beyond antagonizing neurohormonal systems. Advances in the delivery of gene constructs into the vasculature or the myocardium raise the important possibility that gene-therapeutic approaches may one day be used to attenuate the progression of heart failure. These newer strategies might also be adjunctive to and possibly synergistic with existing therapeutic strategies for treating patients with heart failure.

## THE CONCEPTS OF CELL THERAPY AND TISSUE ENGINEERING

As a result of modern reperfusion strategies and advances in pharmacological management, increasing numbers of patients survive after an acute myocardial infarction (AMI). The loss of viable myocardium is conducive to progressive left ventricular remodeling in many patients (see Chapter 15).<sup>1</sup> The extent of cardiac remodeling after an AMI is closely related to the size of the infarct; with larger infarcts, the extent of left ventricular remodeling is greater, and the prognosis is worse.<sup>2</sup> As a consequence, AMI has become the most common cause of heart failure in many countries.<sup>3</sup> No current therapy, except for cardiac transplantation, addresses the underlying cause of the remodeling process: the critical loss of myocardium in the infarcted area.

Cardiac transplantation is, of course, limited by the shortage of donor organs and the side effects associated with long-term immunosuppression.

Researchers have observed that some cardiomyocytes in the infarct border zone may reenter the cell cycle and divide after an AMI.<sup>4</sup> Findings of genetic fate-mapping studies support the notion that endogenous stem cells may be another source of new cardiomyocytes after ischemic injury.<sup>5</sup> Moreover, there is evidence that the injured myocardium attracts circulating stem and progenitor cells that may positively affect the healing response and functional recovery after an AMI, through release of paracrine factors.<sup>6</sup> The overall capacity of the adult heart for regeneration is limited, however, and most necrotic cardiomyocytes are replaced by scar tissue after an AMI. Nonetheless, the existence of endogenous regenerative mechanisms may enable future therapies to mimic and amplify these processes. Two main approaches to achieve myocardial tissue replacement can be envisioned: the use of isolated cells delivered directly to the diseased myocardium (cell therapy) or the use of a combination of cells and biomaterials to generate functional 3-dimensional tissues in vitro before they are implanted into the body (tissue engineering).<sup>7,8</sup> Both strategies would be used to replace, enhance, repair, or regenerate the function of the infarcted heart.

An average infarct in humans destroys approximately 1 to 2 billion cardiomyocytes. Repair strategies consequently aim to replace scarred myocardium with heart muscle consisting of a comparable cell number. Because the heart is composed of 30% cardiomyocytes and 70% nonmyocyte cells (such as endothelial cells, smooth muscle cells, and fibroblasts), cardiac regeneration is a matter not only of cardiac myocyte addition but also of nonmyocyte supplementation.

from the patient and pose no risk of immune rejection. However, the functional activities of autologous cells may be negatively affected by underlying cardiovascular risk factors and disease.<sup>9</sup> Allogeneic cells are obtained from a different donor; therefore, transplantation of most such cells necessitates immunosuppressive therapy to avoid hyperacute and delayed immunological reactions. Mature cells, as well as stem and progenitor cells, have been employed experimentally for cell therapy and tissue engineering. Each cell type has its own profile of advantages, limitations, and practicability issues and may have an effect on cardiac structure or function, or both, through distinct mechanisms (Table 51-1). In general, mature cells show a lower proliferation rate and a diminished survival rate after transplantation than do stem and progenitor cells.<sup>10</sup> Stem cells are capable of self-renewal, transformation into dedicated progenitor cells, and differentiation into specialized progeny. Depending on their differentiation potential, stem cells are classified as being pluripotent (capable of differentiating into any of the three germ layers) or multipotent (capable of giving rise to a limited number of other cell types).

## Cardiomyocytes

Cardiomyocytes may appear as the optimal cell type to repair an infarct. Fetal or neonatal cardiomyocytes have been shown in experimental models to form stable grafts in injured hearts of syngeneic recipients. However, massive cell death, coupled with only limited cell proliferation after transplantation, prevents formation of larger amounts of new myocardium.<sup>11,12</sup> Fetal or neonatal rat cardiomyocytes have been used extensively in experimental tissue engineering studies, which demonstrated that these cells can be used to grow cell sheets or 3-dimensional tissue substitutes that display electrical and functional integration when transplanted onto injured myocardium.<sup>7,8</sup> Because of their allogeneic origin, their limited capacity for ex vivo expansion, and ethical concerns, human fetal or neonatal cardiomyocytes are not a realistic cell source for large-scale clinical applications. Nevertheless, the experimental studies in

## POTENTIAL DONOR CELLS (see Chapter 4)

Two different types of cells may be used for cell transplantation and tissue engineering: autologous and allogeneic cells. Autologous cells are obtained

†Deceased.

**TABLE 51–1 Cell Types Used for Cell Therapy and Tissue Engineering**

Cell Type	Advantages	Disadvantages
Fetal or neonatal cardiac myocytes	Integrate electrically and mechanically with host myocardium	Limited supply Ethical and legal issues Need for use in an allogeneic setting Limited capacity for ex vivo expansion Poor survival after transplantation
Skeletal myoblasts	Easy to obtain (skeletal muscle biopsy) Can be expanded ex vivo	Ex vivo expansion requires several-day culturing process Skeletal muscle phenotype retained after intracardiac transplantation
Mesenchymal stem cells	Can be expanded ex vivo Promote paracrine effects Low immunogenicity (can possibly be used in an allogeneic setting)	Ex vivo expansion requires several-day culturing process No transdifferentiation into mature cardiomyocytes
Endothelial progenitor cells	Easy to obtain from blood or bone marrow Promote paracrine effects Some may differentiate into endothelial cells Enhance neovascularization	Transdifferentiation into cardiomyocytes uncertain
Unfractionated bone marrow cells	Easy to obtain (bone marrow puncture) Contain several stem and progenitor cell populations Promote paracrine effects	Low percentage of stem and progenitor cells Probably no meaningful transdifferentiation into cardiomyocytes
Embryonic stem (ES) cells	Pluripotent cells with capacity for differentiation into vascular cells and cardiomyocytes Can be expanded and differentiated into cardiomyocytes ex vivo before transplantation Potentially useful for tissue engineering applications	Ethical and legal issues Need for use in an allogeneic setting Risk of teratoma formation if contaminating pluripotent cells are transplanted
Induced pluripotent stem (iPS) cells	Pluripotent cells with capacity for differentiation into vascular cells and cardiomyocytes Can be expanded and differentiated into cardiomyocytes ex vivo before transplantation Potentially useful for tissue engineering applications Can be used in an autologous setting	Risk of teratoma formation if contaminating pluripotent cells are transplanted Risk of insertional mutagenesis
Spermatogonial stem cells	Pluripotent cells with capacity for differentiation into vascular cells and cardiomyocytes Can be expanded and differentiated into cardiomyocytes ex vivo before transplantation Potentially useful for tissue engineering applications Can be used in an autologous setting	Can be obtained only from men Risk of teratoma formation if contaminating pluripotent cells are transplanted
Cardiac resident progenitor cells	Allegedly multipotent cells with capacity for differentiation into vascular cells and cardiomyocytes Can be expanded ex vivo	Need for better defining of specific cell surface markers and protocols for cell isolation and expansion

this area are informative and have prompted the search for renewable cardiac cell sources for human applications.

### Cells with No Apparent Capacity for Cardiomyocyte Differentiation

Skeletal myoblasts (satellite cells) are progenitor cells that normally lie in a quiescent state under the basal membrane of mature muscular fibers. Myoblasts can be isolated from skeletal muscle biopsy samples and expanded in vitro.<sup>12</sup> It was originally hoped that these cells could transdifferentiate into cardiomyocytes; however, myoblasts retain skeletal muscle properties when transplanted into infarcted hearts. Although they may contract in response to electrical stimulation, they do not express intercalated disk proteins, which indicates that the majority are not electromechanically coupled to their host cardiomyocytes. Nevertheless, myoblast transplantation has been shown to augment systolic and diastolic performance in animal models, possibly through the release of paracrine factors.<sup>13</sup> Myoblasts, in combination with embryonic fibroblasts and endothelial cells, have been used to engineer vascularized skeletal muscle tissue in vitro.<sup>14</sup> Because of their inability to couple electromechanically and their strict commitment

to a myogenic lineage, myoblasts and myoblast-derived skeletal muscle patches are imperfect substitutes for damaged myocardium. However, genetic manipulation of myoblasts to induce the expression of the cardiac gap-junction protein connexin 43 may provide a means to enhance electromechanical integration of these cells in infarcted hearts.<sup>15</sup>

Mesenchymal stem cells represent a rare population of multipotent progenitor cells present in bone marrow stroma and other mesenchymal tissues. Mesenchymal stem cells can be expanded and induced to differentiate into a variety of mesenchymal cell types in vitro and in vivo.<sup>16</sup> They have been used in preclinical models for tissue engineering of several connective tissues, including bone and cartilage.<sup>17</sup> Along that line of research, mesenchymal stem cells have been used successfully to engineer pulmonary heart valves in sheep.<sup>18</sup> They secrete a large spectrum of bioactive molecules; some of these factors are immunosuppressive, especially for T cells, and allogeneic mesenchymal stem cells may thus be considered for therapeutic use. Because of their trophic activities, mesenchymal stem cells appear to be valuable inducers of endogenous tissue repair and regeneration.<sup>17</sup> When transplanted into freshly infarcted myocardial tissue, mesenchymal stem cells can prevent adverse left ventricular

**FIGURE 51-1** Pluripotent stem cells from different sources can be expanded in vitro and differentiated into cardiac progenitor cells and mature cardiac cell types, thus enabling cell replacement therapy or tissue engineering. CPC, Cardiac progenitor cell; ESC, embryonic stem cell; iPS cell, induced pluripotent stem cell; PSC, parthenogenetic stem cell; SGSC, spermatogonial stem cell. (From Wollert, K. C. and Drexler, H. C. (2010) Cell therapy for the treatment of coronary heart disease: a critical appraisal. *Nat Rev Cardiol.* 7:204–215.)

remodeling. However, these effects appear to be related to a release of paracrine factors rather than to the differentiation of mesenchymal stem cells into mature cardiomyocytes.<sup>19,20</sup>

Circulating endothelial progenitor cells contribute to recovery of blood flow after ischemia by homing to sites of neovascularization, by differentiating into endothelial cells in situ, or by contributing to the release of vasogenic substances in the underperfused tissue.<sup>21,22</sup> The bone marrow constitutes an important, but not the only, source of circulating endothelial progenitor cells.<sup>23</sup> It is becoming increasingly clear that these cells represent a heterogeneous cell population. The majority of circulating endothelial progenitor cells display no capability for clonal expansion; these cells have also been referred to as “circulating angiogenic cells” and have been shown to promote neovascularization in animal models of critical hind-limb ischemia or AMI.<sup>24</sup> Much smaller subpopulations of endothelial progenitor cells behave as true progenitor cells; they can be clonally expanded and differentiate into mature endothelial cells in situ.<sup>24</sup> It has also been proposed that these cells have the potential to transdifferentiate into cardiomyocytes, even though this may be a rare event.<sup>25,26</sup> Coimplantation of culture-expanded human endothelial progenitor cells and mesenchymal stem cells, seeded into a Matrigel matrix, has been used to engineer microvascular networks in immunodeficient mice in vivo. Because both endothelial progenitor cells and mesenchymal stem cells are readily available from patients, these data suggest a possible future strategy for therapeutic tissue vascularization.<sup>27</sup> Strategies to improve the functionality of endothelial progenitor cells may be required when the cells are isolated from patients with cardiovascular risk factors.<sup>28,29</sup>

### Cardiomyocyte Progenitor Cells (see Chapter 4)

Embryonic stem cells are pluripotent stem cells derived from the inner cell mass of blastocysts. Under specific culture conditions, embryonic stem cells can differentiate into cell types from all three germ layers, and they generate, for example, endothelial cells, vascular smooth muscle cells, and cardiomyocytes<sup>30–32</sup>;

this makes them an attractive source for cardiac cell therapy and tissue engineering.<sup>33</sup> Human embryonic stem cell–derived cardiomyocytes display structural and functional properties of early-stage cardiomyocytes that couple with host cardiomyocytes when transplanted into normal or infarcted myocardium. The first reports demonstrated their potential to function as biological pacemakers.<sup>34</sup> More recent data have shown that transplantation of sufficient numbers of cardiac-committed murine embryonic stem cells into infarcted sheep myocardium can promote improvements in systolic function.<sup>35</sup> In theory, infinite numbers of cardiomyocytes could be obtained from human embryonic stem cell clones. However, unresolved ethical and legal issues, concerns about the tumorigenicity of residual embryonic stem cells in embryonic stem cell–derived cardiomyocyte preparations, and the need to use allogeneic cells for transplantation currently hamper their use in clinical studies. It is important to refine cell differentiation and isolation protocols that yield highly purified cell populations for transplantation. This could best be achieved by cell sorting by means of cell type–specific membrane markers; alternative approaches might include genetic methods involving cell type–specific promoter constructs that drive the expression of marker proteins or selected survival by antibiotic resistance.<sup>10</sup>

It has been shown that adult human fibroblasts can be reprogrammed to a pluripotent state by retroviral transduction of four transcription factors (a combination of OCT4, SOX2, KLF4, and Myc, or a combination of OCT4, SOX2, NANOG, and LIN28).<sup>36,37</sup> By genetic and developmental criteria, these induced pluripotent stem (iPS) cells are very similar to embryonic stem cells: They can be maintained in culture for several months and can be induced to differentiate into derivatives of all three germ layers. It has been shown that iPS cells have the potential to differentiate into functional cardiomyocytes, with a gene expression profile and electrophysiological properties that are similar to those of embryonic stem cell–derived cardiomyocytes.<sup>38</sup> In the future, iPS cells may allow derivation of autologous cardiomyocytes and vascular cells for myocardial cell therapy and tissue engineering (Figure 51-1). Safety issues

such as the risks of teratoma formation or insertional activation of proto-oncogenes after retroviral transduction must be addressed, and strategies to create “virus-free” iPS are currently being developed in several laboratories.

The pluripotency of mouse spermatogonial stem cells has been highlighted in several studies. These cells are responsible for maintaining spermatogenesis throughout life in the male mouse.<sup>39,40</sup> In culture, adult spermatogonial stem cells acquire embryonic stem cell properties. These pluripotent adult germline stem cells spontaneously differentiate into derivatives of the three embryonic germ layers in vitro, including cardiomyocytes and vascular cells. It is conceivable that establishment of human multipotent adult germline stem cells from testicular biopsy samples may enable autologous cell-based therapies without the ethical and immunological problems associated with human embryonic stem cells or the risk of proto-oncogene activation inherent in iPS cells.

Distinct cell populations expressing stem cell marker proteins have been identified in the adult mouse heart and the human heart.<sup>41</sup> In humans, a heterogeneous cell population has been isolated from atrial and ventricular biopsy samples that forms clonal multicellular clusters in suspension culture, which have been referred to as “cardiospheres.”<sup>42</sup> Cardiospheres consist of c-Kit–positive cells at the core and cells that express cardiac and endothelial cell markers at the periphery. Injection of culture-expanded, cardiosphere-derived cells into the myocardial infarct border zone reportedly improves systolic function in immunodeficient mice; of note is that this effect was associated with cardiosphere-derived cell differentiation into cardiomyocytes and endothelial cells.<sup>43</sup> If this finding is confirmed, cardiac resident progenitor cells hold great promise for clinical applications, because they may be a source of autologous cells with cardiac differentiation potential.

## CELL TRANSPLANTATION STRATEGIES

The goal of any cell delivery strategy is to transplant sufficient numbers of cells into the myocardial region of interest and to achieve maximum retention of cells within that area (Table 51-2). Cell retention may be defined as the fraction of transplanted cells retained in the myocardium for a short time. The local milieu is an important determinant of cell retention, because it influences short-term cell survival

and, if a transvascular approach is used, cell adhesion, transmigration through the vascular wall, and tissue invasion. Transvascular strategies are especially suited for the treatment of recently infarcted and reperfused myocardium when chemoattractants are highly expressed.<sup>44,45</sup> Selective intracoronary application delivers cells homogeneously to the site of tissue injury. In certain studies, unselected bone marrow cells were delivered through the central lumen of an over-the-wire balloon catheter during transient balloon inflations to maximize the contact time of the cells with the microcirculation of the infarct-related artery.<sup>46,47</sup> As shown in Figure 51-2, when 2-[fluorine-18]-fluoro-2-deoxy-D-glucose (<sup>18</sup>FDG)-labeled unselected bone marrow cells were infused into the infarct-related artery, approximately 3% of the cells were detected in the infarcted myocardium. In experimental models, intravenous delivery of endothelial progenitor cells and mesenchymal stem cells has been shown to improve cardiac function after AMI. However, cell homing to noncardiac organs limits the applicability of this approach. Indeed, in one clinical study, homing of unselected bone marrow cells to the infarcted region was observed only after intracoronary stop-flow delivery but not after intravenous infusion.<sup>47</sup> Direct-injection techniques may be more appropriate for patients who present late in the disease process, when an occluded coronary artery precludes transvascular cell delivery or when homing signals are expressed at low levels in the heart (scar tissue).

## CURRENT STATUS OF CELL THERAPY IN PATIENTS WITH ACUTE MYOCARDIAL INFARCTION AND HEART FAILURE

Preclinical studies have demonstrated that transplantation of bone marrow–derived hematopoietic stem cells, endothelial progenitor cells, or mesenchymal stem cells can promote functional improvements in animal models of AMI. Transdifferentiation of the transplanted cells into cardiomyocytes and endothelial cells has been offered as an explanation for these improvements,<sup>48,49</sup> but the quantitative importance of stable cell engraftment and transdifferentiation for the functional effects has been challenged. It is now believed that the reported improvements in these models are mediated predominantly by paracrine effects (Figure 51-3).<sup>6,19,50-53</sup> Clinicians welcomed these animal studies with great enthusiasm, and, fairly rapidly, clinical trials were designed to translate

**TABLE 51-2** Cell Delivery Strategies

Route of Cell Delivery	Advantages	Disadvantages
Intravenous infusion	Least invasive	Cell trapping in the lungs and other tissues Limited cell delivery to the heart
Intracoronary infusion	Homogeneous cell delivery to the site of injury Cells that are retained will have adequate blood supply	Open infarct-related artery required Limited cell retention in infarcted area Not suitable for delivery of large cells that may cause microembolization (e.g., skeletal myoblasts, mesenchymal stem cells)
Transendocardial injection	Electromechanical mapping of the endocardial surface can be used to delineate viable, ischemic, and scarred myocardium before cell injections	Creates islands of cells with limited blood supply and poor cell survival May not be safe in patients with acute myocardial infarction, when cells are injected in friable necrotic tissue
Transepical injection	Allows for direct visualization of the myocardium and a targeted application of cells to scarred areas, the border zone of an infarct, or both	Creates islands of cells with limited blood supply and poor survival Open-heart surgery required Invasiveness hampers its use as a stand-alone therapy or in the setting of an acute myocardial infarction

## Randomized Trials with Unselected Bone Marrow Cells

CH 51 Most clinical investigators have chosen a pragmatic approach by using unfractionated bone marrow cells, which contain different stem and progenitor cell populations, as well as more differentiated hematopoietic cell types. In all of these studies, after the infarct-related artery was reperfused and a stent was placed, the cells were delivered into the artery in a stop-flow balloon catheter approach. In six trials, cells were delivered within a few days after coronary reperfusion to enhance systolic function and prevent adverse remodeling; in one trial, bone marrow cells were transplanted in patients with ischemic heart failure, months and years after AMI (Table 51-3).<sup>54-60</sup> The

combined experience from these studies indicates that intracoronary delivery of unselected bone marrow cells is feasible and probably safe. The outcomes of these randomized trials have been mixed, however: Some studies have demonstrated significant improvements in global and regional left ventricular systolic function<sup>54-56,59,60</sup>; one trial demonstrated improvements in regional function only<sup>57</sup>; and one trial demonstrated no significant improvements at all.<sup>58</sup> Although the reasons for these heterogeneous results are difficult to resolve, it has been argued that differences in cell preparation methods and the timing of cell transfer may have been critical.<sup>55,57,58,61</sup> Meta-analyses of published randomized and nonrandomized studies, involving a total of approximately 1000 patients, support the notion that bone marrow cell transfer contributes to modest improvements in cardiac function after AMI, above and beyond current interventional and medical therapy.<sup>62-65</sup>

## Ongoing Clinical Trials in Patients with Coronary Heart Disease

On the basis of the favorable safety profile and promising efficacy data, several clinical trials are currently underway to further explore the prospect of cell therapy in patients with various manifestations of coronary heart disease. As discussed below, important issues are addressed in these second-generation trials in an attempt to maximize patient benefit (Table 51-4). Given the variation in outcomes with apparently similar cell isolation protocols in earlier trials it will be important to establish assays that assess cell functionality and the quality of the cell product.

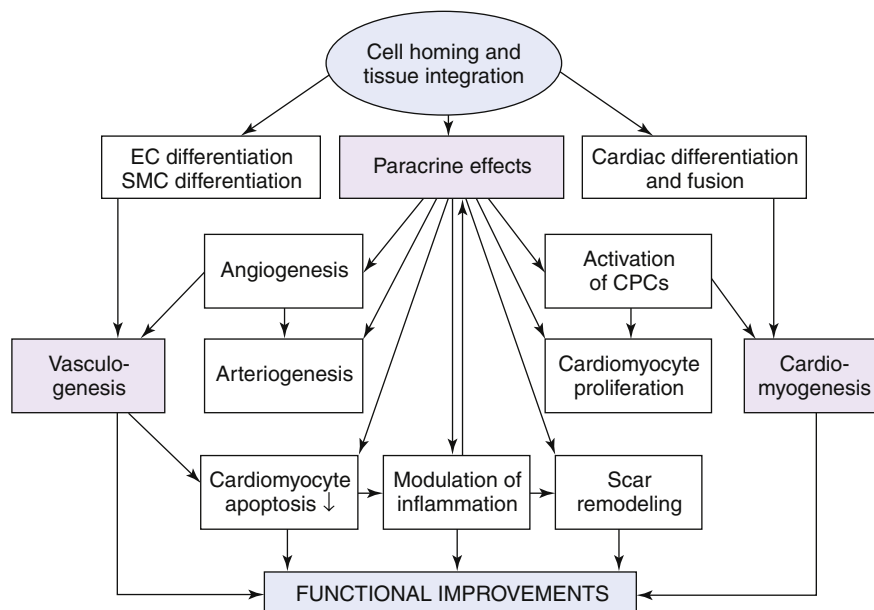

## Skeletal Myoblast Transplantation

In the first randomized, placebo-controlled study of skeletal myoblast transplantation after myocardial infarction,<sup>66</sup> patients were treated with culture-expanded, autologous skeletal myoblasts or with placebo at least 4 weeks after myocardial infarction. Cells were injected into the infarct border zone during bypass surgery. Myoblast transplantation did not improve regional or global left ventricular function, the primary endpoints of the trial. A significant decrease in left ventricular volumes, however, was noted after cell therapy. A greater incidence of arrhythmias was noted in the myoblast-treated patients, but this did not translate into differences in major adverse cardiac events after 6 months.

**FIGURE 51-2** Myocardial homing and biodistribution of unfractionated bone marrow cells after intracoronary infusion. Nine days after primary angioplasty and stent implantation for acute myocardial infarction, the patient received an intracoronary infusion of autologous nucleated bone marrow cells into the left circumflex coronary artery, which had the stent. A small fraction of the cells was radiolabeled with 2-[fluorine-18]-fluoro-2-deoxy-D-glucose (<sup>18</sup>FDG) just before intracoronary transfer. Positron emission tomography (PET) imaging was performed 65 minutes after cell transfer. Left posterior oblique (A) and left anterior oblique (B) PET views of the chest and upper abdomen are shown. Approximately 3% of the cells homed to the lateral wall of the heart; most remaining activity is detected in the liver and spleen. (Adapted from Hofmann M, Wollert KC, Meyer GP, et al. Monitoring of bone marrow cell homing into the infarcted human myocardium. *Circulation* 2005;111:2198-2202.)

**TABLE 51–3 Randomized Cell Therapy Trials in Patients with Acute Myocardial Infarction and Ischemic Heart Failure**

Study	Design	Number of Subjects*	Cell Type	Dosage	Time of Cell Delivery (after AMI)	Outcome	
						Improved	No Change
BOne marrOw transfer to enhance ST-elevation infarct regeneration (BOOST) <sup>54</sup>	Open, controlled	30 Treated, 30 controls	Nucleated BMCs	128 mL	6 ± 1 Days	Global LVEF	LVEDV
Reinfusion of Enriched Progenitor cells And Infarct Remodeling in Acute Myocardial Infarction study (REPAIR-AMI) <sup>55</sup>	Placebo-controlled	95 Treated, 92 controls	Mononucleated BMCs	50 mL	3-6 Days	Global LVEF	LVEDV
Leuven Acute Myocardial Infarction trial (Leuven-AMI) <sup>57</sup>	Placebo-controlled	32 Treated, 34 controls	Mononucleated BMCs	130 mL	1 Day	Regional contractility	Global LVEF LVEDV
Autologous Stem cell Transplantation in Acute Myocardial Infarction (ASTAMI) <sup>58</sup>	Open, controlled	47 Treated, 50 controls	Lymphocytic BMCs	50 mL	6 ± 1 Days	—	Global LVEF LVEDV
FINnish stem CELL study (FINCELL) <sup>59</sup>	Placebo-controlled	39 Treated, 38 controls	Mononucleated BMCs	80 mL	≈3 Days	Global LVEF	LVESV, LVEDV
Myocardial Regeneration by Intracoronary Infusion of Selected Population of Stem Cells in Acute Myocardial Infarction (REGEN) <sup>60</sup>	Open, controlled	97 Treated, 20 controls	Mononucleated BMCs vs. CD34 <sup>+</sup> /CXCR4 <sup>+</sup> BMCs	50-120 mL	3-12 Days	Global LVEF	LVESV, LVEDV
Transplantation Of Progenitor Cells And REcovery of LV functioning in patients with Chronic ischemic Heart Disease (TOPCARE-CHD) <sup>56</sup>	Open, controlled	35 Treated, 23 controls	Mononucleated BMCs	50 mL	81 ± 72 Months	Global LVEF	LVEDV
Myoblast Autologous Grafting in Ischemic Cardiomyopathy (MAGIC) <sup>66</sup>	Placebo-controlled	67 Treated, 30 controls	Skeletal myoblasts	400 or 800 × 10 <sup>6</sup>	>4 Weeks	LVEDV, LVESV	Regional contractility Global LVEF

\*Only patients with complete imaging studies are considered in this table.

In BOOST, cells were prepared by gelatin polysuccinate density gradient sedimentation, which retrieves all nucleated cell types from the bone marrow; REPAIR-AMI, TOPCARE-CHD, and Leuven-AMI employed a Ficoll gradient, which recovers the mononuclear cell fraction. Although a similar cell isolation protocol was used in ASTAMI, the cell yield was lower than that in REPAIR-AMI. “Dosage” refers to the average amount of bone marrow that was harvested, or the number of transplanted skeletal myoblasts (MAGIC). Remodeling was assessed by MRI in Leuven-AMI, BOOST, and ASTAMI; by left ventricular angiography in REPAIR-AMI and TOPCARE-CHD; and by echocardiography in MAGIC. AMI, acute myocardial infarction; BMC, bone marrow cell; LVEDV, left ventricular end-diastolic volume; LVEF, left ventricular ejection fraction; LVESV, left ventricular end-systolic volume; MRI, magnetic resonance imaging.

## Issues to Address at the Bench and the Bedside

The mixed results from the randomized studies of bone marrow cells are a reminder that procedural issues, such as the cell preparation method, cell dosage, and timing of cell transfer, must be further refined in upcoming studies. Different cell populations and cell delivery methods may be necessary to achieve optimum therapeutic effects immediately or later after AMI. Patient subgroups that derive the greatest benefit from cell transfer need to be identified prospectively (e.g., patients presenting late after symptom onset, in whom little myocardial salvage can be expected from reperfusion therapy). The effect of bone marrow cell transfer on clinical endpoints is currently unknown. Significant improvements in combined clinical endpoints have been observed in the largest randomized trial,<sup>67</sup> in one cohort study,<sup>68</sup> and in some of the meta-analyses<sup>63,65</sup>; however, outcome trials in which cell preparation and delivery strategies are optimized are still needed. Results of cell-labeling studies indicate that less than 5% of unselected nucleated bone marrow cells are retained in the infarcted area after intracoronary delivery in patients (see Figure 51-2).<sup>47</sup> It is conceivable that pharmacological strategies might be used to enhance the homing capacity or other functional parameters of the cells; results of experimental studies are pointing in this direction.<sup>28,29</sup> The ultimate goal of stem cell therapy is to replace the infarcted area with new contractile and fully integrated cardiomyocytes. Although unselected bone marrow cells may have a favorable effect on systolic function, they probably do not generate new myocardium. There is evidence that paracrine effects play an important role in bone marrow cell transfer. In fact, bone marrow cells have been shown to secrete

a number of proangiogenic factors,<sup>69</sup> which is consistent with the improvements in microvascular function observed after bone marrow cell transfer in patients.<sup>70</sup> Results of experimental studies suggest that enhanced angiogenesis after AMI may improve infarct healing and energy metabolism in the infarct border zone.<sup>71-74</sup> Further investigation of candidate factors in animal models may ultimately enable more specific and powerful therapeutic strategies after AMI.<sup>75</sup> The lack of true cardiac regeneration should stimulate further basic research into the therapeutic prospects of cardiomyocyte progenitor cells.

## TISSUE ENGINEERING

A myocardial infarct represents a hostile ischemic, necrotic, or scarred environment, or a combination. As a consequence, cell transplantation is generally accompanied by extensive cell death and inadequate cellular integration. Cell transplantation may positively affect the healing response after an AMI (e.g., through paracrine effects); however, it is doubtful whether cell therapy will ever be able to replace a chronic infarct scar with new myocardium that is densely packed with mature cardiomyocytes, supporting blood vessels, interstitial cells, and matrix. Engineering of myocardial tissue may provide a means to achieve true cardiac regeneration. Tissue engineering aims at generating functional 3-dimensional tissues substitutes outside the body that can be tailored in size, shape, and function before they are implanted into the body. Tissue engineering is a highly interdisciplinary field and requires close collaboration among material scientists, engineers, and life scientists. Tissue engineering has been used to

**TABLE 51-4 Ongoing Cell Therapy Trials in Patients with Coronary Heart Disease**

Study Identifier	Trial Name	Number of Patients	Cells	Primary End Point	Route of Cell Delivery

generate heart valves<sup>76</sup> and has already led to initial clinical applications, with encouraging results.<sup>77,78</sup> Similarly, vascular grafts have been generated from autologous cells and have been transplanted successfully into patients.<sup>79</sup>

### Basic Principles of Myocardial Tissue Engineering

Myocardial tissue engineering is confronting scientists with tremendous challenges because restoration of heart function by myocardial tissue replacement necessitates the long-term

electromechanical and vascular integration of a complex, multicellular, 3-dimensional graft into the host tissue. Tissue-engineered myocardial constructs should have clearly defined contractile properties, be large in size, become vascularized and integrated into the host myocardium, and improve the contractile function of the infarcted heart.<sup>80</sup> The classical approach to tissue engineering consists in the construction of a scaffold on which the tissue can grow. Such scaffolds, which are biodegradable to a degree, are then seeded with donor cells, growth factors, or both. Afterwards, the scaffolds

are cultured in a specially designed bioreactor that provides oxygen and nutrients in an optimized physicochemical microenvironment. When the cells have assembled and filled the scaffold, the structure is removed from the bioreactor and implanted into the patient's body (Figure 51-4). Scaffold-ing biomaterials used for cardiac tissue engineering should be autologous and should enhance cell attachment, growth, and differentiation. To achieve functional improvements, the biomaterial must encourage mechanical and electrical integration with the host tissue. Finally, the elastic properties of the biomaterial must match the elastic properties of the native heart to withstand the continuous stretching-relaxing motion of the myocardium that occurs with each heartbeat (Table 51-5).<sup>81</sup> A detailed discussion of synthetic and biological materials used in myocardial tissue engineering is available elsewhere.<sup>82</sup>

**FIGURE 51-4** Basic principles of tissue engineering. See the “Basic Principles of Myocardial Tissue Engineering” section in the text for details.

TABLE 51-5 Requirements for Cardiac Tissue Engineering Scaffolds	
Requirement	Comment
Biocompatibility	The biomaterial must not be rejected or induce an inflammatory response in vivo; it should reflect the extracellular matrix of the tissue it intends to replace. The degradation rate of the biomaterial should match the regeneration rate of the host tissue, and the degradation by-products must be nontoxic and readily removed from the body. The biomaterial should enhance cell adhesion, alignment, survival, and differentiation, and it should encourage vascularization.
Mechanical integrity	The biomaterial should provide mechanical support to withstand the continuous stretching-relaxing motion of the myocardium.
Electrical integrity	The biomaterial must enable electrical integration of the engineered graft with the native tissue to allow matched excitability of host and grafted tissue and support electrical of wavefront propagation.

## Preclinical Experience with Myocardial Tissue Engineering

At least three strategies have been developed to construct contractile heart muscle equivalents: (1) the classic approach of seeding cardiac myocytes on preformed matrices; (2) entrapment in liquid matrices, which supports the propensity of cardiac myocytes to form contracting aggregates; and (3) stacking cardiac myocyte monolayers to form multilayered heart muscle constructs (Figure 51-5 and Table 51-6).<sup>83</sup>

Development of systolic force is the most important feature of artificial myocardium. Data on contractile properties are available for artificial myocardial tissue, which is developed by seeding neonatal rat cardiac myocytes on collagen sponges<sup>84</sup>; for engineered heart tissue, which forms after entrapment of neonatal rat heart cells in an extracellular matrix environment that contains liquid rat collagen type I<sup>85</sup>; and stacked neonatal rat cardiac myocyte monolayers (see Table 51-6).<sup>86</sup> Maximal force of contraction was 0.02 mN in artificial myocardial tissue and 2 to 4 mN in engineered heart tissue and stacked monolayers. The low contractile force in artificial myocardial tissue points to a possible conceptual disadvantage of preformed matrices in myocardial tissue engineering. Essentially, cardiac myocytes are forced to seed a structurally defined environment if preformed matrices are employed, and they seem to be limited in their potential to organize into 3-dimensional force-generating units.<sup>83</sup> In native myocardial tissue, cells are especially dense in comparison with other tissues, such as heart valves and vessels. In addition, cardiomyocytes are tightly interconnected with gap junctions. Preformed scaffolds may therefore attenuate cell-to-cell connections.<sup>87</sup> Current methods support the propensity of cardiac myocytes to freely form contractile aggregates, to produce their own supporting matrix, and to organize into complex myocardial structures in the absence of obstructing preformed scaffold materials; these methods seem to be advantageous from a functional but also structural point of view.<sup>83</sup>

## CHALLENGES AND FUTURE DIRECTIONS

The thickness of cardiac tissue that can be engineered in vitro is limited by the maximum diffusion distances for oxygen and nutrients. Angiogenesis becomes essential in order to engineer cardiomyocyte tissue with a thickness of more than 200  $\mu\text{m}$ .<sup>88</sup> Generation of vascularized grafts is especially important for making the transition from rodent models to larger animal models and, eventually, to patients with an average left ventricular wall thickness of 10 to 15 mm. A number of strategies are currently being explored to create a functioning vascular network inside an engineered myocardial graft before implantation. Prevascularized grafts can rapidly anastomose with the host tissue and enhance tissue survival and differentiation. In addition, growing evidence supports a role of the vasculature in regulating pattern formation and tissue differentiation. Thus, prevascularized tissues also benefit from an intrinsic contribution of their vascular system to their development.<sup>89</sup>

Some investigators have engineered myocardial tissue around a native vessel.<sup>88,90</sup> This has been achieved in vitro with a rat aorta that was mounted in a bioreactor and perfused with cell culture medium. The rate of survival of neonatal rat cardiomyocytes, which were embedded in fibrin glue and positioned around the aortic vessel, was significantly higher when the vessel was perfused.<sup>90</sup> Similarly, neonatal rat cardiomyocytes have been suspended in Matrigel and seeded around an arteriovenous shunt that was created inside a polycarbonate chamber in the groin of a rat.<sup>88</sup> Other investigators have cultured mixed neonatal rat heart cells in vitro and have observed spontaneous formation of cardiomyocyte strands that were lined by newly formed blood vessels that interconnected with the host vasculature after transplantation onto infarcted rat

750 hearts.<sup>91</sup> Vascularized, synchronously contracting human myocardial tissue grafts have been engineered by seeding human embryonic stem cell–derived cardiomyocytes and endothelial cells together with embryonic fibroblasts onto poly-L-lactic acid (PLLA) and polylactic-glycolic acid (PLGA) sponges.<sup>92</sup> Of

interest was that the presence of endothelial cells enhanced proliferation of the cardiomyocytes in the grafts, whereas the presence of embryonic fibroblasts decreased endothelial cell death and stimulated endothelial cell proliferation.<sup>92</sup> Decellularized cadaveric hearts with an intact 3-dimensional geometry

**FIGURE 51-5** Concepts in myocardial tissue engineering. **A**, Cell seeding on preformed matrices. **B**, Entrapment of cells in soluble matrix proteins. **C**, Monolayer cell sheet engineering. TABLE 51-6 Selected Preclinical Studies on Myocardial Tissue Engineering				
Study	Cell Types	Scaffold	In Vitro Performance	In Vivo Performance
<b>Cell Seeding on Preformed Matrices</b>				
Leor et al, 2000 <sup>96</sup>	Fetal rat cardiomyocytes	Alginate	Cells form multicellular aggregates and contract spontaneously in the scaffold	Biograft implantation prevents left ventricular remodeling in a rat infarct model (whether cardiomyocytes contribute is uncertain)
Kofidis et al, 2002 <sup>84</sup>	Neonatal rat cardiomyocytes	Bovine collagen type I	Cells form viable artificial myocardial tissue that contracts spontaneously and generates force	Not determined
Ott et al, 2008 <sup>93</sup>	Neonatal rat cardiomyocytes, rat endothelial cells	Decellularized rat heart	Recellularized heartbeats with a contractile force that is equivalent to ≈2% of adult rat systolic heart function	Not determined
<b>Cell Entrapment in Soluble Matrices</b>				
Zimmermann et al, 2002 <sup>85</sup> and 2006 <sup>91</sup>	Mixed neonatal rat heart cells	Circular casting molds containing liquid rat collagen type I	After cyclic stretching for 7 days, cells form viable engineered heart tissue (EHT) loops that contract spontaneously and generate force	EHT grafts integrate, couple electrically, and support systolic and diastolic function in a rat infarct model
Guo et al, 2006 <sup>94</sup>	Mouse embryonic stem cell–derived cardiomyocytes	Circular casting molds containing liquid rat collagen type I and Matrigel	After cyclic stretching for 7 days, cells form viable engineered cardiac tissue loops that contract spontaneously and generate force	No evidence for teratoma formation after subcutaneous implantation; not yet tested in cardiac applications
<b>Monolayer Cell Sheet Engineering</b>				
Shimizu et al, 2006 <sup>86</sup> and 2002 <sup>97</sup>	Neonatal rat cardiomyocytes	Thermoresponsive PIPAAm	Cells adhere to the matrix at 37° C and detach after cooling to 20° C; cell sheets are then stacked to form spontaneously beating multilayer constructs	Grafts (up to 100 μm in thickness) survive and continue to beat spontaneously after subcutaneous implantation in rats
Furuta et al, 2006, <sup>98</sup> and Itabashi et al, 2005 <sup>99</sup>	Neonatal rat cardiomyocytes	Human fibrin-coated culture dish	Cells adhere to the matrix, digest the fibrin, and can then be removed and stacked to form spontaneously beating bilayered grafts (50 to 100 μm in thickness)	Grafts integrate and contract synchronously with the host heart when transplanted onto thermally injured rat myocardium. Whether the graft contributes to force development is uncertain

PIPAAm, poly-N-isopropylacrylamide.

**FIGURE 51-6** Milestones toward a clinical use of myocardial tissue engineering. GLP, glucose-L-phosphate; GMP, guanosine monophosphate. (Adapted from Zimmermann WH, Didie M, Doker S, et al. Heart muscle engineering: an update on cardiac muscle replacement therapy. *Cardiovasc Res* 2006;71:419-429.)

and vasculature may serve as scaffolds for engineering an entire heart. Proof of concept has been obtained with decellularized rat hearts that were repopulated with neonatal cardiomyocytes and rat aortic endothelial cells under simulated physiological conditions for organ maturation.<sup>93</sup>

In most experimental studies in myocardial tissue engineering, fetal or neonatal rat cardiomyocytes have been used as the main cell source. The identification of cell types that are suitable for human applications continues to be a major challenge. Although results of studies indicate that embryonic stem cell–derived cardiomyocytes can be used for tissue engineering<sup>92,94</sup> and that spermatogonial stem cells and iPS cells can be differentiated into cardiomyocytes,<sup>38-40</sup> the risk of teratoma formation that is associated with these cell types must be addressed. With any of these cell sources, it will be a formidable challenge to acquire sufficient quantities of cells for clinical use.

Synthetic and natural biomaterials that are currently used for myocardial tissue engineering serve mainly as scaffolds to allow proper cell assembly and alignment. Newer, “smart” biomaterials provide additional signals for cell adhesion, growth, or migration. Timed release of factors from these next-generation biomaterials can be regulated by chemical design to direct cellular differentiation pathways such as angiogenesis and vascular maturation.<sup>95</sup> “Smart” biomaterials could also be used for in situ engineering,<sup>81</sup> which involves a direct injection of biomaterials, alone or in combination with cells, into the diseased myocardium. It has been proposed that smart biomaterials can be used to custom design the cardiac microenvironment and stimulate endogenous repair processes.<sup>95</sup>

In conclusion, myocardial tissue engineering has great potential to enhance the function of the failing heart and to reduce the morbidity and mortality rates among patients living with heart failure. Currently, the development of clinical applications of myocardial tissue engineering appears long and arduous. Several milestones need to be achieved (Figure 51-6). Considering the magnitude of the heart failure

epidemic and the current lack of regenerative strategies, intensive research in the area of myocardial tissue engineering will continue and may ultimately enable therapeutic alternatives to heart transplantation.

# Management of Thrombosis in Heart Failure

Ronald S. Freudenberger and Shunichi Homma

Since the discovery of heparin by Jay McLean in 1916<sup>1</sup> and the initial synthesis of acetylsalicylic acid by Felix Hoffmann in 1899<sup>2</sup> and warfarin in the 1940s,<sup>3</sup> the use of antiplatelet and antithrombotic agents in the treatment and prevention of cardiac disease has become widespread. In 1959, the first trial of thrombolytic agents for the treatment of acute myocardial infarction and other thromboembolic disorders in humans was conducted.<sup>4</sup> In the 1960s and 1970s, studies demonstrated the effectiveness of oral anticoagulants for the early treatment of acute myocardial infarction.<sup>5,6</sup> In the 1980s, the efficacy of aspirin in acute coronary syndromes became apparent. However, little is known about the appropriate use of these agents for the treatment and prevention of thrombotic complications in patients with heart failure. It is important to realize that the thrombotic complications of heart failure not only include thrombus formation in the ventricles or atria and embolism but also include acute intracoronary thrombosis and subsequent sudden death. Because of the paucity of controlled clinical trials to guide the practitioner's approach to the prevention of these events and their complications clinicians must have a sound understanding of the pathogenesis of the thrombotic processes in cardiovascular disease and the relative risks of thrombosis and thromboembolism in order to develop a rational approach to antithrombotic therapy. This chapter is a review of what is known about these complications in patients with heart failure and what is known about treatment and prevention from the perspective of pathogenesis and thrombotic and thromboembolic risk.

## OVERVIEW OF HEMOSTASIS AND THROMBOSIS

The endothelium plays an important role in the regulation of thrombosis and hemostasis. Under normal and quiescent conditions, the endothelium helps provide an antithrombotic surface for blood. However, under certain circumstances, the endothelium can become prothrombotic by activating platelets, inhibiting fibrinolysis and promoting activation of the coagulation cascade (Figure 52-1). These processes are interrelated and can potentiate each other. They play a role in both vascular injury and subsequent thrombus formation and in activation of thrombosis in the cardiac chambers. In heart failure, both of these changes are important. Endothelial dysfunction, coagulation cascade, and platelet activation, along with a proinflammatory milieu, directly affect the balance between thrombosis and hemostasis and create the potential for a prothrombotic state. In addition, vascular tone is mediated by many of the same factors that may predispose to vasoconstriction. Many endothelium-derived vasodilators are also platelet inhibitors, and endothelium-derived vasoconstrictors can be platelet activators. The net effects are (1) promotion of fluidity by vasodilators and antiplatelet properties and (2) promotion of stasis with vasoconstrictors and platelet activators. Many factors in the delicate balance between the prothrombotic state and the antithrombotic state are perturbed in heart failure, inasmuch as endothelial dysfunction is known to play an important role in this disease. Furthermore, many of the pharmacological agents that are used in treatment of cardiovascular disease can affect this balance.

Endothelial dysfunction or endocardial injury can promote activation of platelets and the coagulation cascade. As discussed later, endocardial dysfunction resulting from increased hemodynamic pressure can cause downregulation of endocardial thrombomodulin and subsequent increase in thrombin generation, which in turn can cause platelet activation, fibrin formation, and crosslinking and activation of the coagulation system (Figure 52-2).

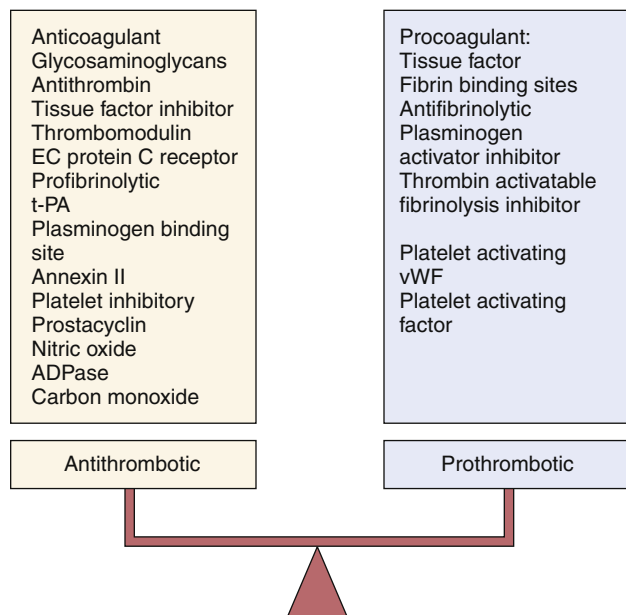

Typically, once platelets are activated, a series of subsequent prothrombotic systems is also activated. Platelets can form a monolayer in minor injury to cover the exposed subendothelium. In more severe injury, the lipid pool activates the platelets and subsequently activates the coagulation system, which leads to thrombus formation. Platelet receptors play a role in its aggregation and adhesion. Glycoprotein Ia binds directly to exposed collagen and serves as a binding site for subendothelial von Willebrand factor. Glycoprotein IIb/IIIa is the receptor for fibrinogen and von Willebrand factor, which promotes platelet-platelet interactions and aggregate formation. Collagen, thrombin, and the release of platelet adenosine diphosphate and thromboxane A<sub>2</sub> cause ongoing propagation of platelet deposition and aggregation.

Platelet aggregation provides a surface for the localization and interaction of coagulation factors and accelerates the conversion of prothrombin to thrombin. This process involves activation of the intrinsic coagulation system. In addition to this system, the extrinsic pathway is activated through the release of tissue factor from damaged endothelium. Factor X is the focal point of convergence of the intrinsic and extrinsic coagulation pathways. Once activated factor Xa converts prothrombin to thrombin—which, as mentioned earlier, further accelerates platelet deposition—thrombin cleaves fibrinogen to form fibrin, which activates factor XII, which in turn then stabilizes the clot and induces additional platelet activation (Figure 52-3).

Several endogenous mechanisms that limit thrombus formation are important in the ongoing balance between coagulation and anticoagulation. Antithrombin III, protein C, and protein S are important

**FIGURE 52-1** Vasoregulation by the endothelium results from a delicate balance between vasodilation and vasoconstriction. inhibitors of thrombosis. Antithrombin-III functions by inhibiting thrombin and activating factors IX, X, XI, and XIII. Heparin accelerates these inhibitory effects. Protein C is a potent anticoagulant. It functions by neutralizing a circulating inhibitor of tissue-type plasminogen activator (t-PA) and activates plasminogen. Plasminogen, in turn, is converted to plasmin, which degrades fibrinogen, prothrombin, and factors VIII and V. Plasmin also cleaves fibrin into soluble fragments on the surface of the fibrin complex. Plasmin is subsequently inactivated by A<sub>2</sub> plasmin inhibitor. Thus, many factors in the delicate balance between the prothrombotic state and the antithrombotic state are perturbed in heart failure.

## CHAMBERS

The development of intracavitary or mural thrombi in patients with acute myocardial infarction, left ventricular (LV) aneurysm, and dilated cardiomyopathy is well described. The pathogenesis of intracavitary thrombosis was described by Rudolph Virchow, who defined three precipitating factors: endothelial injury, blood stasis, and hypercoagulability.<sup>11</sup> The last two factors contribute significantly to fibrin deposition and activation of the coagulation system. Once a thrombus forms, the clinical significance is its potential for embolism.

### Endocardial Injury

Endocardial injury in heart failure is an often neglected contributor to thrombus formation in patients with heart failure. Kapur and colleagues<sup>1</sup> demonstrated that acute elevation of left atrial pressure caused a 70% inhibition of atrial thrombomodulin, which results in downregulation of endocardial thrombomodulin expression, ultimately increasing local thrombin production. Furthermore, these investigators found that the targeted restoration of atrial thrombomodulin expression with adenovirus-mediated gene transfer successfully reduced thrombin generation levels. Further experiments revealed that thrombomodulin downregulation is caused by the paracrine release of transforming growth factor  $\beta$  from cardiac connective tissue in response to mechanical stretch. These findings suggest that increased hemodynamic load adversely affects endocardial

**FIGURE 52-3** The complex relationship between platelets and the coagulation cascade. ADP, adenosine diphosphate.

function and is a potentially important contributor to thrombus formation in patients with heart failure. More research into this important contributing factor is needed.

## Blood Stasis

Blood stasis in areas of akinesis or dyskinesis is an important factor in the predisposition to thrombus formation. It occurs in a diffuse or segmentally dilated ventricle, with or without cardiac failure. The three most classic clinical conditions predisposed to blood stasis are dilated cardiomyopathy, anterior myocardial infarction, and LV aneurysm. Stasis triggers activation of the coagulation system, leading to fibrin formation, which accounts for the predominant pathogenetic mechanism in the development of intracavitary thrombus formation.

## Hypercoagulability

Studies have shown that patients with heart failure have higher levels of circulating fibrinogen, antithrombin III, fibrinopeptide A, and D-dimer.<sup>2,3</sup> Neuroendocrine modulators may also increase the prothrombotic state by increasing angiotensin and endothelin levels, which, in turn, increase levels of von Willebrand factor.<sup>4</sup> Coupled with decreased levels of nitric oxide, this development has been shown to increase endothelial monocyte and platelet adhesion, potentially leading to in situ thrombosis.<sup>5,6</sup> Researchers examining plasma markers of endothelial damage, dysfunction, and activation in patients with acute and chronic heart failure found that levels of von Willebrand factor, soluble thrombomodulin (an index of endothelial damage/dysfunction), soluble E-selectin (an index of endothelial activation), and brain natriuretic peptide (BNP) were all statistically significantly higher in patients with acute and chronic heart failure than in controls.<sup>5,7</sup> Although this was a small study, the results were suggestive of a link between inflammation and thrombosis in heart failure. This link is further suggested by a number of additional observations. Tissue factor, a procoagulant, can be increased by tumor necrosis factor  $\alpha$  and interleukin-1, levels of which are raised in heart failure.<sup>8,9</sup> C-reactive protein can directly increase levels of tissue factor and induce expression of other cytokines, thus further potentiating a prothrombotic milieu<sup>10,11</sup> (Figure 52-4).

## DYNAMIC FORCES OF THE CIRCULATION

Although the combination of these three components of Virchow's triad predisposes to thrombus formation, formation of intracavitary thrombi does not necessarily lead to

embolization. Dynamic forces of the cardiac chambers determine the propensity toward embolization. For example, in the case of LV aneurysm, the isolation from dynamic circulatory forces may be protective from systemic embolization. Therefore, when stratifying risk, clinicians must consider not only the predisposition to thrombus formation but also the risk of subsequent embolization.

## Arterial Thrombosis

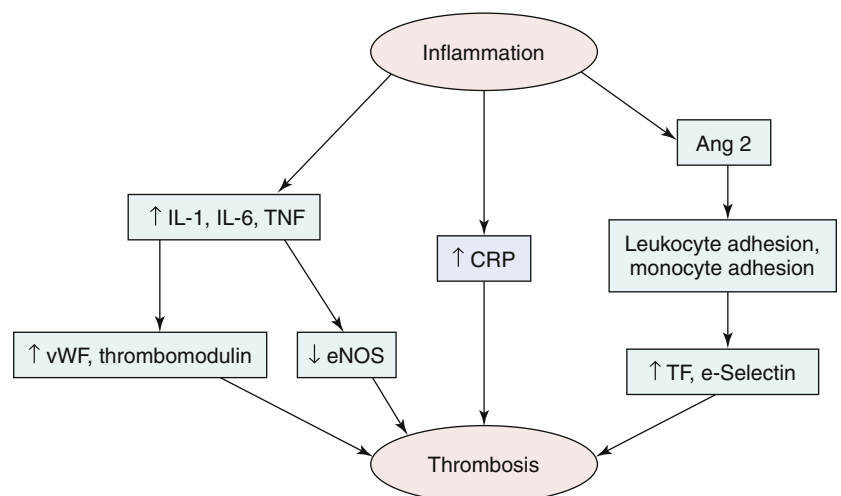

Acute coronary thrombosis can result in nonfatal myocardial infarction or sudden death. This process is well defined in patients with heart failure, patients with coronary artery disease, and those dying of sudden cardiac death. Clinically evident or silent intracoronary plaque rupture and occlusive thrombosis can occur in patients with significant degrees of occlusive atherosclerotic disease or with lesions that are less than 50% occluded.<sup>12</sup> This process may account for many deaths described as sudden cardiac death. It is estimated that one third of deaths classified as "sudden" are caused by acute coronary occlusion by thrombus. Autopsy studies and studies of patients resuscitated from sudden death events have yielded these pathological findings<sup>13,14</sup> (Figure 52-5). Thus, if the definition of thrombosis-related complications is expanded to include deaths from intracoronary thrombosis, the true risk of thrombotic complications of heart failure is greatly increased.<sup>15</sup> In one important heart failure study, nearly 50% of deaths adjudicated as sudden cardiac deaths were reclassified at autopsy as acute myocardial infarction or coronary thrombosis, and 27% of deaths classified as progressive congestive heart failure were actually found to be caused by coronary artery thrombosis.<sup>7</sup> Most population-based studies and retrospective analyses of thrombotic complications of heart failure do not account for patients who experience sudden cardiac death. As a result, the effect of thrombosis in patients with heart failure is probably underestimated.

## Thrombosis

### Chronic Heart Failure

The risk of thromboembolic events (stroke, pulmonary and peripheral thromboembolism) in patients with heart failure is poorly defined. The analyses that currently exist are from retrospective studies of large trials of treatment for heart failure and from population-based studies. Many of these studies included patients with atrial fibrillation and atrial flutter and did not specify thromboembolism as an endpoint. This is problematic because the use of precise scales to detect stroke significantly increases the detection of subtle neurological

**FIGURE 52-4** Relationship of inflammation and thrombosis. Ang II, angiotensin II; CRP, C-reactive protein; eNOS, endothelial nitric oxide synthase; IL-1 and IL-6, interleukin-1 and interleukin-6; TF, tissue factor; TNF, tumor necrosis factor; vWF, von Willebrand factor.

**FIGURE 52-5** Assessment of Treatment with Lisinopril And Survival (ATLAS): effect of autopsy on classification of death. The graph shows the striking difference in classification when autopsies are performed. Nearly 50% of deaths classified as sudden by clinical criteria reflect acute myocardial infarction (MI) or coronary thrombosis. Similarly, 27% of the deaths classified as progressive congestive heart failure (CHF) are associated with recent MI that was not detected clinically. Thus, according to autopsies of patients, MI is the most frequent mechanism of death. These results provide a strong rationale for the use of antithrombotic agents in patients with CHF. (From Uretsky BF, Thygesen K, Armstrong PW, et al. Acute coronary findings at autopsy in heart failure patients with sudden death: results from the Assessment of Treatment with Lisinopril And Survival [ATLAS] trial. *Circulation* 2000;102:611-616.)

events.<sup>16</sup> It is believed that heart failure in the absence of atrial fibrillation is associated with an increased risk of thromboembolic events. This belief is based on several observations. First, many patients with stroke or thromboembolic events have depressed LV function.<sup>17-19</sup> Second, retrospective analysis reveals a yearly incidence of thromboembolism in the range of 1% to 4.5% among patients with heart failure. In the population-based Framingham Heart Study,<sup>20</sup> the relative risk of stroke in individuals with heart failure was 4.1 for men and 2.8 for women, but many of these individuals had concurrent atrial fibrillation. In heart failure trials, annual stroke rates between 1.3% and 3.5% have been reported; however, almost all of these analyses included patients with atrial fibrillation. In one analysis, thromboembolic rates were only 1% per year in a population of patients with New York Heart Association (NYHA) classes II and III heart failure without atrial fibrillation.<sup>21</sup>

Several researchers have attempted to identify potential risk factors for the development of stroke or thromboembolism. Other than ejection fraction, a prior thromboembolic event, and perhaps the presence of a pedunculated thrombus, their analyses have shed little light on potential risk factors and have provided results difficult to interpret. In a retrospective analysis of the Study of Left Ventricular Dysfunction (SOLVD)<sup>22</sup> (after patients with atrial fibrillation were excluded), the annual rate of thromboembolic events was 2.4% among women and 1.8% among men. Lower ejection fraction was associated with higher event rates in women but not in men. In addition, women were observed to have a higher proportion of pulmonary embolism. In an analysis of the Survival and Ventricular Enlargement (SAVE) trial,<sup>23</sup> the overall risk of stroke was 8.1% at 5 years, and the only independent risk factors for stroke were LV dysfunction, older age, and nonuse of aspirin or anticoagulants. The risk of stroke was found to be twofold higher among patients with ejection fractions lower than 28% than among those with ejection fractions higher than 28%. Every 5% decrease in ejection fraction was associated with an 18% increase in stroke risk. This analysis of angiotensin-converting

**FIGURE 52-6** Proportions of patients in the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) trial who experienced a thromboembolic event. These proportions were stratified by three levels of baseline ejection fraction (EF). (From Freudenberger RS, Hellkamp AS, Halperin JL, et al. for the SCD-HeFT Investigators. Risk of thromboembolism in heart failure: An analysis from the sudden cardiac death in heart failure trial (SCD-HeFT). *Circulation*, May 2007; 115:2637-2641.)

enzyme (ACE) inhibitors versus placebo in patients after myocardial infarction did not exclude patients with atrial fibrillation; the researchers studied only stroke events. In a more recent analysis of patients with moderately severe heart failure and an ejection fraction of 35% or lower who participated in the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) (Figure 52-6), the 4-year rates of thromboembolic events were 3.5% with ejection fractions of 30% to 35%, 3.6% with ejection fractions of 20% to 30%, and 4.6% with ejection fractions lower than 20% (which means that the annual rates were approximately 0.9%, 0.9%, and 1.2% respectively) (Figure 52-6).<sup>21</sup> Patients with atrial fibrillation at the time of randomization were excluded from this analysis. The annual rate of thromboembolic events was found to be approximately 1%. Both hypertension at the time of randomization and ejection fraction were independent predictors of thromboembolic events. No other measured variables were significant in terms of outcome.

With regard to prior stroke, the Northern Manhattan Study (NOMAS) was conducted to examine 270 patients with first occurrence of ischemic stroke and 288 age-, gender-, and race-matched controls. Patients in one hospital were assessed for the incidence, risk factors, and clinical outcome of stroke. LV systolic function was measured and categorized as normal (ejection fraction > 50%), mildly reduced (41% to 50%), moderately reduced (31% to 40%), or severely decreased ( $\leq 30\%$ ). Decreased ejection fraction was found to be strongly associated with ischemic stroke even after other stroke risk factors were adjusted. LV dysfunction of any degree was more frequent in patients with stroke (24.1%, in comparison with 4.9% of controls;  $P < .0001$ ). Moderate or severe LV dysfunction was also more common in patients with stroke (13.3%) than in controls (2.4%;  $P < .001$ ). The adjusted odds ratio was 3.96 for mild LV dysfunction and 3.88 for moderate or severe LV dysfunction (adjusted for other stroke risk factors).<sup>24</sup> In another study, the rate of recurrent stroke after a first stroke was 9% to 10% per year in patients with heart failure, which suggested that a previous event confers a high risk of recurrence.<sup>25</sup> In yet another study, the presence of intracardiac

thrombus was identified in half the patients with neurological events, and patients with thrombus had a significantly higher rate of thromboembolism (5.3% per year).<sup>26</sup> The results of all these studies together suggest a risk association with the presence and degree of systolic dysfunction.

Not all, or even most, cerebrovascular events are thromboembolic in origin. Clinicians must also consider the possibility that vascular sources or hemodynamic fluctuations, such as low cardiac output, episodic hypotension, or silent arrhythmias (including asymptomatic episodic atrial fibrillation), and resultant reduction in cerebral perfusion may be a contributing or causative factor. The presence of hypertension and diabetes mellitus significantly increases the risk of vascular disease and subsequent cerebrovascular events. In an imaging study of hypertensive patients,<sup>27</sup> the combined presence of these risk factors was the most powerful independent determinant of the presence of silent cerebral infarcts (especially for multiple silent cerebral infarcts). These authors found the prevalence of silent cerebral infarcts and multiple silent cerebral infarcts increased threefold in hypertensive patients with diabetes mellitus, independent of age and ambulatory blood pressure. The evidence for vascular sources of silent cerebral infarcts is abundant. Büsing and associates<sup>28</sup> prospectively evaluated patients before and after diagnostic and interventional cardiac catheterization with magnetic resonance imaging studies. These investigators found that 15% of patients had new silent cerebral infarctions, with no association between ejection fraction and risk of cerebral infarction; this rate was much higher than that observed for symptomatic stroke after cardiac catheterization, which is reported as 0.11%. Similarly, patients who have undergone coronary artery bypass grafting have a high incidence of silent cerebral infarcts,<sup>29</sup> and patients with manifest vascular disease were found to have a 17% incidence of asymptomatic stroke.<sup>30</sup>

In addition to the mechanistic causes of cerebrovascular incidents in heart failure patients, many of these patients, particularly with more advanced heart failure, have low cardiac output and reduced cerebral blood flow. Counter-regulatory mechanisms with increased neurohormonal activation and changes in the distribution of cardiac output are assumed to secure vital organ perfusion. However, clinical examination of patients with congestive heart failure frequently reveals neurological symptoms with dizziness and memory problems, suggestive of altered brain perfusion. In a study of 12 patients with NYHA functional classes III and IV heart failure, cerebral blood flow (CBF) was found to be significantly reduced, in comparison with 12 healthy control subjects: the patients' average CBF was  $36 \pm 1$  mL/min per 100 g, corresponding to a 31% reduction in comparison with CBF of the control group ( $52 \pm 5$  mL/min per 100 g;  $P < .05$ ). Of interest was that CBF increased from  $35 \pm 3$  mL/min per 100 g before heart transplantation to  $50 \pm 3$  mL/min per 100 g within the first postoperative month ( $P < .05$ ).<sup>31</sup> In another study of 52 patients with advanced nonischemic cardiomyopathy, CBF was 19% less in patients with congestive heart failure than in controls ( $P < .01$ ). CBF became normalized in four patients with congestive heart failure who underwent cardiac transplantation. In a univariate linear regression analysis, global CBF was significantly associated with severity of NYHA functional class, disease duration, atrial fibrillation, serum BNP level, the ratio of early mitral velocity to early diastolic annular velocity, and pulmonary artery systolic pressure. Global CBF was not found to be associated with the ejection fraction, peak oxygen consumption, or anaerobic threshold. In a stepwise multivariate linear regression analysis, serum BNP level ( $P = .047$ ) and NYHA functional class ( $P = .003$ ) were significantly related to global CBF (global CBF =  $48.373 - [0.05 \times \text{serum BNP level}] - [3.283 \times \text{NYHA functional class}]$ ;  $r^2 = 0.401$ ).<sup>32</sup> Thus, reduced CBF and vascular disease may in fact be additive and further

**FIGURE 52-7** A, Cerebral blood flow (CBF) in 12 patients with congestive heart failure (right) and an age-matched control group of 12 (left). \* $P < .05$  in comparison with control. B, CBF in 5 patients with congestive heart failure before (left) and 1 month after (right) heart transplantation. \* $P < .05$  in comparison with pretransplantation status. Factors associated with decreased cerebral blood flow in congestive heart failure secondary to idiopathic dilated cardiomyopathy. *Am J Cardiol* 2006;97:1365-1369.)

potentiate the risk of cerebrovascular events in patients with heart failure (Figure 52-7).

#### Intracardiac Thrombosis After Myocardial Infarction

LV thrombus was previously estimated to develop in approximately 30% of patients with anterior myocardial infarction and was associated with a medium risk of subsequent embolization.<sup>33</sup> In the era of primary stent placement, the incidence may be significantly lower. One retrospective analysis of 2911 patients who had undergone successful primary stent placement revealed that 73 patients (2.5%) had intracardiac thrombi 3 to 5 days after presentation. The presence of LV thrombus was strongly associated with anterior myocardial infarction, ejection fraction lower than 40%, and history of hypertension; size of myocardial infarct and anterior location were the strongest predictors.<sup>34</sup> In a more recent evaluation of patients with heart failure (predominantly after myocardial infarction), delayed-enhancement cardiac magnetic resonance imaging was used to detect LV thrombi. This sensitive method revealed a 7% prevalence of ventricular thrombus. The presence of thrombus was associated with lower ejection fraction and a unique index of myocardial scarring.<sup>35</sup> Thus, the current prevalence of LV thrombus in anterior myocardial infarction is lower than previously reported, possibly because of changes in management of anterior myocardial infarction. Preservation of LV function is probably an important mechanism, as is the use of various antithrombotic and antiplatelet agents.

The risk of embolization of an intracardiac thrombus after its detection is also unknown. It is thought that the risk would decrease over time after the myocardial infarction because of the organization of the thrombus. However, the true risk of embolization and its risk factors are unknown.

According to the American Heart Association/American Stroke Association Council on Stroke guidelines, the following actions are recommended<sup>36</sup>:

1. For patients with an ischemic stroke or transient ischemic attack (TIA) caused by an acute myocardial infarction in whom LV mural thrombus is identified by echocardiography or another form of cardiac imaging, oral anticoagulation is reasonable; the aim is to achieve an international normalized ratio (INR) of 2.0 to 3.0 for at least 3 months and up to 1 year (class IIa, level of evidence B).

2. Aspirin should be used concurrently for ischemic coronary artery disease during oral anticoagulant therapy in doses up to 162 mg/day (class IIa, level of evidence A).
3. In patients who have had an ST wave–elevation myocardial infarction (STEMI) with LV thrombus noted on an imaging study, warfarin should be prescribed for at least 3 months (level of evidence B) and indefinitely in patients who have no increased risk of bleeding (level of evidence C).<sup>37</sup>

### Thrombosis in Left Ventricular Aneurysms in Patients with Heart Failure

An LV aneurysm is a circumscribed, thin-walled, noncontractile outpouching of the ventricle<sup>38</sup> and is observed most commonly after an anterior transmural myocardial infarction (see Chapters 15 and 23).<sup>39</sup> In the current era of reperfusion therapy, an LV aneurysm is present in approximately 10% to 15% of patients with STEMI.<sup>40</sup> The presence of a poorly contracting, dilated left ventricle promotes stasis of blood and leads to an increased risk of thrombus formation.<sup>41</sup>

Demonstrating thrombus within the aneurysm is clinically important because such thrombi can lead to embolic complications. Results of studies differ widely, but both postmortem and surgical studies have demonstrated that approximately 50% of aneurysms contain a thrombus.<sup>42</sup>

Currently, echocardiography, either transthoracic or transesophageal, is the diagnostic standard for characterizing the aneurysm and determining the presence of LV thrombus. Echocardiography provides information about anatomy, size, and location of the aneurysm; information about associated valvular disease; and an estimate of ventricular function, along with blood flow characteristics within the chamber. Magnetic resonance imaging has been reported to be highly accurate in determining the size and location of the aneurysm.<sup>43</sup> Although it lacks the portability of echocardiography, additional advantages include the ability to distinguish among pericardium, thrombus, and myocardium.

The incidence of embolic events in patients with an LV aneurysm may approach 50%.<sup>44</sup> No randomized clinical trial results have supported the use of routine anticoagulation in these patients, but a pooled analysis of reported study results revealed a substantial benefit in patients who received anticoagulation.<sup>45</sup> The usual recommendation for duration of therapy is 3 to 6 months after the diagnosis to allow for endothelialization of the surface of the thrombus. A chronic aneurysm containing an “organized” thrombus probably carries a

lower risk of embolization, and the clinical effect of anticoagulation is unclear. On the other hand, a mobile or protruding thrombus, regardless of age, probably carries a high risk for embolization, and anticoagulation is therefore recommended.

### Atrial Fibrillation and Left Atrial Thrombus in Patients with Heart Failure

Atrial fibrillation and chronic heart failure are two major cardiovascular problems that are increasing in prevalence. Although precise data are lacking, the prevalence of both atrial fibrillation and congestive heart failure is estimated to be higher than 1% in the general population and increases sharply with age.<sup>46</sup> Atrial fibrillation and heart failure often coexist and may predispose to each other (see Chapter 53).<sup>47,48</sup> The prevalence of atrial fibrillation increases with the severity of systolic heart failure, from 10% to 15% of patients with mild to moderate heart failure (NYHA classes II to III) to more than 40% of patients with advanced heart failure<sup>49</sup> (Figure 52-8). LV dysfunction or clinical heart failure is a major additive risk factor in the development of thromboembolic stroke in patients with atrial fibrillation. Furthermore, most patients with heart failure and atrial fibrillation also have other known risk factors for stroke (hypertension, prior cerebral ischemia—either stroke or TIA—and diabetes mellitus). The presence of any heart failure with or without additional stroke risk factors significantly raises the risk of stroke<sup>48</sup> (Tables 52-1 and 52-2). Several scoring methods to predict the risk of thromboembolism in atrial fibrillation have been developed, including CHADS<sub>2</sub> (measure of congestive heart failure, hypertension, age, diabetes, and stroke or transient ischemic attack), all of which count heart failure as a significant risk factor for thromboembolism.

In addition to stasis in the atria and ventricles of these patients, as mentioned previously, hemostatic abnormalities have been shown to occur in patients with heart failure. Similarly, atrial fibrillation also leads to a hypercoagulable state; this may contribute further to the hemodynamic and hemostatic abnormalities conferred by heart failure.

A substudy of Candesartan in Heart Failure Assessment of Reduction in Mortality and Morbidity (CHARM) revealed that atrial fibrillation is associated with a worse outcome in stable patients with heart failure, regardless of whether heart failure is associated with depressed or relatively preserved LV function; however, those with preserved LV function had better survival than did those with impaired LV function.<sup>51</sup>

**FIGURE 52-8** The prevalence of atrial fibrillation (AF) in several major clinical trials of heart failure, illustrated by severity of heart failure in patients enrolled in each clinical trial. CHF-STAT, Congestive Heart Failure: Survival Trial of Antiarrhythmic Therapy; CONSENSUS, Cooperative North Scandinavian Enalapril Survival Study; DIAMOND CHF, Danish Investigations of Arrhythmia and Mortality on Dofetilide; GESICA, Grupo de Estudio de la Supervivencia en la Insuficiencia Cardíaca en Argentina; NYHA, New York Heart Association; SOLVD, Studies of Left Ventricular Dysfunction; V-HeFT, Veterans Administration Cooperative Vasodilator-Heart Failure Trial. **TABLE 52-1 Risk of Stroke in National Registry of Atrial Fibrillation (NRAF) Participants, Stratified by CHADS<sub>2</sub> Score\***

CHADS <sub>2</sub> Score	No. of Patients (N = 1733)	No. of Strokes (Total = 94)	NRAF Crude Stroke Rate per 100 Patient-Years	NRAF Stroke Statistics	
				Adjusted Stroke Rate†	95% Confidence Interval
0	120	2	1.2	1.9	1.2-3.0
1	463	17	2.8	2.8	2.0-3.8
2	523	23	3.6	4.0	3.1-5.1
3	337	25	6.4	5.9	4.6-7.3
4	220	19	8.0	8.5	6.3-11.1
5	65	6	7.7	12.5	8.2-17.5
6	5	2	44.0	18.2	10.5-27.4

\*CHADS<sub>2</sub> score is calculated by adding 1 point each for recent congestive heart failure, hypertension, age at least 75 years, and diabetes mellitus and then adding 2 points for having had a prior stroke or a transient ischemic attack.

†The adjusted stroke rate is the expected stroke rate per 100 patient-years from the exponential survival model, assuming that aspirin was not taken.

Modified from Neuberger HR, Mewis C, van Veldhuisen DJ, et al. Management of atrial fibrillation in patients with heart failure. *Eur Heart J* 2007;28:2568-2577.

**TABLE 52-2 Risk Factors for Ischemic Stroke and Systemic Embolism in Patients with Nonvalvular Atrial Fibrillation**

Risk Factors	Relative Risk
Previous stroke or transient ischemic attack	2.5
Diabetes mellitus	1.7
History of hypertension	1.6
Heart failure	1.4
Advanced age (continuous, per decade)	1.4

Data derived from collaborative analysis of five untreated control groups in primary prevention trials. As a group, patients with nonvalvular atrial fibrillation have a risk of thromboembolism about sixfold higher than that of patients in sinus rhythm. Relative risk refers to comparison between patients with atrial fibrillation and patients without these risk factors. (From Fuster V, Rydén LE, Cannom DS, et al. ACC/AHA/ESC 2006 Guidelines for the Management of Patients with Atrial Fibrillation: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines (Writing Committee to Revise the 2001 Guidelines for the Management of Patients With Atrial Fibrillation); developed in collaboration with the European Heart Rhythm Association and the Heart Rhythm Society. *Circulation* 2006;114(7):e257-e354.) © American Heart Association. Reprinted with permission.

A similar trend was noted in patients in whom a deterioration necessitated hospitalization. In a series of 478 patients hospitalized with atrial fibrillation and heart failure, those with preserved LV function had a similarly poor prognosis, as did those with depressed LV function.<sup>52</sup>

Anticoagulation with warfarin is extremely effective in preventing stroke in patients with atrial fibrillation (risk reduction, 68%),<sup>53</sup> and is recommended for primary and secondary stroke prevention in these patients. The target INR should be 2 to 3.<sup>50</sup> Of note is that the major bleeding risks of anticoagulation are also present or increased in patients in whom heart failure accompanies atrial fibrillation.<sup>54</sup> However, risk-benefit considerations strongly favor anticoagulation.

#### Deep Venous Thrombosis in Patients with Heart Failure

Hospitalized patients with heart failure appear to be at increased risk of developing deep venous thrombosis (DVT) in comparison with patients who do not have heart failure. This is probably because stasis of blood increases the risk of DVT formation. Patients with lower ejection fractions have a higher risk of DVT, and the risk appears to be highest in patients who have right-sided heart failure, particularly with excessive lower extremity edema.<sup>55</sup> Heart failure by itself

is associated with hypercoagulable state, thereby increasing the chance of intravascular thrombus formation.<sup>41,56</sup> In addition to heart failure itself, traditional risk factors for DVT formation include chronic lung disease and immobilization. Symptoms and signs of concomitant heart failure may overshadow DVT and hinder its detection. Therefore, a high degree of clinical suspicion for DVT is warranted for patients with heart failure.

The reported frequency of DVT in patients with heart failure ranges widely, from 10% to 59%.<sup>17,57</sup> The risk of DVT in patients with heart failure is thought to be similar to that in patients undergoing moderate-risk surgery and in patients with other medical conditions such as malignancy, stroke, acute infection, acute respiratory failure, acute rheumatic disorder, and inflammatory bowel disease.<sup>58</sup> According to the results of the National Hospital Discharge Survey, 0.73% of patients hospitalized with heart failure also received a diagnosis of pulmonary embolism, and 1.03% received a diagnosis of DVT. In patients who had heart failure, in comparison with patients who had no heart failure, the relative risk for pulmonary embolism was 2.15; the relative risk for DVT was 1.21. Of patients with heart failure, patients younger than 40 years had the highest relative risk for pulmonary embolism (11.72), and their relative risk for DVT was 5.46.<sup>59</sup>

Therefore, thromboprophylaxis during immobilization or hospital admission in such patients may be advisable,<sup>60</sup> but DVT prophylaxis is significantly underused in the population of patients with heart failure. In one study, prophylaxis was prescribed for only 46% of the medical patients who had risk factors for DVT.<sup>58</sup>

The regimen for DVT prophylaxis includes unfractionated heparin (5000 IU three times daily) or low molecular weight heparin (LMWH). One study on DVT prophylaxis demonstrated that enoxaparin (40 mg once daily), when given during prolonged bed rest, was at least as effective and safe as treatment with unfractionated heparin (5000 IU three times daily) in preventing DVT. In this study, enoxaparin produced greater benefits in patients with heart failure than in patients with severe respiratory disease.<sup>61</sup>

Treatment of DVT in patients with heart failure is similar to treatment of other medical diseases. Treatment for proximal DVT is clearly indicated. In the guidelines from the Seventh American College of Chest Physicians (ACCP) Conference on Antithrombotic and Thrombolytic Therapy, the following strategies were recommended for treatment of DVT<sup>62</sup>:

1. For patients with objectively confirmed DVT, short-term treatment with subcutaneous LMWH or, alternatively, intravenous unfractionated heparin (both grade 1A).

2. For patients with a high clinical suspicion of DVT, treatment with anticoagulants while the outcome of diagnostic tests are awaited (grade 1C+).
3. In acute DVT, initial treatment with LMWH or unfractionated heparin for at least 5 days (grade 1C), initiation of vitamin K antagonist together with LMWH or unfractionated heparin on the first treatment day, and discontinuation of heparin when the INR is stable and greater than 2.0 (grade 1A).
4. For the duration and intensity of treatment for acute DVT of the leg, the recommendations include the following:
  - a. For patients with a first episode of DVT secondary to a transient (reversible) risk factor, long-term treatment with a vitamin K antagonist for 3 months is recommended over treatment for shorter periods (grade 1A).
  - b. For patients with a first episode of idiopathic DVT, treatment with a vitamin K antagonist for at least 6 to 12 months (grade 1A). The dose of vitamin K antagonist should be adjusted to maintain a target INR of 2.5 (INR range, 2.0 to 3.0) for all treatment durations (grade 1A).
  - c. For the prevention of the postthrombotic syndrome, the use of an elastic compression stocking (grade 1A).

## PREVENTIVE THERAPY

### Aspirin Use for the Prevention of Thromboembolism in Heart Failure

In several analyses, researchers have examined whether aspirin decreases rates of thromboembolic events in patients with heart failure. In the Survival And Ventricular Enlargement (SAVE) trial, patients taking aspirin were observed to have a 56% decreased risk of stroke after a myocardial infarction. In the SOLVD trial, aspirin also decreased the risk of thromboembolic events, but this association was observed only in women, for whom the relative risk reduction was 53%. The first Veteran's Administration Cooperative Vasodilator-Heart Failure Trial (V-HeFT) showed a trend toward a reduction in thromboembolic events, but the second V-HeFT did not show a benefit with aspirin. Results of the more recent Warfarin/Aspirin Study in Heart failure (WASH) and the Warfarin and Antiplatelet Therapy in Chronic Heart Failure (WATCH) trial raised concern about the safety of aspirin use in patients with heart failure: Both demonstrated an increased risk of hospitalization for heart failure, and no mortality-related benefit was observed. In WASH, there was a trend toward a higher mortality rate among patients taking aspirin than among those taking warfarin and those taking placebo. Similarly, when analyzing the SOLVD treatment and prevention conditions, Al-Khadra and colleagues<sup>63</sup> found that patients who took antiplatelet agents had retained but reduced benefit from enalapril.

There are mechanistic reasons and data to support this finding. Upregulation of prostaglandin synthesis may be an important compensatory mechanism that counteracts various mediators of vasoconstriction in patients with heart failure. By interfering with prostaglandin production, aspirin and other cyclooxygenase inhibitors may exert harmful effects. Also, in addition to causing platelet activation and aggregation, thromboxane  $A_2$  directly causes vasoconstriction and is thought to mediate, at least in part, the vasoconstricting effect of angiotensin II.<sup>64</sup> In this case, selective inhibition of thromboxane production may be beneficial. Hall and associates<sup>65</sup> performed a hemodynamic analysis of patients with heart failure in which they demonstrated that enalapril, when given with aspirin or on the day after, blunts

vasodilatory hemodynamic effects. These studies and others have raised concern regarding the potential interaction between angiotensin-converting enzyme (ACE) inhibitors and aspirin (Figure 52-9). Aspirin may attenuate the protective effects of ACE inhibitors by inhibiting prostaglandins and thereby enhancing vasoconstriction. In view of these data, it is uncertain whether aspirin provides a benefit in this patient population (Figure 52-10).

### Warfarin Use for the Prevention of Thromboembolism

Until the 2000s, there were no randomized controlled trials to help guide physicians in the use of warfarin for prevention of thromboembolism in patients with heart failure. Unfortunately, the controlled trials that do exist are characterized by poor recruitment and have not been sufficiently powered to yield definitive conclusions. In retrospective analyses of large heart failure trials such as SAVE, SOLVD, and V-HeFT, conflicting results have been found. In SOLVD and SAVE, there was a suggestion that warfarin was beneficial in patients with heart failure. In SOLVD, anticoagulant treatment with warfarin was associated with statistically significant decreases in death or hospitalization for heart failure, but the benefit was not derived from decreased risk of thromboembolic events. Warfarin conferred a 24% overall relative risk reduction for all-cause mortality. The SAVE trial demonstrated an 81% reduction in stroke risk in patients treated with anticoagulants.

Other analyses of large heart failure studies have suggested that warfarin does not reduce rates of thromboembolic events in patients with heart failure. In the analysis of the V-HeFT trial data,<sup>66</sup> no significant difference in thromboembolic events was found when patients treated with anticoagulants were compared with those not so treated. In the analysis of the SCD-HeFT data, warfarin use was not associated with reduced risk of thromboembolic events<sup>21</sup> (see Figure 52-7). Unfortunately, these findings are of limited value because anticoagulant use was not randomized or controlled, data were collected retrospectively, and endpoints were not predefined or standardized.

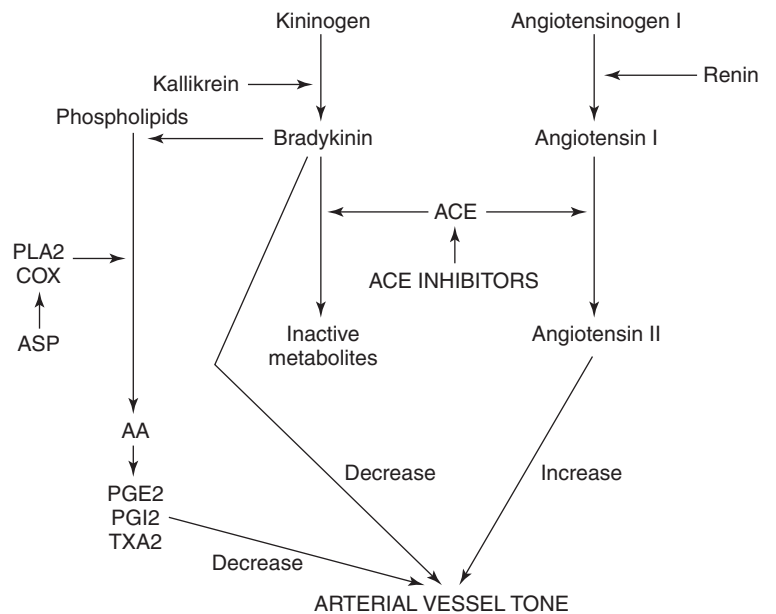

More recently, three randomized controlled trials have been conducted to determine the optimal preventive therapy for thromboembolic events in patients with systolic heart failure (Table 52-3). WASH was a small pilot study designed to assess the feasibility of performing a larger outcome study of whether medical therapy with either aspirin or warfarin could affect outcomes in patients with heart failure.<sup>67</sup> The study included 279 patients with LV systolic dysfunction and ejection fractions lower than 35%. It was an open-label, randomized, placebo-controlled study in which subjects received warfarin (INR target, 2.5), aspirin (300 mg), or placebo. Patients with an absolute indication for or contraindication to aspirin or warfarin were excluded. The combined primary endpoint was all-cause mortality, nonfatal myocardial infarction, and nonfatal stroke; no difference in this endpoint was found among subjects (26% among those taking placebo, 32% among those taking aspirin, and 26% among those taking warfarin). However, patients taking warfarin did have fewer hospitalizations for congestive heart failure (freedom from hospitalization: 48% of those taking placebo and 47% of those taking aspirin, in comparison with 64% of those taking warfarin). Of importance is that this was a small pilot study and therefore not powered to make conclusive statements.

The WATCH study was a randomized, blinded, non-placebo-controlled trial in which 1587 patients with heart failure and ejection fractions lower than 30% were randomly assigned to receive warfarin (target INR, 2.5), aspirin, or

**TABLE 52-3 Studies to Determine Optimal Preventive Therapy for Thromboembolic Events**

Trial	N	Intervention	Endpoints	Comment
Warfarin/Aspirin Study in Heart failure (WASH)	279	Warfarin (INR, 2.5) versus ASA (300 mg)	Pilot study	Underpowered, signal of increased hospitalizations for heart failure in ASA recipients
Warfarin and Antiplatelet Therapy in Chronic Heart failure (WATCH)	1587	Warfarin versus ASA (162.5 mg) versus clopidogrel (75 mg)	Pilot study	Underpowered, signal of increased hospitalizations for heart failure in ASA recipients
Heart failure Long-term Antithrombotic Study (HELAS)	197	Ischemic: ASA or warfarin Nonischemic: warfarin or placebo (Target INR 2-3)	Stroke, embolization, infarction, hospitalization, exacerbation of heart failure, all-cause death	Underpowered

ASA, acetylsalicylic acid (aspirin); INR, international normalized ratio.

clopidogrel. Unfortunately, WATCH was terminated early because of poor recruitment and was therefore underpowered to yield any definitive conclusions. Nevertheless, there was a strong trend favoring warfarin over aspirin in the incidence of nonfatal stroke (0.7% vs. 2.1%), and there was significantly less hospitalization among the patients taking warfarin (16.1%, in comparison with 22.2% of those taking aspirin and 18.3% of those taking clopidogrel). However, this was offset by a significantly higher rate of bleeding in the patients taking warfarin (5.5%, in comparison with 3.6% of those taking aspirin and 2.5% of those taking clopidogrel).<sup>68</sup>

The findings of a third multicenter, randomized, placebo-controlled trial, the Heart failure Long-term Antithrombotic Study (HELAS), have been reported.<sup>69</sup> This was a double-blind trial of 197 patients with NYHA class II to class IV heart failure and ejection fractions of 35% or lower. Patients with known ischemic heart disease were randomly assigned to receive aspirin (325 mg daily) or warfarin (target INR 2-3). Patients with idiopathic dilated cardiomyopathy were randomly assigned to receive warfarin or placebo. Patients with reversible ischemia, atrial fibrillation, mitral valve disease, hypertrophic cardiomyopathy, known LV thrombi, contraindication to aspirin or warfarin, and uncontrolled hypertension were excluded. Subjects who developed atrial fibrillation were withdrawn from the study. Primary endpoints were nonfatal stroke, peripheral or pulmonary embolism, myocardial infarction, rehospitalization, exacerbation of heart failure, or death from any cause. Overall, the event rate was very low; the incidence of thromboembolic events was 2.2 per 100 patient-years. No difference was observed between aspirin and warfarin in the patients with ischemic cardiomyopathy, whereas among patients with nonischemic cardiomyopathy, there was a trend toward a benefit of warfarin (8.9 events per 100 patient-years, in comparison with 14.8 events per 100 patient-years among the placebo recipients). Unfortunately, this study was also characterized by enrollment problems, which again left the data underpowered to distinguish the differences in outcome between the treatment conditions.

When clinicians consider the option of anticoagulation, it is prudent to assess potential bleeding risks. Previous studies of risks of major hemorrhage in patients receiving long-term warfarin have revealed ranges of two to three events per 100 patient-years. In the Stroke Prevention in Atrial Fibrillation (SPAF) trial, the risk of major bleeding was 2.3% per 100 patient-years.<sup>70</sup> A more recent study was designed to assess the rates of thromboembolism and bleeding in a cohort of ambulatory patients with atrial fibrillation. Of the 425 patients, 40% had concomitant heart failure, and the overall rate of major bleeding events was 2.6% over 2 years.<sup>71</sup> In another study of patients older than 65 years with atrial fibrillation who had just initiated warfarin treatment,

the aggregate rate of major hemorrhage was 7.2% per 100 person-years and significantly higher among patients older than 80 years (13.08%, in comparison with 4.75% for patients younger than 80 years). This rate, higher than previously reported, is probably a reflection of an older cohort and the fact that only patients initiating warfarin treatment were included. In view of the aging population and the growing number of elderly patients with heart failure, this study underscores the importance of considering the potential risks of anticoagulation.<sup>72</sup>

## THE FUTURE

There is great interest in developing newer agents to inhibit the coagulation cascade and platelet activation. The motivation for this development is related to improving the efficacy, safety, and ease of use of current agents. In addition, large patient populations would benefit from better drugs. The antithrombotic agents currently used have a poor safety index. Among patients taking long-term anticoagulant agents, the yearly incidence of a severe bleeding complication is 1% to 2%. In addition, currently available antithrombotic agents are sometimes difficult to use because of their mode of administration (continuous intravenous or multiple subcutaneous injections) and the requirement of repeated control of intensity and dose adjustments. The older anticoagulants such as heparins and coumarins are nonspecific inhibitors of the coagulation pathway. Specific inhibitors have been investigated, and interest continues in development of new nonspecific drugs. Similarly, new platelet function inhibitors are being developed for cardiovascular disease (Table 52-4, Figure 52-11). Researchers are investigating which of these broad categories of drugs—antiplatelet or coagulation cascade inhibitors—will be optimal for prevention of death, myocardial infarction, stroke, and thromboembolism, balanced against the risk of bleeding. The ongoing Warfarin versus Aspirin in Reduced Cardiac Ejection Fraction (WARCEF) trial is a double-blind, multicenter study of patients with ejection fraction lower than 35% and NYHA classes I to IV heart failure, in which researchers are investigating rates of all-cause mortality, stroke, and intracranial hemorrhage in patients receiving aspirin or warfarin<sup>73</sup>; the results should provide a basis for the question of whether anticoagulants are superior to antiplatelet agents. Once this study is completed, secondary-level questions pertaining to newer antithrombotic and antiplatelet agents in comparison with older agents can be studied. So far, the newer agents have not proved to be safer because they confer similar bleeding risks, but they may be more effective and easier to use than the currently available treatments.

**FIGURE 52–11** Schematic representation of the function of the coagulation system and specific effect of the new antithrombotic agents. Coagulation starts when tissue factor is exposed to the blood and binds to factor VIIa. The tissue factor–factor VIIa complex then activates factor X, which leads to conversion of prothrombin to thrombin and subsequent formation of fibrin. An essential amplification loop consists of factor IX activation mediated by the tissue factor–factor VIIa complex, which leads to additional activation of factor Xa (interrupted arrows). A second amplification loop is formed by activation of factor XI by thrombin (broken arrows), which results in more activation of factor IXa and, subsequently, more generation of factor Xa. Supraventricular and ventricular arrhythmias are common in patients with a cardiomyopathy and heart failure, regardless of the etiology. Arrhythmia can cause symptoms, a worsening of heart failure or angina, increased morbidity (such as stroke in atrial fibrillation), or sudden cardiac death. This chapter is a discussion of the evaluation and management of patients with a cardiomyopathy and heart failure who also have arrhythmia.

## ATRIAL FIBRILLATION

Although any supraventricular arrhythmia may occur in patients with a cardiomyopathy and heart failure, the most common supraventricular arrhythmia is atrial fibrillation. Also common is atrial flutter, which is generally evaluated and treated in the same way as atrial fibrillation. Atrial fibrillation is present in 22% of patients with heart failure and is associated with increasing age, nonischemic cardiomyopathy, and more severe New York Heart Association (NYHA) functional class (i.e., in <10% of patients with NYHA functional class I heart failure and in ≤50% of those with NYHA functional class IV heart failure).<sup>1,2</sup> It has

been observed in almost 25% of patients with diastolic dysfunction, particularly those with a hypertrophic cardiomyopathy.<sup>3</sup>

Both left ventricular dysfunction and heart failure are significant risk factors for atrial fibrillation, increasing the relative risk by more than sixfold.<sup>1,4</sup> In the Framingham Heart Study of 2326 men and 2866 women monitored for 24 years, the 2-year risk ratio for permanent (chronic) atrial fibrillation in patients with heart failure was 8.5 for men and 13.7 for women; the values for transient (paroxysmal) atrial fibrillation were 8.2 and 20.4, respectively.<sup>4</sup> At the 38-year follow-up, heart failure remained the most powerful predictor of atrial fibrillation. Similar findings were noted in another series of 344 patients with heart failure who were monitored for a mean period of 19 months: 28 (8%) developed atrial fibrillation, which became chronic in 17 (5%).<sup>5</sup>

The incidence of atrial fibrillation is high among patients with new-onset heart failure, and the incidence of new heart failure is high among those with atrial fibrillation. As reported by the Framingham Heart Study, 382 patients had both atrial fibrillation and heart failure; 38% had atrial fibrillation first, 41% had heart failure first, and in 21%, both were diagnosed at the same time.<sup>6</sup> The incidence of heart failure among patients with atrial fibrillation was 33 per 1000 person-years, and the incidence of atrial fibrillation among those with heart failure was 54 per 1000 person-years. A multivariate analysis of patients in the Framingham Heart Study showed that in those with a preserved ejection fraction (diastolic dysfunction), an important predictor for the development of heart failure is atrial fibrillation (odds ratio = 4.23).<sup>6</sup>

## Hemodynamic Consequences

Atrial fibrillation causes a number of hemodynamic changes that in turn can cause hemodynamic deterioration with worsening symptoms in people who already have clinical heart failure. In addition, atrial fibrillation can precipitate heart failure in patients with asymptomatic left ventricular dysfunction. In patients with normal left ventricular function, it may also cause left ventricular dysfunction and precipitate heart failure; this is termed “*tachycardia-mediated cardiomyopathy*.” As an example, in one study of 3288 subjects in whom atrial fibrillation was diagnosed between 1980 and 2000, 24% developed heart failure during a mean follow-up period of 6.1 years.<sup>7</sup> The following factors may contribute to the hemodynamic changes in atrial fibrillation:

1. Rapid heart rate, which by shortening diastolic filling time can alter left ventricular filling, stroke volume, and cardiac output.
2. Chronic irregularity of rhythm, which results in beat-to-beat (RR) changes in left ventricular filling and left ventricular mechanics. The reduction in left ventricular filling during short RR intervals is not completely compensated by the increased filling during the longer RR intervals.
3. Loss of the atrial contraction, which is required for optimal left ventricular filling; this is of particular importance in patients with underlying heart disease.
4. The development of a rate-related cardiomyopathy (atrial, ventricular, or both) can result in mechanical atrial remodeling and enlargement, which may be associated with the development of mitral regurgitation, another important factor associated with hemodynamic changes in atrial fibrillation.<sup>8,9</sup>
5. Activation of neurohumoral vasoconstrictors such as angiotensin II and norepinephrine<sup>18</sup> and possible secretion of other substances by the cardiomyopathic heart, including proinflammatory cytokines and natriuretic peptide.<sup>10</sup>

Atrial fibrillation and the resultant hemodynamic and neuroendocrine alterations

cause electrical and structural (fibrosis) remodeling of the atria, which in turn increases the susceptibility to atrial fibrillation. As a result, atrial fibrillation may beget atrial fibrillation.<sup>11</sup>

### Rate Control

CH 53

The hemodynamic changes resulting from atrial fibrillation can be altered with rate control or conversion to sinus rhythm, which may often result in an improvement in left ventricular function and a decrease in symptoms of heart failure.<sup>12</sup> Rate control can be achieved with drugs that block the atrioventricular node, such as digoxin,  $\beta$ -blockers, calcium channel blockers, or amiodarone,<sup>13</sup> or with radiofrequency ablation of the atrioventricular node.<sup>14</sup> The interruption of atrioventricular conduction by a catheter that delivers radiofrequency energy usually produces complete atrioventricular nodal block, and then a permanent pacemaker must be implanted in order to control the ventricular rate adequately.<sup>15</sup> Atrioventricular nodal ablation with implantation of a permanent pacemaker does not adversely affect long-term outcome, overall quality of life, NYHA functional class, or objective measurements of cardiac function.<sup>15</sup>

Atrioventricular nodal modification, which may reduce the risk of complete atrioventricular block and the need for a pacemaker, is less successful than nodal ablation for rate control in patients with heart failure.

### Risk Factors for Atrial Fibrillation

Dilation and an increase in pressure within the left atrium can alter its electrophysiological properties, predisposing to atrial fibrillation; this phenomenon is known as “*electromechanical feedback*.”<sup>16</sup> Increases in left atrial pressure and size may occur as a result of increased LV end-diastolic pressure, as occurs with diastolic or systolic dysfunction; an increase in intravascular volume; or the development of mitral regurgitation, as often occurs with left ventricular dilation. Left atrial size is also correlated with height and body surface area.

In animal studies, left atrial enlargement and increased left atrial pressure produced by volume expansion, as occurs in heart failure, decreased the atrial refractory period and action potential duration, thereby predisposing to atrial fibrillation.<sup>17</sup> Stretch of the left atrium results in activation of specific ionic currents, which leads to increased dispersion of refractoriness and alterations in conduction properties that facilitate the occurrence of atrial fibrillation. Lowering left atrial pressure resulted in prompt alleviation of the arrhythmia. The role of left atrial stretch caused by volume or pressure overload was further supported by an animal study in which gadolinium, a blocker of the stretch-activated ion channels in the myocardium, reduced the vulnerability to atrial fibrillation during acute atrial dilation.<sup>18</sup> In patients with a hypertrophic cardiomyopathy, enlarged left atrial volume and reduced left atrial function are predictors of atrial fibrillation.<sup>19</sup>

Slowing or blockage of intra-atrial conduction is manifested as a prolonged P-wave duration (>132 msec) or as late atrial potentials on a signal-averaged electrocardiogram (SAECG). The presence of such slowing or blockage may help predict paroxysmal atrial fibrillation in patients with heart failure, as well as recurrence of atrial fibrillation after cardioversion.<sup>20</sup> An increase in P-wave duration on the SAECG is correlated with increases in pulmonary capillary wedge pressure and left atrial pressure. P-wave dispersion (i.e., the difference between maximum and minimum P-wave durations) evident on a 12-lead electrocardiogram (ECG) may also help predict recurrence of atrial fibrillation.<sup>21</sup>

With heart failure, there is neurohormonal activation with elevated levels of catecholamines and angiotensin II, which promotes structural remodeling and fibrosis in the atrium, predisposing to atrial fibrillation. Atrial natriuretic peptide

(ANP) is released from the atria in response to volume expansion and atrial stretch. ANP release is increased in heart failure, and an elevated plasma ANP level may be predictive of atrial fibrillation. In one study of 100 patients with and without atrial fibrillation, those with atrial fibrillation were found to have higher levels of N-terminal ANP (2.6 ng/mL) than were subjects without atrial fibrillation (1.7 ng/mL); this association was independent of left atrial volume and left ventricular ejection fraction (LVEF).<sup>22</sup>

### Relationship Between Heart Failure and Stroke Risk in Atrial Fibrillation

There are conflicting data as to whether left ventricular dysfunction and heart failure increase the risk of stroke in patients with atrial fibrillation. In the Stroke Prevention in Atrial Fibrillation (SPAF) trial of 586 patients monitored for a mean of 1.3 years, the yearly incidence of stroke among patients with atrial fibrillation who did not receive anticoagulants was higher than that among patients without clinical heart failure (7% vs. 2.5%).<sup>23</sup> Echocardiographic evidence of left atrial and left ventricular enlargement and dysfunction was the strongest independent predictor of stroke. In contrast, the results of the Veterans Administration Cooperative Vasodilator–Heart Failure Trial (V-HeFT) I and II studies of 1446 men with heart failure monitored for up to 2.5 years did not indicate that atrial fibrillation increased the risk for embolism over that associated with heart failure.<sup>24</sup>

Among patients with a hypertrophic cardiomyopathy, the presence of atrial fibrillation was an independent risk factor for stroke; the risk was significantly higher in patients who did not receive warfarin (31%) than in those who did receive warfarin therapy (18%).<sup>25</sup>

Although atrial fibrillation of any origin is associated with a high risk of systemic embolism, it is likely that in patients with advanced cardiomyopathy, a low cardiac index, and heart failure, atrial fibrillation confers a significant increase in thromboembolism rate. Indeed, in the CHADS<sub>2</sub> scoring system (congestive heart failure, hypertension, age, diabetes, and stroke or transient ischemic attack), the presence of heart failure is an independent predictor of a thromboembolic event in patients with atrial fibrillation.<sup>26</sup> Anticoagulation is beneficial in all such patients, and warfarin therapy is recommended for most; the target international normalized ratio is 2.5 (range, 2.0 to 3.0).<sup>27</sup>

### Relationship Between Atrial Fibrillation and Mortality in Heart Failure

The relationship between atrial fibrillation and mortality in heart failure is another area of controversy. Several studies have revealed that atrial fibrillation is not associated with an increase in the rate of mortality, sudden cardiac death, or hospitalization after important prognostic variables are adjusted. In the Carvedilol Or Metoprolol European Trial (COMET) of 3029 patients, the presence of atrial fibrillation was not an independent risk factor for mortality in patients who were taking a  $\beta$ -blocker, according to a multivariate analysis.<sup>28</sup> However, the development of atrial fibrillation during the trial was associated with an increase in mortality in a time-dependent analysis (risk ratio, 1.90;  $P < .0001$ ).

In contrast, other studies have demonstrated that atrial fibrillation is associated with an increased rate of mortality. For example, a 3-year follow-up assessment of 6517 patients in the Studies of Left Ventricular Dysfunction (SOLVD) trials revealed that atrial fibrillation was a significant factor in all-cause mortality (34% vs. 23% of patients without atrial fibrillation), in death from pump failure (16.7% vs. 9.4%), and in the combined endpoint of death or hospitalization for heart failure (45% vs. 33%).<sup>29</sup> In a multivariate analysis,

atrial fibrillation remained significantly associated with each of these outcomes (Figure 53-1). Similar results were reported from the Candesartan in Heart Failure Assessment in Reduction of Mortality (CHARM) trial of 7599 patients with symptomatic heart failure caused by either systolic or diastolic dysfunction.<sup>30</sup> Approximately 18% of these patients had atrial fibrillation at baseline. After a median follow-up of 38 months, atrial fibrillation was independently associated with an increase in all-cause mortality in patients with either systolic dysfunction (37% vs. 28% of patients without atrial fibrillation) or diastolic heart failure (24% vs. 14%). In the Valsartan in Acute Myocardial Infarction Trial (VALIANT) of 14,703 patients in whom an acute myocardial infarction was complicated by heart failure or left ventricular dysfunction, atrial fibrillation was associated with significantly higher rates of long-term mortality (adjusted hazard ratio = 1.25;  $P = .03$ ) and adverse cardiovascular events (adjusted hazard ratio = 1.15,  $P = .08$ ).<sup>31</sup>

According to a meta-analysis of studies involving patients with heart failure and either sinus rhythm or atrial fibrillation, the prevalence of atrial fibrillation ranged from 15% to 23% (Figure 53-2).<sup>32</sup> The presence of atrial fibrillation was

associated with a worse outcome than was sinus rhythm (odds ratio, 1.33).

Optimal pharmacological therapy for heart failure may influence the relationship between atrial fibrillation and survival. This possibility was suggested by observations of patients treated at different times. In one study, the outcomes of 359 patients managed between 1985 and 1989 was compared with those of 391 patients managed between 1990 and 1993; patients with atrial fibrillation managed at the later time had outcomes similar to those of patients without atrial fibrillation. The later patients with atrial fibrillation also had a higher rate of 2-year survival than did earlier patients with atrial fibrillation; this change may have reflected more frequent use of angiotensin-converting enzyme (ACE) inhibitors and amiodarone and less frequent use of class I antiarrhythmic drugs. In another study of 234 patients evaluated for heart transplantation between 1993 and 1996, the presence of atrial fibrillation was not associated with decreased event-free survival (death, placement of a left ventricular assist device, or transplantation).

### Treatment of Atrial Fibrillation in Heart Failure

Despite the uncertainty concerning the prognostic implications of atrial fibrillation, treatment is often required for relief of symptoms and for improvement of heart failure, which may worsen or be difficult to manage in the presence of atrial fibrillation. The two approaches to therapy are (1) rate control with an atrioventricular nodal blocking agent (digoxin,  $\beta$ -blocker, or calcium channel blocker) along with anticoagulants and (2) rhythm control with an antiarrhythmic agent to maintain sinus rhythm. Although rate control results in an improvement in symptoms, normal hemodynamics are not restored. This may be an important concern in some patients with systolic heart failure and possibly of more importance in those with heart failure caused by diastolic dysfunction. In addition, there is still a small risk for an embolism even when anticoagulation with warfarin is used. Although rhythm control restores normal hemodynamics and may eliminate the risk of an embolism, this approach often necessitates the use of an antiarrhythmic drug, which may be associated with potential toxicity. Pulmonary vein isolation through radiofrequency ablation is an alternative approach for prevention of intermittent atrial fibrillation; its role in therapy for permanent atrial fibrillation is less well established. In addition, the role of ablation in patients with heart failure is less certain because data are limited.

Drug therapy for atrial fibrillation may be associated with an increase in mortality. In the SPAF trial, for example, in patients with heart failure and atrial fibrillation who did not have ventricular arrhythmias, the use of class I antiarrhythmic drugs was associated with increased mortality (relative risk of 3.3 for cardiac death and 5.8 for arrhythmia-related death).<sup>33</sup> However, SPAF was not a study of mortality and was not designed to evaluate therapy for atrial fibrillation, and the indications for therapy with antiarrhythmic drugs were not certain. Nevertheless, significantly reduced LVEF, a history of clinical heart failure (risk ratio of 2.3), sustained ventricular tachyarrhythmia as the presenting arrhythmia (risk ratio of 3.4), and structural heart disease (risk ratio of 2 to 3) have all been identified as risk factors for the development or aggravation of an arrhythmia with class I antiarrhythmic agents.<sup>34</sup> These drugs are best avoided by patients with heart failure. It has been reported that the class III antiarrhythmic agents are safer in patients with heart failure and are the preferred agents when rhythm control is the approach pursued.

#### Drugs Used for Rhythm Control in Heart Failure

**Amiodarone.** Amiodarone is a class III antiarrhythmic agent that has  $\beta$ - and  $\alpha$ -blocking activity; potassium-, sodium-, and

**FIGURE 53-1** Among 6517 patients entered in the Studies of Left Ventricular Dysfunction (SOLVD), the presence of atrial fibrillation (AF), in comparison with sinus rhythm, was associated with significantly decreased cumulative rates of survival (66% vs. 77%,  $P < .001$ ) (A) and with an increased risk of death or hospitalization for heart failure (45% vs. 33%,  $P < .001$ ) (B). (From Dries DL, Exner DV, Gersh BJ, et al. Atrial fibrillation is associated with an increased risk of mortality and heart failure progression in patients with asymptomatic left ventricular systolic dysfunction: a retrospective analysis of the SOLVD trials. *J Am Coll Cardiol* 1998;32:695.)

**FIGURE 53-2** In a meta-analysis involving 32,946 patients with heart failure who were enrolled in randomized trials, the presence of atrial fibrillation was associated with a worse outcome than was sinus rhythm (odds ratio, 1.33 to 1.57). COMET, Carvedilol Or Metoprolol European Trial; V-HeFT, Veterans Administration Cooperative Vasodilator-Heart Failure Trial; SOLVD, Studies Of Left Ventricular Dysfunction; PRIME, Perspective Randomized studies of Ibopamine on Mortality and Efficacy; CHARM, Carvedilol in Heart failure Assessment of Reduction in Mortality and morbidity; DIAMOND, Danish Investigation of Arrhythmia and Mortality ON Dofetilide. (With permission from Wasywch CA, Pope AJ, Somaratne J, et al. Atrial fibrillation and the risk of death in patients with heart failure: a literature-based meta-analysis. *Intern Med J*, 40:317, 2009.)

calcium channel-blocking activity; and antithyroid activity. It is effective for converting atrial fibrillation to, and for maintaining, sinus rhythm. It also has depressant effects on the atrioventricular node and can slow the ventricular response rate during atrial fibrillation. In the Congestive Heart Failure Survival Trial of Antiarrhythmic Therapy (CHF-STAT) trial, the rate of conversion of atrial fibrillation was higher with amiodarone (31%) than with placebo (8%).<sup>35</sup> Among patients who remained in atrial fibrillation, there was also a 16% to 20% reduction in the mean ventricular rate and a 14% to 22% reduction in the maximum ventricular rate. In addition, amiodarone significantly reduced the development of atrial fibrillation among patients initially in sinus rhythm (4.1%), in comparison with patients who did not receive amiodarone therapy (8.3%).

Amiodarone does not increase mortality among patients with heart failure, although several potential complications are associated with this agent, including bradycardia that may necessitate placement of a pacemaker, as well as hypothyroidism. According to a meta-analysis involving data from 1465 patients treated for a minimum of 12 months, amiodarone was associated with a higher incidence of complications, including thyroid abnormalities, neurological side effects, ocular changes, and bradycardia. Of importance was that there were no cases of torsades de pointes or other forms of proarrhythmia despite the marked prolongation of the QT interval observed with this agent.<sup>36</sup>

Although amiodarone is not approved for treatment of atrial fibrillation, it is the safest and most effective drug for this indication in patients with heart failure; it is therefore the preferred therapy.

**Dofetilide.** Dofetilide, another class III antiarrhythmic agent, is also effective and safe in heart failure. This fact was established by the Danish Investigation of Arrhythmia and Mortality On Dofetilide in Congestive Heart Failure (DIAMOND-CHF), which enrolled 1518 patients with symptomatic heart failure, including 391 with atrial fibrillation at baseline.<sup>37</sup> Conversion to sinus rhythm was higher with dofetilide than with placebo (12% vs. 1%), and the probability of remaining in sinus rhythm was higher. During a mean follow-up period of 18 months, there was no overall difference in mortality between the patients taking dofetilide (41%) and those taking placebo (42%). However, an analysis by baseline-corrected QT (QTc) interval did reveal a difference in mortality: In patients with a QTc interval shorter than 429 msec, dofetilide was associated with a significant reduction in mortality (risk ratio = 0.4), whereas in patients with a QTc interval longer than 429 msec (risk ratio = 1.3), it was associated with increased mortality. In addition, dofetilide significantly

reduced the risk of hospitalization for worsening of heart failure (30%) in comparison with placebo (38%), regardless of the presence of atrial fibrillation or sinus rhythm at baseline.

**Sotalol.** Although sotalol is effective in the prevention of atrial fibrillation, there are no studies available in patients with heart failure. There has been a concern for worsening of heart failure and an increased risk of significant QTc prolongation and torsades de pointes in these patients. Therefore, it is not considered a first-line therapy for atrial fibrillation in patients with heart failure.

**Azimilide.** Azimilide is an investigational class III antiarrhythmic agent that is also effective in converting atrial fibrillation and preventing its occurrence. This was evaluated in the Azimilide Postinfarct Survival Evaluation (ALIVE) trial, which enrolled 3381 patients with left ventricular dysfunction who had suffered myocardial infarction.<sup>38</sup> Atrial fibrillation was present at presentation in 93 patients; 27 patients developed atrial fibrillation after study enrollment. Patients treated with azimilide developed atrial fibrillation less often than did those given placebo ( $P = .04$ ). Among patients with atrial fibrillation, those treated with azimilide were more often in sinus rhythm 1 year later ( $P = .04$ ).

**Dronedronarone.** Dronedronarone is an antiarrhythmic drug with electrophysiological properties similar to those of amiodarone, but it is devoid of iodine. It does not cause the adverse reactions generally attributed to iodine. The effect of this agent was evaluated in the Anti-arrhythmic Trial with Dronedronarone in Moderate to Severe Congestive Heart Failure Evaluating Morbidity Decrease (ANDROMEDA).<sup>39</sup> Although there was no difference in the occurrence of the primary endpoint of total mortality or heart failure hospitalization between patients taking dronedronarone (17%) and those taking placebo (12.6%;  $P = .12$ ), this study was terminated after 627 patients were enrolled because of a significant increase in mortality after a median follow-up of 2 months (8.1% of patients taking dronedronarone vs. 3.8% of those taking placebo; hazard ratio = 2.13,  $P = .03$ ). The excess mortality was attributable primarily to a worsening of heart failure. Although dronedronarone is approved for therapy of atrial fibrillation, it is contraindicated in patients with class IV heart failure or those with class II-III heart failure with recent decompensation.

**Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers.** Although the ACE inhibitors and angiotensin receptor blocking (ARB) agents are not considered specific therapy for atrial fibrillation, data have suggested that they may be effective for prevention of new-onset or recurrent atrial fibrillation. Proposed mechanisms include

direct effects of angiotensin blockade on the structural and electrical properties of the atria (reduction in atrial stretch, prevention of atrial fibrosis, prevention of electrical remodeling, and direct antiarrhythmic effects) and indirect effects through improved control of heart failure and hypertension, which are known risk factors for atrial fibrillation. The potential role of these agents in atrial fibrillation was suggested by a meta-analysis involving more than 56,000 patients enrolled in studies of heart failure, status post myocardial infarction, and hypertension and in postcardioversion studies. Overall, ACE inhibitors and ARB agents reduced the relative risk of atrial fibrillation by 28% ( $P = .0002$ ).<sup>40</sup>

### Radiofrequency Ablation

There is growing interest in the use of radiofrequency ablation to produce pulmonary vein isolation in the treatment of atrial fibrillation. However, the role of this technique in preventing atrial fibrillation in patients with underlying left ventricular dysfunction and heart failure is uncertain because data are limited. In one small study, the results of atrial fibrillation ablation in 58 patients with heart failure (NYHA classes II to IV) and LVEF lower than 40% were compared to those in 58 control patients without heart failure.<sup>41</sup> A second ablation was required in 50% of patients with heart failure. At the end of 1 year, 78% of the patients with heart failure and 84% of the controls remained in sinus rhythm, although several patients still required antiarrhythmic drugs. Patients with heart failure experienced a significant increase in exercise duration (from 11 to 14 minutes,  $P < .001$ ), LVEF increased by a mean of 21%, and left ventricular fractional shortening increased by 11%. Although these data are encouraging, there are a number of important limitations, including the small number of highly selected patients, the absence of a control group of patients who did not undergo ablation, and the inclusion of many patients who probably had a tachycardia-mediated cardiomyopathy rather than preexisting structural myocardial disease, as indicated by the fact that LVEF returned to normal in 72% of patients.

In another trial, the same investigators randomly assigned 81 patients with class II or III heart failure and LVEF of 40% or lower to undergo pulmonary vein isolation or atrioventricular nodal ablation and biventricular pacing.<sup>42</sup> After a 6-month follow-up period, 88% of those who underwent ablation were free of atrial fibrillation (although 20% required repeated ablation and 17% were still taking antiarrhythmic drugs). Results for the composite primary endpoint (6-minute walk test, ejection fraction, and quality-of-life score) favored ablation.

Nevertheless, the long-term role of ablation in patients with underlying dilated cardiomyopathy—who often have progressive heart failure, significant left atrial dilation, and fibrosis—is still uncertain.

Radiofrequency ablation has also been used in patients with hypertrophic cardiomyopathy.<sup>43</sup> However, the recurrence rate is as high as 48%, and repeated ablations are often required. In addition, many patients still require antiarrhythmic drug therapy. Therefore, its role in the prevention of atrial fibrillation in hypertrophic cardiomyopathy is also uncertain.

### Drugs Used for Rate Control

A strategy of rate control necessitates atrioventricular nodal blockade. Rate control must be assessed not only at rest but also during exercise. Although there are no guidelines in regard to adequate rate control, heart rate targets for the patients in the rate control arm of the Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial are probably reasonable and include<sup>44</sup> resting heart rate of 80 beats/min or less, 24-hour Holter average heart rate of 100 beats/min or less, and no greater than 110% of the age-predicted maximum, and heart rate of 110 beats/min or less

in the 6-minute walk. Rate control can also be assessed with submaximal or maximal exercise electrocardiographic testing. Control is deemed adequate when the peak heart rate is 100% or less of the predicted maximum. An essential component of rate control over time is the absence of symptoms during normal activities or exercise.

**β-Blockers** (see Chapter 46). Oral β-blockers have a limited role in rhythm control (prevention of atrial fibrillation) in patients with heart failure, although they may be effective when atrial fibrillation is precipitated by marked sympathetic activation: for example, during exercise or with hyperthyroidism.<sup>45</sup> However, they are more widely used as primary therapy for rate control in permanent atrial fibrillation. β-Blockers decrease the resting heart rate but, of more importance, blunt the heart rate response to exercise. β-Blockers have the additional advantage of improving survival in patients with heart failure. However, these drugs must be used with caution because they may exacerbate heart failure, particularly in patients with decompensated heart failure.

Although most β-blockers appear to have similar efficacy, metoprolol or carvedilol are often preferred, largely because they have been shown to reduce mortality among patients with heart failure and are approved therapy for rate control. Bisoprolol, although effective in heart failure, is not approved for rate control.

**Digoxin.** Digoxin is an effective agent in atrioventricular nodal blockade, the result of increased vagal tone. It is generally less effective for rate control than are β-blockers or calcium channel blockers, particularly during exercise, when vagal tone is low and sympathetic tone is high, blunting any increase in vagal tone. However, in patients with atrial fibrillation who have heart failure caused by systolic dysfunction, the improvement in contractility and the reduction in sympathetic tone, in addition to the increase in vagal tone, may result in a significant reduction in the ventricular rate. Although β-blocker therapy in these patients has been considered preferable, digoxin may be useful in patients who do not achieve adequate control of heart rate with β-blockers alone, in patients who cannot tolerate the addition or increased doses of a β-blocker because of acute decompensated heart failure, or in patients for whom digoxin would be added to improve heart failure symptoms that are independent of atrial fibrillation. In patients with the acute onset of atrial fibrillation that is the result of decompensated heart failure, digoxin and the improvement in left ventricular function and hemodynamics may result in conversion of atrial fibrillation to sinus rhythm.

**Calcium Channel Blockers.** The nondihydropyridine calcium channel blockers verapamil and diltiazem are useful in directly blocking the atrioventricular node and slowing the ventricular rate in atrial fibrillation. Verapamil is more effective than diltiazem. However, both these agents have negative inotropic effects and are therefore not often prescribed in patients with heart failure because of a risk of heart failure exacerbation; if they are necessary, they should be used cautiously.

**Amiodarone.** Although amiodarone is usually used to maintain sinus rhythm, this agent can also slow the ventricular rate in patients who remain in atrial fibrillation or in whom atrial fibrillation recurs; this is a result of its β- and calcium channel-blocking activity.

### Nonpharmacological Therapy for Rate Control

Radiofrequency ablation of the atrioventricular node is an alternative approach when rate control is not achieved with pharmacological therapy or when the atrioventricular nodal blocking drugs are poorly tolerated. Because atrioventricular nodal ablation produces complete heart block, a permanent pacemaker is usually necessary. However, right ventricular pacing may cause interventricular and intraventricular dyssynchrony,

simulating the effect of left bundle branch block.<sup>46</sup> The right ventricle contracts before the left ventricle, and the septum contracts before the lateral wall of the left ventricle. Thus, ventricular pacing can impair left ventricular systolic function, reduce functional status, and increase mortality. This is of particular importance for patients with underlying left ventricular dysfunction and heart failure, who may be at the highest risk for clinical deterioration with right ventricular pacing. In such patients, biventricular pacing, also called “cardiac resynchronization therapy” (CRT), may be a preferred approach. This was studied in the Post AV [atrioventricular] Nodal Ablation Evaluation (PAVE), in which 184 patients with chronic atrial fibrillation and heart failure underwent atrioventricular node ablation and were randomly assigned to receive standard right ventricular pacing or CRT.<sup>47</sup> After a 6-month follow-up period, CRT was associated with significantly greater postablation increases in 6-minute walking distance, peak oxygen consumption with exercise, and exercise duration than was standard right ventricular pacing. CRT resulted in preservation of baseline systolic function, whereas the LVEF fell from 45% to 41% in patients treated with right ventricular pacing. The benefits of CRT were more prominent in patients with an LVEF of 45% or lower or with NYHA class II or III heart failure than in patients with a higher LVEF or NYHA class I heart failure. On the basis of these observations, CRT has been approved in patients who have undergone atrioventricular nodal ablation and have NYHA class II or III heart failure.

### Rate Control Versus Rhythm Control

For the management of atrial fibrillation, a strategy of rate control with anticoagulation has been compared with that of rhythm control with an antiarrhythmic drug. The largest study, AFFIRM, enrolled 4060 patients; 26% had depressed left ventricular function, and 23% had a history of heart failure.<sup>44</sup> Overall, rates of occurrence of the primary endpoint (overall mortality) and the composite secondary endpoint (death, disabling stroke, disabling anoxic encephalopathy, major bleeding, and cardiac arrest) were the same with the two strategies. A subset analysis of patients with heart failure or an LVEF lower than 50% likewise revealed no difference in outcome between the two strategies.

In the Atrial Fibrillation and Congestive Heart Failure (AF-CHF) trial, rate versus rhythm control was evaluated in 1376 patients with atrial fibrillation who either had an LVEF of 35% or lower and symptoms of heart failure (NYHA classes II to IV) or had been hospitalized previously for heart failure or an LVEF of 25% or lower.<sup>48</sup> After a 2-year follow-up period, there was no difference in occurrence of the primary endpoint of total cardiovascular mortality (27% of patients who received rhythm control, in comparison with 25% of those who received rate control;  $P = .59$ ) (Figure 53-3). The occurrences of secondary endpoints, including total mortality (3% vs. 4%), worsening heart failure (28% vs. 31%), and stroke (3% vs. 4%), were similar between the two groups, as were the occurrences of the composite endpoint of cardiovascular death, worsening heart failure, and stroke (43% vs. 46%) (Figure 53-4). During the course of the study, 21% of patients switched from rhythm control to rate control, primarily because of the inability to maintain sinus rhythm, and 10% switched from rate control to rhythm control, primarily because of worsening heart failure. At 1 year, more patients receiving rhythm control (46%) had been hospitalized than were those receiving rate control (39%;  $P = .06$ ); hospitalization was mainly for atrial fibrillation (14% vs. 9%) and bradyarrhythmias (6% vs. 3%).

#### Recommendations

The results of the AFFIRM and AF-CHF studies do not justify a strategy of rhythm control for atrial fibrillation management in patients with heart failure to improve survival.<sup>44,48</sup>

**FIGURE 53-3** In the Atrial Fibrillation and Congestive Heart Failure (AF-CHF) trial, a strategy of rate control was compared with a strategy of rhythm control in 1376 patients with heart failure and atrial fibrillation. There was no difference in the primary endpoint of total cardiovascular mortality ( $P = .59$ ). (With permission from Roy D, Talajic M, Nattel S, et al. Rhythm control versus rate control for atrial fibrillation and heart failure. *N Engl J Med* 2008;358:2667. Copyright © 2008, Massachusetts Medical Society. All rights reserved.)

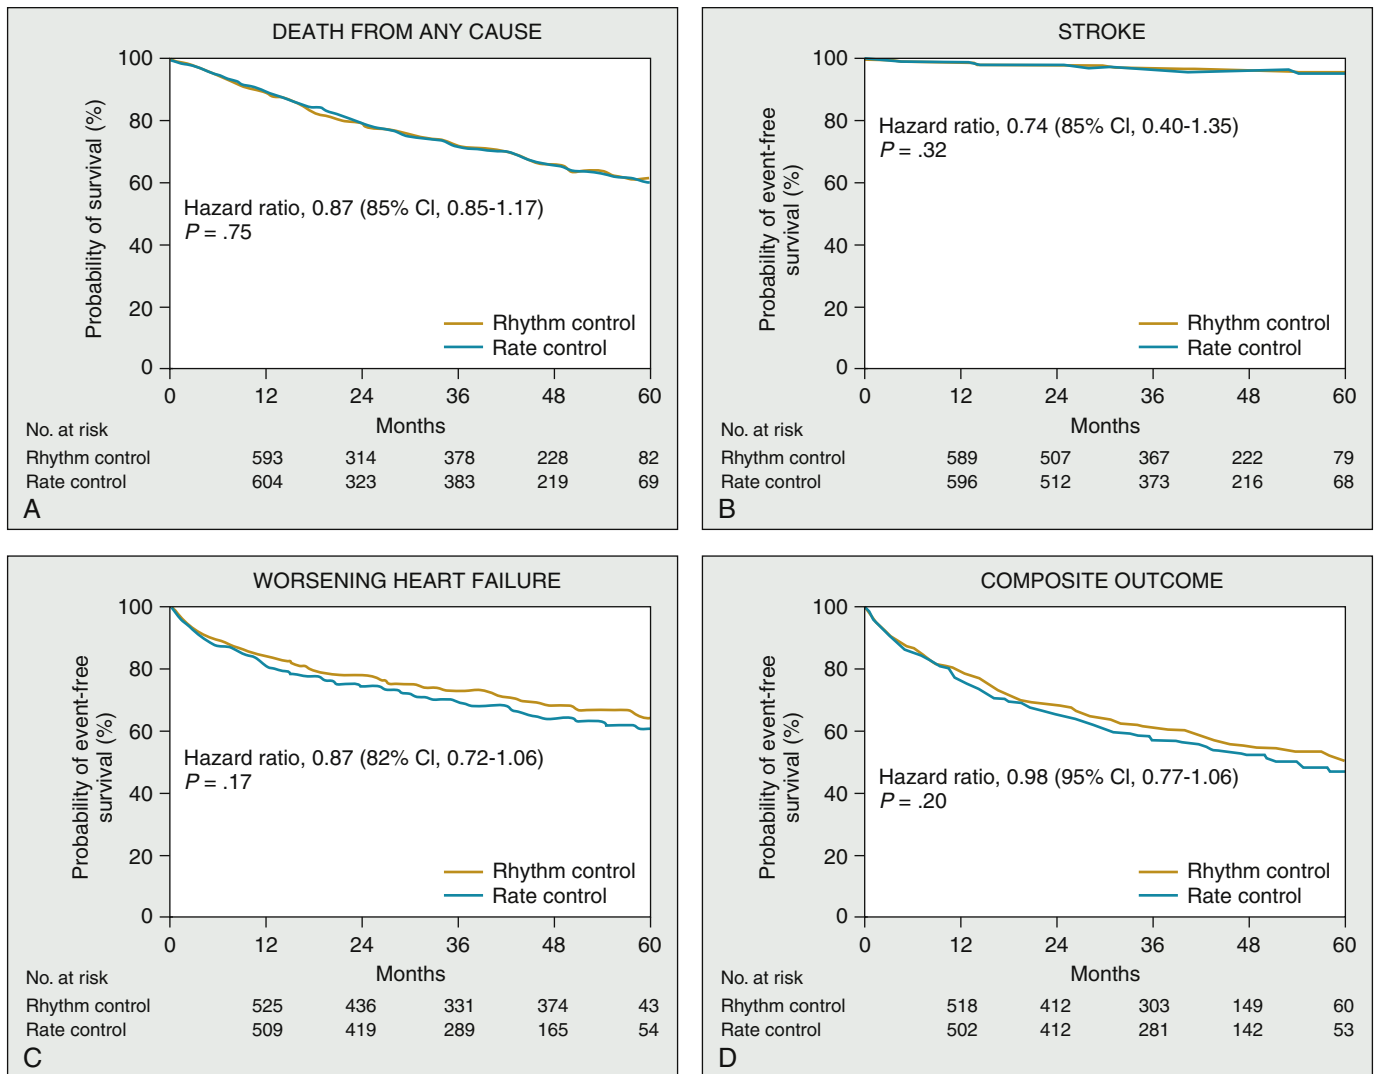

Although these studies also revealed no difference in worsening of heart failure symptoms when a rate control strategy was compared with a rhythm control strategy, there were some patients with heart failure in whom atrial fibrillation causes a worsening of symptoms or in whom heart failure symptoms could not be controlled medically. As indicated, 10% of patients in the AF-CHF trial switched from rate control to rhythm control because of worsening heart failure. In addition, patients with diastolic dysfunction were not included in this trial, and maintenance of sinus rhythm may be of greater importance in these patients. Therefore, although rate control with anticoagulation is an acceptable approach for patients with heart failure and atrial fibrillation in whom heart failure symptoms are stable and controlled, rhythm control may be required for patients in whom heart failure symptoms worsen or continue despite adequate rate control. This may be more frequently the case in patients with diastolic heart failure or very severe systolic dysfunction.

#### Rhythm Control

A strategy of rhythm control involves two steps. The first is conversion of atrial fibrillation to sinus rhythm, and the second is prevention of atrial fibrillation recurrence. Conversion of atrial fibrillation to sinus rhythm is not frequently achieved with antiarrhythmic drugs in patients with heart failure; as a result, electric cardioversion is often necessary. The guidelines of the American College of Cardiology (ACC), the American Heart Association (AHA), and the European Society of Cardiology (ESC) recommend amiodarone and dofetilide as the drugs of choice for maintenance of sinus rhythm in patients with atrial fibrillation; however, these drugs may increase the likelihood of spontaneous conversion to sinus rhythm, in comparison with placebo.<sup>48a</sup>

Amiodarone and dofetilide are recommended as effective and safe agents for prevention of atrial fibrillation once sinus rhythm has been restored. Although neither amiodarone nor dofetilide has been shown to reduce mortality among patients with heart failure, they do not increase mortality and are safe; torsades de pointes is rarely seen with amiodarone therapy, and its incidence was 3.3% with dofetilide as reported by the DIAMOND-CHF trial.<sup>49</sup> However, amiodarone is associated with a risk of symptomatic bradycardia that may necessitate discontinuation

**FIGURE 53-4** A-D, In the Atrial Fibrillation and Congestive Heart Failure (AF-CHF) trial, a strategy of rate control was compared with a strategy of rhythm control in 1376 patients with heart failure and atrial fibrillation. There was no difference in occurrences of any of the secondary endpoints, including total mortality, worsening of heart failure, or stroke, or in the composite endpoint of cardiovascular death, worsening heart failure, and stroke. CI, confidence interval. (With permission from Roy D, Talajic M, Nattel S, et al. Rhythm control versus rate control for atrial fibrillation and heart failure. *N Engl J Med* 2008;358:2667. Copyright © 2008, Massachusetts Medical Society. All rights reserved.)

of digoxin or  $\beta$ -blockers or implantation of a permanent pacemaker. Nevertheless, amiodarone is preferred when prevention of atrial fibrillation is indicated in patients with heart failure; dofetilide is an alternative agent. Sotalol can be used, but with caution and careful reassessment of the patient.

Although pulmonary vein isolation with radiofrequency ablation has been reported to be an effective therapy for preventing intermittent atrial fibrillation, it is less effective in patients with permanent atrial fibrillation, and its role in patients with heart failure, left ventricular dysfunction, and marked left atrial enlargement is uncertain because only a few small studies have been conducted (by the same group), and there is no long-term follow-up. Patients with heart failure often have permanent atrial fibrillation, as well as significant left atrial dilation, fibrosis, and electrical and mechanical remodeling; therefore, the role of this procedure is not well established.

#### Rate Control

When atrial fibrillation is to be maintained as the underlying rhythm, anticoagulation and rate control are essential, as in patients without heart failure; however, anticoagulation is underused in this population. For example, in one study of 2093 patients 65 years of age or older with heart failure and

atrial fibrillation, only 20% were receiving therapy with an oral anticoagulant.<sup>50</sup>

In patients with atrial fibrillation and decompensated heart failure, digoxin is often the initial drug used for rate control, because its positive inotropic activity can also ameliorate the symptoms of heart failure. In some patients, digoxin may result in the conversion of atrial fibrillation to sinus rhythm. However, digoxin is often ineffective when used alone, especially in patients with heart failure in whom sympathetic activity is elevated. Thus, combined therapy with a  $\beta$ -blocker (once compensation is achieved) or, less preferably, a calcium channel blocker is often necessary. In patients with atrial fibrillation and compensated heart failure,  $\beta$ -blockers are often the initial therapy for rate control, and digoxin or a calcium channel blocker is added if heart rate control is not adequate with a  $\beta$ -blocker alone. If drugs are ineffective or poorly tolerated, a strategy of ablation and pacing can be used.

## VENTRICULAR ARRHYTHMIAS

More than 80% of patients with heart failure caused by systolic dysfunction have frequent and complex ventricular arrhythmias, as documented on Holter monitoring, and almost 50%

demonstrate runs of nonsustained ventricular tachycardia (NSVT). The frequency of arrhythmia appears to be related to the severity, but not to the type, of underlying heart disease. It may be correlated with ventricular cavity size.

Ventricular arrhythmia, including premature ventricular complexes (PVCs) and NSVT, is also common in patients with a hypertrophic cardiomyopathy. In a community-based study of 178 patients with hypertrophic cardiomyopathy who underwent ambulatory Holter monitoring, PVCs were present in 88%, couplets were present in 42%, and NSVT was present in 31%.<sup>51</sup> The presence of NSVT was associated with greater degrees of left ventricular hypertrophy and NYHA functional class III or IV symptoms.

Ventricular arrhythmias may be asymptomatic or accompanied by such symptoms as palpitations, lightheadedness, presyncope or syncope, and a worsening of heart failure. Of particular concern is the association of ventricular arrhythmia with sustained ventricular tachycardia and ventricular fibrillation, the usual mechanisms for sudden cardiac death (SCD).

## Causes of Ventricular Arrhythmias in Heart Failure

Multiple factors are responsible for the frequency of ventricular arrhythmias in patients with heart failure and cardiomyopathy.

### Underlying Structural Disease

Extensive myocardial hypertrophy, damage and fibrosis, or the loss of cell-to-cell coupling in patients with dilated cardiomyopathy provides the proper conditions for anisotropy and reentry, the mechanism thought to be responsible for most ventricular arrhythmias. Other mechanisms in the failing heart play a role, including remodeling of ion channels, calcium-handling proteins, and gap junction–related proteins.<sup>52</sup> In patients with a hypertrophic cardiomyopathy, an additional factor is the myocyte disarray.

A focal mechanism, probably resulting from an ectopic focus or triggered activity arising from either early or delayed afterdepolarizations, may also contribute to ventricular arrhythmia in patients with a nonischemic cardiomyopathy.

Myocardial repolarization is altered in heart failure, independent of the cause of the cardiomyopathy. This is primarily the result of abnormalities of the calcium-independent transient outward potassium current and inward rectifier potassium current. The development of spatial heterogeneity in repolarization is manifest on the surface ECG, which may show increased QT dispersion or beat-to-beat fluctuation in the QT interval. The abnormalities in repolarization may be associated with a potential for polymorphic ventricular tachycardia and ventricular fibrillation.

### Mechanical Factors

Mechanical factors in ventricular arrhythmias, which can alter the electrophysiological properties of myocardial tissue in heart failure, include an increase in wall stress and left ventricular dilation; this has been termed “electromechanical feedback.”<sup>53,54</sup> In an animal model of dilated cardiomyopathy, refractoriness and action potential duration were significantly prolonged without a change in conduction times. Additional volume loading resulted in further prolongation of these parameters.

Because regions of the heart have differing mechanical function, electromechanical feedback may result in an increase in dispersion of action potential duration and membrane recovery. In addition, electromechanical feedback decreases in magnitude as steady-state heart rate increases. This may have implications in the setting of frequent PVCs, because the occurrence of short and long intervals from beat to beat may enhance dispersion of recovery.

The dilation of the left ventricle and an increase in left ventricular size can increase the incidence of arrhythmias. For example, in the SOLVD trial of 311 patients, there was a direct correlation between left ventricular end-diastolic volume and the prevalence of ventricular arrhythmia (Figure 53-5).<sup>54</sup>

### Neurohormonal Factors

Heart failure results in the activation of the sympathetic nervous and renin-angiotensin systems. Markers for sympathetic activation and withdrawal of parasympathetic tone include increased heart rate, reduced variability in heart rate, and depressed baroreceptor sensitivity. One study demonstrated that depressed baroreceptor sensitivity was associated with the presence of NSVT (odds ratio = 3.8); in the presence of high pulmonary capillary wedge pressure (an indirect index of left ventricular stretch or wall stress), the odds ratio for NSVT increased to 6.5.<sup>55</sup> This observation is suggestive of a synergistic effect of autonomic system imbalance and left ventricular stretch in predisposing to ventricular arrhythmia.

Neurohumoral activation can promote arrhythmogenesis through a variety of mechanisms:

1. Catecholamines have direct effects on the electrophysiological properties of the myocardium, thereby enhancing arrhythmogenicity; these include increases in automaticity and triggered activity and an alteration of conduction and refractoriness, which may promote reentry.
2. Angiotensin II can indirectly promote arrhythmia through the loss of potassium and magnesium in the urine. It can also potentiate the effects of the sympathetic nervous system through central or peripheral actions. Moreover, it can promote left ventricular remodeling and fibrosis, which enhance the potential for arrhythmia.
3. The sympathetic and renin-angiotensin systems may be arrhythmogenic because the associated vasoconstriction alters loading conditions, affecting wall stress and mechanical factors.

**FIGURE 53-5** The incidence of ventricular premature beats (VPBs) and nonsustained ventricular tachycardia (NSVT) in patients with left ventricular dysfunction increases as the left ventricle (and thus end-diastolic volume) becomes larger. (From Koilpillai C, Quinones MA, Greenberg B, et al. Relation of ventricular size and function to heart failure status and ventricular dysrhythmia in patients with severe left ventricular dysfunction. *Am J Cardiol* 1996;77:606.)

4. Idiopathic dilated cardiomyopathy may be associated with inhomogeneous distribution of sympathetic fibers, and regions with necrosis and dense scarring show myocardial denervation. This, in turn, may lead to denervation hypersensitivity, with increased sensitivity to circulating catecholamines. In contrast, other regions of the myocardium may show an increase in sympathetic innervation, possibly the result of injury-related nerve sprouting.<sup>56</sup>
5. Autoantibodies against  $\beta_1$ -adrenergic receptors can be detected in up to 50% of patients with idiopathic dilated cardiomyopathy. One subgroup of such autoantibodies exerts sympathomimetic activity, partly as a result of an increase in cyclic adenosine monophosphate production. These autoantibodies may be closely associated with serious ventricular arrhythmias; in one study, they were independent predictors of SCD.<sup>57</sup>

### Electrolyte Abnormalities

Patients with heart failure often have electrolyte abnormalities, particularly diuretic-induced hypokalemia and hypomagnesemia, which may be directly arrhythmogenic and associated with a higher incidence of SCD. In addition, stimulation of  $\beta_2$  receptors by circulating epinephrine can transiently lower the plasma potassium concentration by enhancing potassium entry into cells.

Hypokalemia and possibly hypomagnesemia may be directly arrhythmogenic, contributing to abnormal repolarization and potentiating the arrhythmogenic effects of catecholamines, digitalis, or antiarrhythmic agents.

### Ischemia

Silent or overt ischemia may lead to alteration in myocardial electrophysiological properties, including regional alterations in conduction and refractoriness and enhanced automaticity. Hypokalemia, increased catecholamine levels, digitalis, and antiarrhythmic agents may further enhance these alterations. The role of ischemia, caused by an acute coronary event, in provoking SCD was suggested by one autopsy study of 171 patients with heart failure.<sup>58</sup> In patients with significant coronary artery disease, an acute coronary thrombus was found in 54% who died suddenly and in 32% who died of myocardial failure, although an acute coronary event had not been clinically diagnosed before death. In contrast, an acute coronary thrombus was uncommon in those without coronary disease, present in 5% of those who died suddenly, and present in 10% of those who died from heart failure.

### Drugs

Some of the drugs used to treat heart failure can directly or indirectly precipitate arrhythmia.

**Phosphodiesterase Inhibitors.** Phosphodiesterase inhibitors are positive inotropic agents that are available only for intravenous use. These drugs increase intracellular calcium concentration which can increase levels of cyclic adenosine monophosphate and precipitate afterdepolarizations, resulting in triggered activity. They can also exacerbate ventricular arrhythmias by inducing ischemia. Several trials have shown that one such agent, milrinone, increased the frequency of all forms of spontaneous arrhythmia. In a long-term survival trial (Prospective Randomized Milrinone Survival Evaluation [PROMISE]), milrinone was associated with a 20% excess in mortality in comparison with placebo.<sup>59</sup>

**Sympathomimetic Drugs.** Studies with the sympathomimetic agents dobutamine, pirbuterol, salbutamol, and xamoterol have demonstrated an increased frequency of ventricular arrhythmias, increased mortality rates, or both. The use of sympathomimetic drugs is also associated with an increased incidence of hospitalization for arrhythmia, especially atrial fibrillation, ventricular tachycardia, and ventricular fibrillation.

**Digoxin.** There have been conflicting data about the effects of digoxin on the frequency and clinical significance of arrhythmias in heart failure. Relatively large and well-controlled studies revealed that digoxin did not significantly affect the frequency of ventricular arrhythmias in patients with heart failure.<sup>60</sup> In contrast, several, but not all, retrospective studies in patients with heart failure after an acute myocardial infarction revealed excessive mortality among patients who had complex ventricular arrhythmias that were treated with digitalis.<sup>61</sup> The Digitalis Investigation Group (DIG) evaluated the efficacy of digoxin in heart failure in approximately 6800 patients; digoxin was associated with an increase in cardiac mortality not related to congestive heart failure that included a trend toward increased mortality from arrhythmia.<sup>61</sup> This trend counterbalanced the fewer deaths from progressive heart failure among patients treated with digoxin; thus, there was no effect on overall patient survival.

## Mortality from Sudden Cardiac Death in Heart Failure

The rate of mortality from heart failure is high. In the Framingham Heart Study, the 4-year mortality rates were 62% among men and 42% among women.<sup>62</sup> The mortality rate is related to the severity of heart failure; in the Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS) trial, for example, patients with NYHA class IV heart failure had a 1-year mortality rate of 52% (Figure 53-6).<sup>63</sup>

Approximately 50% to 60% of deaths in heart failure result from unexpected SCD or SCD during episodes of clinical worsening of heart failure and are most often attributed to a ventricular tachyarrhythmia, often ventricular tachycardia that degenerates into ventricular fibrillation. Bradyarrhythmias are less common and are responsible for SCD in 5% to 33% of cases; it is more frequent in patients with more advanced heart failure (NYHA class III or IV).<sup>64</sup> However, distinguishing an arrhythmic from a nonarrhythmic cause of death is often difficult. One problem with attributing death to arrhythmia is the lack of relation between apparent SCD and the severity of heart failure. In spite of an increased frequency

**FIGURE 53-6** Survival rate varies markedly with New York Heart Association (NYHA) functional class, from as high as 81% at 4 years in asymptomatic patients (NYHA class I) to as low as 36% at 1 year in patients with NYHA class IV heart failure. (Data from SOLVD Investigators: Effect of enalapril on mortality and the development of heart failure in asymptomatic patients with reduced left ventricular ejection fraction. *N Engl J Med* 1992;327:685; Data from SOLVD Investigators: Effect of enalapril on survival in patients with reduced left ventricular ejection fractions and congestive heart failure. *N Engl J Med* 1991;325:293; and Data from CONSENSUS Trial Study Group: Effects of enalapril on mortality in severe congestive heart failure. *N Engl J Med* 1987;316:1429.)

of ventricular arrhythmias with worsening heart failure and left ventricular dysfunction, the percentage of SCD declines. For example, in one trial, the 1-year mortality rates were 29% of patients with class III heart failure and 53% of those with class IV heart failure; however, SCD was responsible for 61% and 21% of deaths, respectively.<sup>65</sup>

## Risk Assessment for Sudden Cardiac Death in Patients with Heart Failure

A number of invasive and noninvasive methods have been used to identify the patient with heart failure who is at risk for SCD. Unfortunately, no single factor alone is highly predictive of a fatal arrhythmia. Moreover, the accuracy of these methods may be related to the cause of the cardiomyopathy (ischemic versus nonischemic).

### Left Ventricular Ejection Fraction

Dilated cardiomyopathy is characterized by a variable reduction in LVEF, the assessment of which is probably the cardiac function test most frequently performed in patients with heart failure. There is no predictable relationship between symptoms or exercise tolerance and the LVEF. However, survival is generally reduced in patients with a lower LVEF.<sup>66</sup> For example, in the SOLVD trials and registry of 1172 patients with an echocardiogram obtained at baseline and at 1 year, LVEF lower than 35% was associated with an increase in all-cause mortality (risk ratio = 1.8) (Figure 53-7).<sup>66</sup> In addition, reduction in LVEF by one standard deviation was associated with increases in all-cause mortality (risk ratio = 1.62) and in cardiovascular hospitalization (risk ratio = 1.59). In the Marburg Cardiomyopathy Study, arrhythmia risk was prospectively evaluated in 343 patients with idiopathic dilated cardiomyopathy who were monitored for 52 months.<sup>67</sup> According to a multivariate analysis, LVEF was the only significant arrhythmia risk predictor in patients with sinus rhythm (risk ratio = 2.3 per 10% decrease in LVEF;  $P = .0001$ ). In patients with atrial fibrillation, LVEF and absence of  $\beta$ -blocker therapy were the only significant predictors of risk. Another study of 554 patients revealed with multivariate analysis that only NYHA classes III and IV and LVEF lower <sup>67a</sup> than 30% were associated with a higher sudden cardiac death risk.

**FIGURE 53-7** In the Studies of Left Ventricular Dysfunction (SOLVD) and the SOLVD registry of 1172 patients, a left ventricular ejection fraction (LVEF) lower than 35% was associated with increased rates of all-cause mortality (risk ratio = 1.8, in comparison with LVEF  $\approx$  35%;  $P = .012$ ). (From Quinones MA, Greenberg BH, Kopelen HA, et al. Echocardiographic predictors of clinical outcome in patients with left ventricular dysfunction enrolled in the SOLVD registry and trials: significance of left ventricular hypertrophy. *J Am Coll Cardiol* 2000;35:1237.)

### Ventricular Arrhythmia

PVCs and NSVT are observed in 80% to 90% of patients with heart failure caused by cardiomyopathy. There is still controversy about the prognostic significance of asymptomatic ventricular arrhythmias, particularly NSVT, in patients with heart failure. It is possible that the prognostic significance of PVCs and NSVT varies with the cause of the cardiomyopathy. In patients with left ventricular systolic dysfunction caused by ischemic cardiomyopathy, NSVT and PVCs are associated with an increased risk of SCD. The link between NSVT and SCD is most convincing after myocardial infarction in patients with left ventricular dysfunction; these patients have the highest incidence of SCD during the first year after an acute myocardial infarction.

In contrast, these arrhythmias do not appear predictive of SCD in nonischemic cardiomyopathy, although the data are conflicting. For example, the Marburg Cardiomyopathy Study revealed that the presence of NSVT on Holter monitoring was associated with a nonsignificant trend toward higher risk of arrhythmia (risk ratio = 1.7;  $P = .11$ ).<sup>67</sup> However, this study did show that the length of the NSVT runs, but not the rate, was predictive of outcome. The incidences of major arrhythmic events in patients without NSVT, in those with 5- to 9-beat NSVT, and in those with more than 10-beat NSVT were 2%, 5%, and 10% per year, respectively. In contrast, another study of 355 patients with a dilated cardiomyopathy demonstrated that NSVT evident on ambulatory monitoring was an independent predictor of mortality (risk ratio = 1.63;  $P = .02$ ).<sup>68</sup> Other findings on ambulatory monitoring that were predictive of risk included mean heart rate and heart rate range. A meta-analysis of 11 prognostic studies that involved more than 100 patients per study revealed that NSVT contributed significantly to the prediction of SCD in patients with left ventricular dysfunction, and this contribution was independent of LVEF (Figure 53-8).<sup>69</sup> It was concluded that the absence of NSVT indicated a low probability of SCD in patients with a left ventricular systolic dysfunction.

NSVT is predictive of SCD in patients with hypertrophic cardiomyopathy.<sup>70</sup> In one study of 531 patients with hypertrophic cardiomyopathy, 19.6% had NSVT.<sup>70</sup> The presence of NSVT was associated with an increased risk of sudden cardiac death, particularly in younger patients. The odds ratio of SCD for patients aged 30 years or younger with NSVT was 4.35, in comparison with 2.16 in those older than 30. There was no relation among duration, frequency, and rate of NSVT episodes and prognosis at any age.

### Use of Left Ventricular Ejection Fraction and Nonsustained Ventricular Tachycardia as Predictors of Survival

The use of only a univariate predictor such as LVEF or NSVT to estimate survival in the individual patient does not yield high predictive accuracy. It is possible that risk prediction can be improved when the finding of NSVT on ambulatory monitoring is combined with measures of left ventricular function (Figure 53-9). This issue was addressed in one study of 202 patients with idiopathic cardiomyopathy and no history of sustained ventricular tachycardia who underwent ambulatory monitoring, echocardiography, and signal-averaged electrocardiography and were monitored for 32 months.<sup>71</sup> After adjustments for baseline and follow-up medical therapy, only left ventricular end-diastolic diameter, LVEF, and the presence of NSVT were independent predictors of arrhythmic events. The combination of a left ventricular end-diastolic diameter of 70 mm or more and NSVT was associated with a 14.3-fold risk, and the combination of NSVT and LVEF of 30% or less increased the risk 14.6-fold; the sensitivity, specificity, and positive and negative predictive values were 59%, 84%, 40%, and 92%, respectively.

**FIGURE 53-8** Meta-analysis of 11 studies in which Holter monitoring was performed in patients with heart failure or a nonischemic cardiomyopathy. The presence of nonsustained ventricular tachycardia (NSVT) was found to be a significant predictor of mortality. This finding was independent of left ventricular ejection fraction. (From de Sousa, M.R., Morillo, C.A., Rabelo, F.T., et al. non-sustained ventricular tachycardia as a predictor of sudden cardiac death in patients with left ventricular dysfunction: a meta-analysis. *Eur J Heart Fail* 2008; 10: 1007.)

**FIGURE 53-9** The presence of both nonsustained ventricular tachycardia (NSVT) on an ambulatory monitor and a low left ventricular ejection fraction (LVEF) is associated with arrhythmic mortality after acute myocardial infarction. The rate of mortality is highest among patients with both NSVT and a low LVEF. (From the Multicenter Postinfarction Research Group: Risk stratification and survival after myocardial infarction. *N Engl J Med* 1983;309:331.)

### Electrophysiological Testing

A number of investigators have evaluated the role of electrophysiological study in selecting patients with heart failure and ventricular arrhythmias who are at high risk for SCD and who might benefit from prophylactic therapy.<sup>72</sup> In general, most have not found electrophysiological study to be useful for identifying patients at risk, especially those with nonischemic cardiomyopathy. However, the studies are flawed in various ways, including retrospective study design, unrandomized pharmacological therapy, and inconsistent definition of induced ventricular tachycardia; these flaws make meaningful conclusions impossible.

One study, Multicenter Unsustained Tachycardia Trial (MUSTT)—which involved 704 patients with coronary disease and with or without a remote myocardial infarction, asymptomatic NSVT, LVEF of 40% or lower—did demonstrate that the rate of inducibility was higher in patients with

a history of a myocardial infarction and in men and was progressively higher with an increasing number of diseased coronary arteries and number of fixed thallium defects; this rate was lower in patients who had undergone prior bypass surgery and had noncoronary cardiac disease.<sup>72</sup> Although these associations were statistically significant, the accuracy in discriminating patients with and without inducible sustained monomorphic ventricular tachycardia was only modest.

In conclusion, no data yet suggest that electrophysiological study can identify patients with nonischemic cardiomyopathy, heart failure, and ventricular arrhythmia who are at risk for SCD. The results of MUSTT suggest that electrophysiological study may have a role in risk stratification in patients with ischemic cardiomyopathy, particularly those with a prior myocardial infarction and left ventricular dysfunction.

Electrophysiological study may have a role in establishing arrhythmia as the cause of syncope or unexplained palpitations in patients with cardiomyopathy, in establishing ventricular tachycardia as the mechanism of a wide complex tachycardia, or in localizing the site of origin of ventricular tachycardia before radiofrequency ablation.

### Signal-Averaged Electrocardiography

It has been suggested that signal-averaged electrocardiography is a useful noninvasive method to select patients with heart failure, cardiomyopathy, and ventricular arrhythmias who are at high risk for SCD. In patients with ischemic heart disease, late potentials on the SAECG are thought to represent areas of delayed or slow subendocardial conduction. The SAECG is a predictor of SCD and sustained ventricular tachycardia in patients after myocardial infarction, independent of left ventricular function, ventricular ectopic activity, and transient hemodynamic abnormalities. The SAECG has also been evaluated in patients with nonischemic cardiomyopathy; its predictive role in this setting is less certain.<sup>73</sup>

A task force of the ACC concluded that the SAECG may be valuable in the clinical care of patients with dilated cardiomyopathy but suggested that further supportive evidence is required before signal-averaged electrocardiography can be recommended in these patients.

QT or JT dispersion, measured as interlead variability of QT or JT intervals on the surface ECG, is an indirect measure of myocardial repolarization inhomogeneity. It has been associated with an increased risk for an arrhythmic event and SCD in patients with a recent myocardial infarction and with the congenital long QT syndrome. Although QT dispersion is increased in patients with heart failure caused by idiopathic dilated cardiomyopathy who have had an arrhythmic event, its role in predicting the risk of SCD in these patients is uncertain because the results of studies are conflicting.<sup>74</sup>

#### Heart Rate Variability

Heart rate variability measurements provide a simple method for assessing the status of the parasympathetic and sympathetic nervous system and for predicting cardiovascular events, especially cardiac death and sustained ventricular tachyarrhythmias in patients with coronary heart disease. Although earlier data suggested that heart rate variability may be of predictive value in dilated cardiomyopathy and heart failure,<sup>75</sup> several more recent studies have not demonstrated this technique to be of value.<sup>76</sup> However, the Defibrillators in Non-Ischemic Cardiomyopathy Treatment Evaluation (DEFINITE) of 274 patients with a nonischemic cardiomyopathy did show that preserved heart rate variability identified patients at low risk who had an excellent prognosis (0% at 3 years, in comparison with 7% to 10% when heart rate variability was absent).<sup>77</sup>

#### Repolarization (T Wave) Alternans

Repolarization, or T wave, alternans is a variability in the timing or structure of repolarization that occurs in alternate beats on the surface ECG; T wave alternans is associated with repolarization heterogeneity. However, T wave alternans of sufficient magnitude to be detected visually is uncommon. Computerized filtering and analysis allow T wave alternans on the level of microvolts to be detected. Such detection is both sensitive and specific for predicting ventricular arrhythmias in various groups of patients.<sup>78</sup>

The role of T wave alternans for predicting the risk of SCD in patients with heart failure is uncertain. Several studies have revealed that it is predictive of arrhythmic risk in patients with heart failure caused by ischemic or nonischemic cardiomyopathy. One study showed that at 2 years, the hazard ratio for SCD or a nonfatal sustained ventricular arrhythmia was 6.5 in patients with an abnormal T wave alternans, in comparison with patients with normal T wave alternans.<sup>79</sup> It has been reported that T wave alternans is useful for identifying patients with a cardiomyopathy who are at high risk for a life-threatening ventricular tachyarrhythmia and would benefit from prophylaxis with an implantable cardioverter-defibrillator (ICD).<sup>80</sup> It has also been reported that its prognostic utility is independent of QRS duration. It may be better than QRS duration in patients with ischemic cardiomyopathy. For example, in one study modeled on the Multicenter Automatic Defibrillator Implantation Trial (MADIT) II, 177 patients were monitored for 20 months; the hazard ratio for 2-year mortality was 4.8 for patients with an abnormal T wave alternans and 1.5 for those with a QRS width of more than 120 msec.<sup>81</sup> The actuarial mortality rate was 3.8% for a normal T wave alternans finding and 12% for a narrow QRS complex.

In contrast, more recent data from the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) trial revealed that among 490 patients monitored for a median of 30 months, there was no difference in rates of events (SCD, ventricular fibrillation or tachycardia, or appropriate ICD discharge) between those with or without T wave alternans.<sup>82</sup> The results of this study suggested that T wave alternans is not useful for

selecting patients with heart failure and left ventricular dysfunction as candidates for an ICD.

## Prophylactic Pharmacological Therapy to Prevent Sudden Cardiac Death

The role of prophylactic pharmacological therapy to prevent SCD and prolong life in patients at high risk who have cardiomyopathy, heart failure, and asymptomatic ventricular arrhythmia is uncertain and varies with the type of agent.

#### Effect of Heart Failure Therapies on Arrhythmia

Several drugs that are used to treat heart failure may affect the incidence of arrhythmias and reduce the incidence of SCD.

**$\beta$ -Blockers.**  $\beta$ -Blockers reduce the incidence of SCD in the immediate postinfarction period, and this benefit is most marked in patients with heart failure. A number of studies have shown that  $\beta$ -blockers significantly improve survival in patient with heart failure. This beneficial effect results in part from a reduction in ventricular arrhythmias and SCD. In the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF) of 3991 patients with class II to IV heart failure and LVEF of 40% or lower, there were significantly fewer SCD events among the patients treated with metoprolol (3.9%) than among those treated with placebo (6.6%); however, with the increasing severity of heart failure, the proportion of SCD decreased whereas deaths due to heart failure increased.<sup>83</sup> In the Cardiac Insufficiency Bisoprolol Study (CIBIS)-II, the survival benefit with bisoprolol was primarily reflected by a reduction in SCD (3.6% vs. 6.3% for placebo), with only a nonsignificant trend toward fewer deaths from heart failure.<sup>84</sup> In the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) trial, patients receiving carvedilol exhibited a significant reduction in the incidence of ventricular tachycardia and SCD.<sup>85</sup>

The precise mechanism of  $\beta$ -blocker protection is unclear, but the antisympathetic effect is almost certainly important:

1.  $\beta$ -Blockers block the effect of circulating catecholamines, which are elevated in patients with cardiomyopathy and have direct detrimental effects on the ventricular myocardium.
2. Long-term exposure to catecholamines causes a reduction in the density of and responsiveness to  $\beta$ -adrenergic agonists as a result of desensitization of the  $\beta$ -receptor.  $\beta$ -Blockers result in the upregulation of  $\beta$ -receptors.
3. The vasoconstriction induced by norepinephrine increases afterload, a change that promotes the rate of progression of cardiac dysfunction.
4.  $\beta$ -Blockers have a beneficial effect on left ventricular remodeling and can decrease left ventricular end-systolic and end-diastolic volume.
5. Diastolic dysfunction is one of the adverse prognostic findings in patients with heart failure.  $\beta$ -Blockers may improve diastolic function in association with a reduction in left ventricular end-diastolic pressure.
6. During the development of heart failure, adrenergic activation contributes to increased myocardial expression of inflammatory cytokines;  $\beta$ -blockade may reduce myocardial gene expression and protein production of some of these cytokines, thereby attenuating left ventricular dilation and systolic dysfunction.

**Angiotensin-Converting Enzyme inhibitors and Angiotensin Receptor Blockers.** The effect of ACE inhibitors and ARBs on ventricular arrhythmias in patients with heart failure remains controversial. Although these agents do reduce mortality, some trials, such as CONSENSUS, SOLVD, and Survival And Ventricular Enlargement (SAVE), revealed that the survival benefit arose primarily from slowed progression of heart failure, with little or no reduction in SCD.<sup>86</sup> In

contrast, other trials such as V-HeFT II, Trandolapril Cardiac Evaluation (TRACE)<sup>86a</sup>, and Acute Infarction Ramipril Efficacy (AIRE), showed a significant reduction in SCD.<sup>87</sup>

A meta-analysis of trials involving 15,104 patients within 14 days of an acute myocardial infarction revealed that ACE inhibitor therapy modestly but significantly reduced the risk of SCD (odds ratio = 0.80; absolute benefit  $\approx$  1.4%).<sup>88</sup>

The ARBs appear to be as beneficial as ACE inhibitors, or perhaps slightly less so, in patients with heart failure, although data are limited.

**Spironolactone.** Spironolactone, an aldosterone antagonist, has been reported to reduce the frequency of PVCs and NSVT.<sup>89</sup> The beneficial effect of this drug was observed in the Randomized Aldactone Evaluation Study (RALES) trial of patients with advanced heart failure; spironolactone significantly reduced overall mortality (35% vs. 46% for placebo), including a 29% reduction in sudden cardiac death ( $P = .02$ ).<sup>90</sup> The benefit of spironolactone was evident at 3 months and persisted for the 2-year duration of the study. A reduction in SCD was also reported in the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) (relative risk = 0.79;  $P = .03$ ).<sup>91</sup> The benefit of these agents may arise from a reduction in aldosterone effect on the heart or the maintenance of a higher serum potassium concentration.

**Statins.** Although the beneficial effect of statins in patients with cardiomyopathy and heart failure is uncertain, data suggest that they may improve survival. The effect of these agents on SCD in patients with a nonischemic cardiomyopathy was suggested by the DEFINITE trial.<sup>92</sup> Patients treated with a statin had significantly lower rates of arrhythmic sudden cardiac death (0.9%) and total mortality (4.5%) than did those not treated with a statin (5.2% and 18.4%, respectively). Similar data were reported from patients enrolled in the MADIT II study.<sup>93</sup> The cumulative rates of ICD discharge for ventricular tachycardia and ventricular fibrillation or cardiac death were significantly reduced in patients taking statins for 90% of the time or more, in comparison with those taking statins less frequently. The hazard ratios for statin use versus no statin use were 0.65 for ventricular tachycardia and ventricular fibrillation and 0.72 for cardiac death.

#### Pharmacological Therapy with Antiarrhythmic Agents

Studies of antiarrhythmic drugs have shown that most of these agents, when given prophylactically, are of no benefit for preventing SCD in patients with cardiomyopathy and heart failure. For example, in the ALIVE trial, in which azimilide was evaluated in 3717 patients with an ischemic cardiomyopathy, most of whom had symptomatic heart failure,<sup>94</sup> azimilide had no effect on mortality in comparison with placebo. Prophylactic dofetilide in the DIAMOND-CHF trial of 1518 patients with symptomatic heart failure had no effect on mortality (41% vs. 42% with placebo).<sup>37</sup>

In addition to the lack of efficacy, there are other problems with the use of these agents in patients with heart failure, which limits their prophylactic use:

1. Antiarrhythmic drugs are less efficacious in patients with depressed LVEF.<sup>95</sup> Furthermore, long-term studies of survival in patients treated with antiarrhythmic drugs identified as being effective for arrhythmia suppression have revealed that heart failure and depressed LVEF are major predictors of adverse outcome.<sup>95</sup>
2. The pharmacokinetic activity of antiarrhythmic drugs is significantly and unpredictably altered in the presence of heart failure. The volume of distribution is decreased, which affects the dose given and blood level achieved; hepatic metabolism of these agents and renal excretion of drug or metabolites are impaired; and the time to achieve a steady state is prolonged, which can lead to premature escalation of drug dose and thereby possibly result in excessive drug levels and toxicity.

3. Most antiarrhythmic drugs have some negative inotropic effects and, in patients with reduced left ventricular function, can precipitate heart failure.<sup>96</sup>

4. Aggravation of arrhythmia or proarrhythmia is a complication of each of the antiarrhythmic drugs.<sup>34</sup> Although this serious adverse effect is unpredictable and can occur in any patient, it is far more common in patients with cardiomyopathy and clinical heart failure.

**Pharmacological Therapy with Amiodarone.** Amiodarone can reduce the incidence of ventricular arrhythmias, but data from two of the largest trials—Grupo de Estudio de la Sobrevida en la Insuficiencia Cardíaca en Argentina (GESICA) and CHF-STAT—have conflicted with regard to its effect on patient survival.<sup>97,98</sup>

**GESICA.** The GESICA trial enrolled 516 patients with advanced heart failure (NYHA classes II to IV and LVEF < 35%), which resulted primarily from nonischemic cardiomyopathy, and NSVT. The patients, who received 24-hour Holter monitoring, were randomly assigned to receive either placebo or amiodarone.<sup>97</sup> After a 2-year follow-up period, a 28% reduction in total mortality was noted with amiodarone, with favorable trends noted for deaths classified as caused by heart failure or arrhythmia. The beneficial effect of amiodarone was observed primarily in patients with a baseline heart rate of 90 or more beats per minute. Among these patients, the mortality rate at 2 years was lower with amiodarone treatment (38.4%) than with placebo (62.4%); there were also reductions in SCD (19.7% vs. 10.7%, respectively) and in death from progressive heart failure (25.8% vs. 18.0%, respectively). The higher above beats per minute the baseline heart rate was, the greater was the reduction in mortality with amiodarone treatment. In contrast, when the heart rate was 90 beats per minute or less, there was no difference in mortality between amiodarone (44.8%) and placebo (44.7%).

**CHF-STAT.** The randomized CHF-STAT trial involved 674 patients with symptomatic heart failure (class II to IV), caused primarily by ischemic cardiomyopathy, in whom cardiac enlargement was demonstrated on echocardiogram or chest radiograph, LVEF was lower than 40%, and 10 or more PVCs per hour had occurred during ambulatory monitoring.<sup>98</sup> Even though there was more than an 80% reduction in PVCs or elimination of NSVT, amiodarone did not improve overall survival at 2 years (69.4% vs. 70.8% for placebo). There was also no significant difference in SCD mortality (15% vs. 19% with placebo). There was, however, a significant 46% reduction in events (cardiac events or hospitalization) in the subgroup of patients with nonischemic cardiomyopathy. Amiodarone did not affect noncardiac death, including the subgroup with underlying chronic obstructive lung disease.

**SCD-HeFT.** The largest trial to evaluate the role of amiodarone was SCD-HeFT, in which 2521 patients with both ischemic and nonischemic cardiomyopathy were randomly assigned to receive an ICD (single-lead shock only), amiodarone, or placebo.<sup>99</sup> Entry criteria included an LVEF of 35% or lower and NYHA class II or III heart failure. After a mean follow-up period of 45.5 months, mortality was not reduced by amiodarone therapy (28%) in comparison with placebo (29%; hazard ratio = 1.06).

**Meta-analysis.** In a meta-analysis of 13 randomized amiodarone trials, which included 6553 patients, there were 5 trials involving 1452 patients with heart failure. In these trials, amiodarone reduced total mortality and arrhythmia or SCD in patients with heart failure by 17% and 23%, respectively (Figure 53-10).<sup>100</sup> LVEF, NYHA functional class, or the presence of asymptomatic arrhythmias on Holter monitoring did not influence the effectiveness of amiodarone.

Although the role of amiodarone in the prevention of SCD or ventricular tachycardia is not certain, because researchers have reported conflicting results, the drug does significantly reduce the rate of the ventricular tachycardia, often making it hemodynamically stable and improving the potential for survival.

**FIGURE 53-10** Meta-analysis of randomized trials involving 6553 patients with congestive heart failure or a recent myocardial infarction. A meta-analysis of randomized amiodarone trials involving 6553 patients indicated there were 1452 patients with heart failure treated with this drug. Amiodarone reduced total mortality and arrhythmia or SCD in this group of patients with heart failure by 17% and 23%, respectively. There was no difference in the treatment effect between postinfarction and congestive heart failure trials. (From Amiodarone Trials Meta-analysis Investigators: Effect of prophylactic amiodarone on mortality after acute MI and in congestive heart failure: meta-analysis of individual data from 6500 patients in randomized trials. *Lancet* 1997;350:1417.)

**Pharmacological Therapy with Dronedronarone.** Dronedronarone is an antiarrhythmic drug that has electrophysiological properties similar to those of amiodarone. However, it does not contain iodine and does not cause iodine-related side effects. In one study, 627 patients with heart failure and severe left ventricular dysfunction were randomly assigned to receive dronedronarone or placebo.<sup>39</sup> The study was stopped after a median follow-up period of 2 months because mortality was increased among the dronedronarone recipients (8.1% vs. 3.8% for placebo; hazard ratio = 2.13;  $P = .03$ ). The increase in mortality resulted primarily from worsening of heart failure.

### Prophylactic Use of an Implantable Cardioverter-Defibrillator (Primary Prevention) (see Chapter 47)

The role of the ICD as prophylactic therapy in patients with heart failure and cardiomyopathy, who are at high risk for SCD, has been evaluated in a number of studies. These trials have demonstrated that the ICD, in comparison with antiarrhythmic drug therapy, significantly reduces mortality in patients at high risk with ischemic and nonischemic cardiomyopathy.

#### Trials in Ischemic Cardiomyopathy

ICDs have been evaluated in several studies of ischemic cardiomyopathy:

1. MADIT I enrolled 196 asymptomatic patients with a prior myocardial infarction, an LVEF lower than 35%, evidence of NSVT on monitoring, a positive SAECG, and inducible sustained monomorphic ventricular tachycardia that was unresponsive to intravenous procainamide. Patients were randomly assigned to receive an ICD or conventional therapy.<sup>101</sup> During an average follow-up period of 27 months, there were 15 deaths among the patients with an ICD (11 from cardiac causes) and 39 deaths among those receiving the conventional therapy (27 from cardiac causes; for overall mortality, hazard ratio = 0.46;  $P = .009$ ).
2. In MADIT II, 1232 patients with myocardial infarction and an LVEF of 30% or lower were randomly assigned

to receive an ICD or conventional therapy; the presence of NSVT was not an entry criterion, and electrophysiological study was not performed.<sup>102</sup> During an average follow-up period of 20 months, the mortality rates were significantly lower among patients receiving an ICD (14.2%) than among those receiving the conventional therapy (19.8%). The hazard ratio for the risk of death from any cause in the ICD recipients, in comparison with the conventional therapy recipients, was 0.69 ( $P = .016$ ). The effect of the ICD on survival was similar in subgroup analyses stratified according to age, sex, LVEF, NYHA class, and the QRS interval. However, there was a higher rate of hospitalization for heart failure among the ICD recipients (20%) than among recipients of conventional therapy (15%).

3. MUSTT enrolled 704 patients with chronic coronary heart disease, an LVEF of 40% or lower, and NSVT.<sup>103</sup> Although the study was not designed to evaluate the role of an ICD in these patients, it did reveal that the risk of cardiac arrest or death from arrhythmia among the patients who received treatment with an ICD was significantly lower than that among the patients discharged without an ICD (relative risk = 0.24;  $P < .001$ ).
4. In contrast to MUSTT and MADIT, which enrolled patients several years after myocardial infarction, the Defibrillator in Acute Myocardial Infarction Trial (DIN-AMIT) was an evaluation of the role of a prophylactic ICD in 574 patients who had suffered a myocardial infarction within the preceding 6 to 40 days (mean, 18 days), had an LVEF of 35% or lower, and had either reduced heart rate variability or elevated resting heart rate ( $\geq 80$  beats/min).<sup>104</sup> The risk of SCD after myocardial infarction is highest during this time period. After a 30-month follow-up period, no difference in all-cause mortality was found between the ICD recipients (18.7%) and controls (17.0%;  $P = .66$ ). However, deaths from arrhythmia were more frequent among controls (hazard ratio = 0.42;  $P = .009$ ), whereas deaths from nonarrhythmic causes were more frequent among the ICD recipients (hazard ratio = 1.75;  $P = .02$ ).

On the basis of the results of these trials, an ICD is the recommended therapy for primary prevention of SCD in patients who had a prior myocardial infarction at least 40 days previously, have an LVEF of 30% or lower, have NYHA functional class II or III heart failure, are receiving chronic optimal medical therapy, and have reasonable expectation of survival with a good functional status for more than 1 year.

#### Trials in Nonischemic Cardiomyopathy

Two small studies of patients with a nonischemic cardiomyopathy—the Cardiomyopathy Trial (CAT) and Amiodarone Versus Implantable Defibrillator in Patients with Nonischemic Cardiomyopathy and Asymptomatic Nonsustained Ventricular Tachycardia (AMIOVIRT)—did not reveal that a prophylactic ICD improved survival in comparison with conventional therapy or amiodarone. However, these studies were limited by small numbers of patients.

1. The DEFINITE trial enrolled 458 patients with a nonischemic dilated cardiomyopathy, an LVEF of 35% or lower, and PVCs or NSVT; these patients were randomly assigned to receive an ICD or standard medical therapy.<sup>105</sup> At 2 years, there was a strong trend toward a reduction in the primary endpoint of all-cause mortality with an ICD (7.9%), in comparison with medical therapy alone (14.1%). Significantly fewer sudden cardiac deaths occurred among the ICD recipients, although the numbers were very small (3 vs. 14).
2. The largest prophylactic ICD trial was SCD-HeFT, in which 2521 patients with an LVEF of 35% or lower (median, 25%) and NYHA class II or III heart failure

were randomly assigned to receive an ICD, amiodarone, or placebo; 48% had a nonischemic cardiomyopathy.<sup>106</sup> At a median 46-month follow-up assessment, ICD therapy significantly reduced overall mortality in comparison with placebo (22% vs. 29%). ICD therapy was associated with a 23% decreased risk of death (hazard ratio = 0.77;  $P = .007$ ) and an absolute decrease in mortality of 7.2% points (Figure 53-11). The mortality rate among the amiodarone recipients (28%) was nearly the same as that among placebo recipients (29%; hazard ratio = 1.06;  $P = .53$ ). In prespecified subgroup analysis, the benefit of ICD therapy was demonstrated among patients with either an ischemic or nonischemic cardiomyopathy (Figure 53-12). In a post hoc analysis, the benefit of an ICD was observed in patients with an LVEF of 30% or lower, but not in those with an LVEF higher than 30%.

3. In a meta-analysis of 1854 patients with nonischemic cardiomyopathy, the use of an ICD was examined for primary prevention.<sup>107</sup> There was a significant reduction in all-cause mortality with an ICD in comparison with medical therapy (relative risk = 0.69). According to the averaged mortality rate in the control group (7% per year), the absolute risk reduction was 2% per year.

On the basis of the results of these trials, the ICD is the recommended therapy for primary prevention of SCD in patients with nonischemic dilated cardiomyopathy who have an LVEF of 30% or lower, have NYHA class II or III heart failure, and have a reasonable expectation of survival with a good functional status for more than 1 year. The Center for Medicare Services in the United States approved coverage for ICD use for primary prevention with an additional criterion: only if the nonischemic dilated cardiomyopathy has been present for more than 9 months.

#### Identifying the Patient at High Risk Who Is Most Likely to Benefit from a Prophylactic Implantable Cardioverter-Defibrillator

The ICD is costly, and its implantation carries some risk. A number of researchers have evaluated the cost effectiveness of this device. For example, an analysis of data from SCD-HeFT revealed that the device was economically attractive in patients with an LVEF of 35% or lower and NYHA class

II heart failure, as long as the benefits observed persisted for 8 years.<sup>108</sup> Similar data were observed in MADIT II: During the 3.5-year follow-up period, the average survival gain with the ICD was 2 months, and the incremental cost-effectiveness ratio was \$235,000 per year of life saved; however, this value was projected to be substantially lower for patients who survived longer.<sup>109</sup> Thus, the magnitude of benefit depends on the baseline risk for SCD.

By using only LVEF, researchers have identified a very large number of patients who are candidates for the ICD. However, it has become obvious that the majority of such patients do not experience a ventricular tachyarrhythmia and hence do not benefit from this device. Therefore, an important challenge is the identification of the individual patient who has not yet suffered a sustained ventricular arrhythmia but is at high risk for such an event and hence is likely to derive benefit from an ICD. Unfortunately, most of the methods for risk stratification, discussed previously, have limited usefulness.<sup>67</sup> Although T wave alternans may be of some importance, its utility in identifying patients at low and high risk is still uncertain. It has not been evaluated in both patients with ICD and those without ICD, which is particularly important because assessment of the risk for a life-threatening ventricular arrhythmia is not always correlated with ICD efficacy.

Thus, the number of patients receiving an ICD is far greater than the number who experience an appropriate ICD discharge and actually benefit from this device (i.e., the number to treat in order to save one life is very high). Because the absolute risk reduction is 2% per year, 100 devices would need to be implanted to save 2 lives per year. Reliance on LVEF alone is therefore inadequate for identifying the patient who will benefit from an ICD, because this parameter is not specific for predicting mode of death and because the risk of SCD in patients with LVEF of 30% or lower is not uniform. Moreover, some patients with LVEF higher than 30% are at increased risk for SCD.

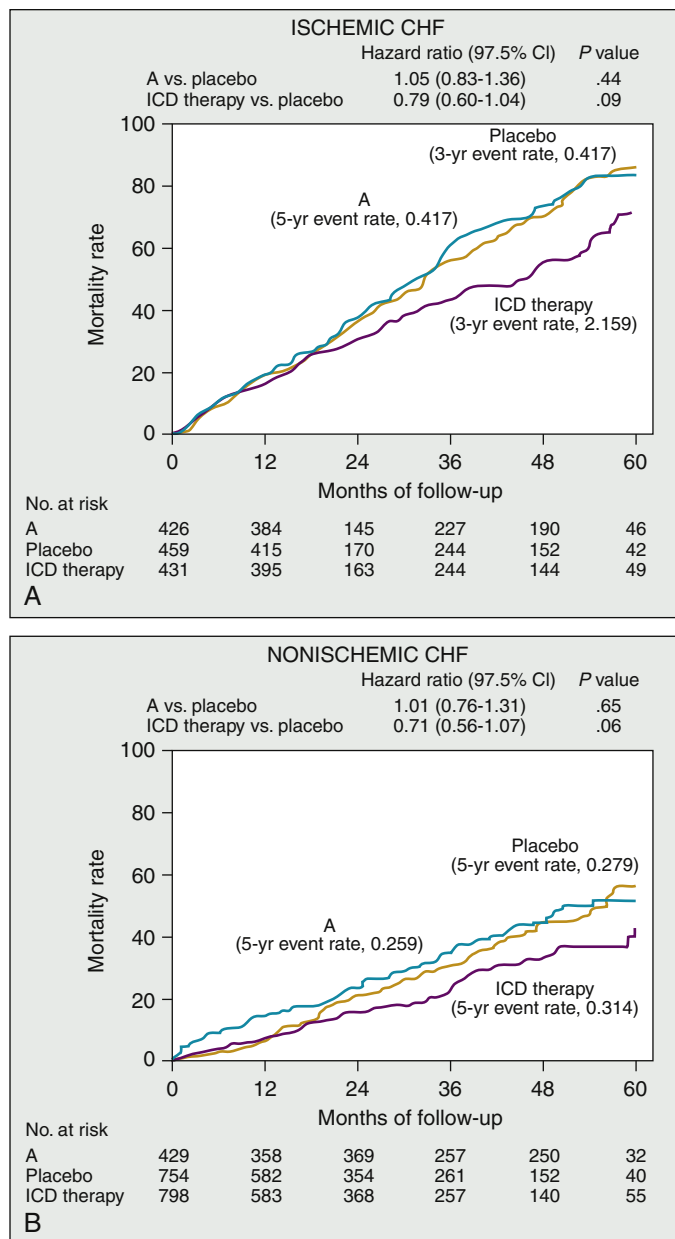

Several researchers have evaluated a number of clinical variables in order to identify patients at low risk who are not likely to benefit from the ICD:

1. In the MUSTT study, researchers evaluated 25 variables in 674 patients who did not have inducible arrhythmia or had inducible arrhythmia that was not treated.<sup>110</sup> In a multivariate analysis, variables found to have the

**FIGURE 53-11** In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) of 2521 patients with a left ventricular ejection fraction (LVEF) of 35% or lower and clinical heart failure, therapy with an implantable cardioverter-defibrillator (ICD) significantly reduced total mortality, in comparison with placebo or amiodarone therapy ( $P = .007$ ). There was no difference in outcome between placebo and amiodarone therapy. (From Bardy GH, Lee KL, Mark DB, et al. Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure. *NEJM* 2005; 352:225-237 Copyright © 2008, Massachusetts Medical Society. All rights reserved.)

**FIGURE 53-12** In the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) of 2521 patients with a left ventricular ejection fraction (LVEF) of 35% or lower and clinical heart failure, subset analysis revealed that an implantable cardioverter-defibrillator (ICD) reduced mortality among patients with ischemic or nonischemic cardiomyopathy. CHF, congestive heart failure; CI, confidence interval; ICD, implantable cardioverter-defibrillator. (From Bardy GH, Lee KL, Mark DB, et al. Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure. *NEJM* 2005; 352:225-237. Copyright © 2008, Massachusetts Medical Society. All rights reserved.)

greatest prognostic impact included NYHA functional class, history of clinical heart failure, NSVT not related to coronary artery bypass surgery, LVEF, age, left ventricular conduction abnormalities, inducible sustained ventricular tachycardia, inpatient status, and atrial fibrillation. According to these data, patients with an LVEF of 30% or lower but no other risk factors had a 2-year risk of death from arrhythmia of less than 5%.

2. The Triggers of Ventricular Arrhythmias (TOVA) study of 1140 patients revealed that in addition to LVEF, clinical NYHA class III heart failure was an independent risk factor for the occurrence of a ventricular arrhythmia that prompted an ICD discharge.<sup>111</sup>

3. In MADIT II, which enrolled 1232 patients, investigators used a clinical risk score that included NYHA functional class higher than II, age of more than 70 years, blood urea nitrogen (BUN) level higher than 26 mg/dL, QRS duration longer than 0.12 seconds, and atrial fibrillation.<sup>112</sup> Patients at very high risk (5% of the total population as defined by BUN level  $\geq 50$  mg/dL and/or serum creatinine level  $\geq 2.5$  mg/dL) were excluded from this evaluation. Of the patients with a risk score of 0 (one third of the patients), those who had an ICD and those without an ICD had similar 2-year rates of mortality (9% and 8%). Among patients with a risk score 1 or 2, the 2-year mortality rate was significantly lower in those with an ICD (9% and 15%, respectively) than in those without an ICD (22% and 32%, respectively;  $P = .002$  and  $P < .001$ ). In contrast, the mortality rates among patients with a risk score of 3 or higher (15% of patients) were the same with or without an ICD (29% vs. 32%). Likewise, the mortality rates in the patients at very high risk were the same with and without an ICD (51% vs. 43%).

Therefore, in patients with an ischemic cardiomyopathy, a number of clinical variables can be used to identify patients with an LVEF of 30% or lower who have a low mortality rate and for whom the ICD is of no benefit. These clinical parameters are not static, and continued reassessment of the patient is necessary. As yet, no data are available for patients with nonischemic cardiomyopathy.

### Therapy for Patients with Heart Failure Who Have Experienced a Sustained Ventricular Tachyarrhythmia (Secondary Prevention) (see Chapter 47)

Patients with heart failure who survive an episode of SCD or who experience sustained ventricular tachycardia are at high risk of future arrhythmic events and SCD. In these patients, an ICD is usually implanted for secondary prevention of SCD. Some patients may receive treatment with other therapies, such as antiarrhythmic drugs, radiofrequency ablation, surgery, and cardiac transplantation. However, these other treatments are not as effective as an ICD in improving survival. For this reason, they are used either as an adjunct to an ICD or as an alternative in patients who are not candidates for ICD therapy.

#### Implantable Cardioverter-Defibrillator

The ICD reduces overall mortality and mortality from SCD in comparison with amiodarone when used for secondary prevention in patients with cardiomyopathy (LVEF  $\leq 35\%$ ) and heart failure who have experienced a ventricular tachyarrhythmia or SCD.<sup>113</sup> However, its effect on overall mortality in patients with severe heart failure and an LVEF lower than 20% is uncertain because the mode of death in many of these patients is progressive heart failure or asystole, which cannot be prevented by the ICD.

The role of the ICD in secondary prevention of SCD was evaluated in three randomized trials. On the basis of the results of these trials, the ACC/AHA/ESC guidelines recommended the ICD for secondary prevention of SCD in patients with ischemic or nonischemic cardiomyopathy who are receiving optimal medical therapy and who have a reasonable expectation of survival with a good functional status for more than 1 year.

#### AVID Trial

The Antiarrhythmics Versus Implantable Defibrillators (AVID) trial enrolled 1016 patients with a history of ventricular tachycardia, ventricular fibrillation, or syncope judged to be secondary to arrhythmia. This trial was stopped because survival rates were higher in the patients receiving the ICD

than in those receiving d,l sotalol or amiodarone (89% vs. 82% at 1 year, 82% vs. 75% at 2 years, and 75% vs. 65% at 3 years).<sup>114</sup> However, the unadjusted improvement in mean survival was only 2.6 months (31 vs. 29 months with amiodarone), a difference that was reduced by 15% when adjustments were made for heart failure and the LVEF. The major effect of the ICD was, not expectedly, to prevent arrhythmic death (4.7% vs. 10.8% with antiarrhythmic drugs); rates of nonarrhythmic cardiac death were equivalent, and patients treated with drugs had an insignificantly greater incidence of noncardiac death, primarily from renal and pulmonary causes. Survival, when analyzed by LVEF, was no different with an ICD or with antiarrhythmic drugs among patients with an LVEF of 35% or higher; in contrast, among patients with an LVEF between 20% and 34%, survival rate was significantly better with the ICD. In patients with an LVEF lower than 20%, survival tended to be better with the ICD than with drugs, but the difference was not statistically significant (Figure 53-13). Unfortunately, there are no data about the role of the ICD in the presence or absence of clinical heart failure.

### CIDS

The randomized Canadian Implantable Defibrillator Study (CIDS) enrolled 659 patients with ventricular tachycardia, ventricular fibrillation, or syncope deemed to be secondary to arrhythmia. After a 5-year follow-up period, the total rate of mortality with the ICD was not significantly reduced in comparison with amiodarone (8.3% vs. 10.2% per year;  $P = .142$ ), and there was a nonsignificant reduction in arrhythmic death (3% vs. 4.5% per year,  $P = .094$ ).<sup>115</sup> There was no difference in outcome according to the presenting arrhythmia. A multivariate risk model identified age of 70 or older, LVEF of 35% or lower, and NYHA class III or IV as independent predictors of risk; on the basis of these parameters, quartiles of risk were constructed. Among patients in the highest risk quartile, who had two or more risk factors, the death rate was reduced significantly with the ICD in comparison with amiodarone (14% vs. 30%); no benefit was observed among patients in the other three quartiles.

### CASH Trial

In the Cardiac Arrest Study Hamburg (CASH) trial, 349 survivors of cardiac arrest due to a documented ventricular tachyarrhythmia were randomly assigned to receive an ICD, metoprolol, propafenone, or amiodarone; propafenone was subsequently dropped from the trial because of a higher mortality rate with this drug, according to an interim 2-year analysis.<sup>116</sup> After a mean follow-up period of 57 months, there was an insignificant 23% reduction in total mortality with the ICD in comparison with amiodarone (36.4%) or metoprolol (44.9%;  $P = .08$ ); the benefit of the ICD was more evident during the first 5 years after the index event. The secondary endpoint of SCD was also reduced by the ICD (13%) in comparison with drug therapy (33%;  $P = .005$ ). However, when amiodarone and metoprolol were considered separately, there was no difference among the three groups.

### Meta-analysis of Secondary Prevention Trials

A meta-analysis of the three major ICD trials (AVID, CIDS, and CASH) revealed a significant 28% reduction in mortality with an ICD in comparison with amiodarone, which was attributable entirely to a 50% reduction in SCD.<sup>113</sup> Over a 6-year period, survival was extended by 4.4 months with an ICD. The mortality benefit was observed only in patients with an LVEF of 35% or lower<sup>113</sup> (Figure 53-14).

### Long-Term Outcome

Despite the use of the ICD, the mortality rate among patients with heart failure remains high as a result of death that cannot be prevented by the ICD, including progressive heart failure,

**FIGURE 53-13** Subset analysis of 1013 survivors of sudden cardiac death or hemodynamically significant ventricular tachycardia who were enrolled in the Antiarrhythmics Versus Implantable Defibrillators (AVID) trial. The hazard ratios for death from any cause with the implantable cardioverter defibrillator, in comparison with amiodarone, were not significantly different for any of the prespecified subgroups. (From the Antiarrhythmics Versus Implantable Defibrillators [AVID] Investigators: A comparison of antiarrhythmic-drug therapy with implantable defibrillators in patients resuscitated from near-fatal ventricular arrhythmias. *N Engl J Med* 1997;337:1576.)

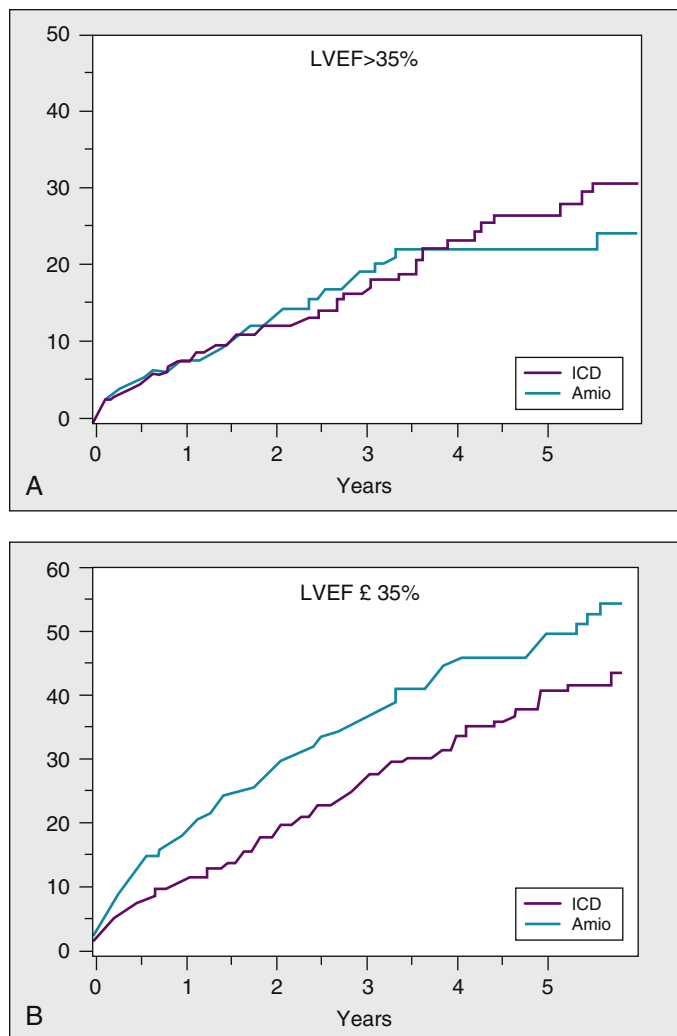

refractory ventricular arrhythmias that may occur with terminal heart failure, asystole, or pulseless electrical activity. An important predictor of outcome is left ventricular function. This was illustrated in an analysis of 36 clinical and treatment variables in 3559 patients with a sustained ventricular tachyarrhythmia who were enrolled in the AVID registry.<sup>116a</sup> Actuarial rates of survival at 2 and 3 years were 79% and 72%, respectively. The strongest risk factors for prognosis were age and the severity of underlying heart disease, as reflected by the extent of left ventricular dysfunction and the presence of heart failure. The hemodynamic effect of the arrhythmia was not a predictor of outcome.

In contrast to these findings in SCD, there is generally a good outcome in patients with idiopathic dilated cardiomyopathy and clinical sustained monomorphic ventricular tachycardia in whom inducibility of ventricular tachycardia is suppressed by antiarrhythmic drugs.

### Antiarrhythmic Drug Therapy

In patients with heart failure who have experienced a ventricular tachyarrhythmia, the use of antiarrhythmic drugs to prevent recurrent ventricular arrhythmia is currently limited because no studies have shown these agents to be effective. Thus, the ICD has become the preferred therapy. However, antiarrhythmic therapy has an important role in several situations:

1. The Center for Medicare Services requires that a patient be expected to survive at least 1 year in order to qualify for ICD therapy. Therefore, antiarrhythmic drug therapy (usually amiodarone) is prescribed to patients who are not candidates for an ICD because of age, the presence

**FIGURE 53-14** Meta-analysis of three implantable cardioverter-defibrillator (ICD) trials: Antiarrhythmics Versus Implantable Defibrillators (AVID), Canadian Implantable Defibrillator Study (CIDS), and Cardiac Arrest Study Hamburg (CASH). For patients with left ventricular ejection fraction (LVEF) of approximately 35% (**B**), the cumulative risk of death was found to be 28% lower with the implantable cardioverter-defibrillator (ICD) than with amiodarone; this was attributable entirely to a reduction in sudden cardiac death. In contrast, among patients with LVEF higher than 35% (**A**), there was little difference in survival between patients who had ICD and those who took amiodarone. (From Connolly SJ, Hallstrom AP, Cappato R, et al. Meta-analysis of the implantable cardioverter defibrillator secondary prevention trials. AVID, CASH and CIDS studies. *Antiarrhythmics vs Implantable Defibrillator Study. Cardiac Arrest Study Hamburg. Canadian Implantable Defibrillator Study. Eur Heart J* 2000;21:2071.)

of comorbid conditions (especially renal impairment or cancer), or perhaps class IV heart failure, which confers increased risk of death from progressive pump failure or from noncardiac causes.

2. Drug therapy is recommended for the suppression of NSVT or atrial fibrillation that causes symptoms or interferes with ICD function, which results in inappropriate ICD discharges.
3. Drug therapy is recommended for the prevention of frequent ICD discharges that result from recurrent sustained ventricular tachyarrhythmias.
4. Drug therapy is recommended to slow the rate of a ventricular tachyarrhythmia, which makes it better tolerated hemodynamically or more amenable to termination with antitachycardia pacing or a cardioversion shock.

### Radiofrequency Ablation

Radiofrequency catheter ablation of ventricular tachycardia can be an effective therapy in some patients if a reentrant circuit can be adequately mapped and if the area of slow conduction can be defined and ablated. Such a circuit is present more commonly in patients with an ischemic cardiomyopathy and a prior infarction; the reentrant circuit is often located at the border zone of the scar.<sup>116b</sup> Although not commonly used as primary therapy in these patients, radiofrequency ablation is occasionally performed as an adjunct treatment in patients with an ICD to reduce the frequency of ventricular tachyarrhythmias that are associated with symptoms or ICD discharges.<sup>116c</sup>

In contrast, patients with a nonischemic cardiomyopathy have diffuse disease, and there may be multiple reentrant circuits or even other mechanisms for arrhythmia, such as enhanced automaticity or triggered activity. Thus, ablation currently has a low success rate in such patients.

Patients with ischemic or nonischemic cardiomyopathy and heart failure have a unique, albeit uncommon, form of ventricular tachycardia that is called “bundle branch reentrant ventricular tachycardia.” This arrhythmia is the result of abnormal conduction through the bundle of His and the left bundle branch. Many patients with this arrhythmia have a baseline nonspecific conduction delay or left bundle branch block, and most have a prolonged His-to-ventricle interval. Presyncope and syncope are common presenting symptoms. Catheter ablation of the right bundle branch, which leads to complete right bundle branch block, effectively and safely eliminates the arrhythmia.

Catheter ablation is generally performed in three situations:

1. As an adjunct to an ICD in patients who have frequent sustained ventricular arrhythmias and ICD therapies.
2. As an alternative to an ICD in patients who do not want or are not candidates for an ICD.
3. When the cause of the ventricular tachycardia is bundle branch reentry.

### Surgery

Arrhythmia surgery is an effective way to eliminate reentrant circuits. However, the concerns regarding ablation in cardiomyopathy also apply to a surgical approach because of the requirement for localization of the reentrant circuit.<sup>116d</sup> Surgery may be a reasonable approach for patients with coronary artery disease, those who have had a previous myocardial infarction, those with left ventricular aneurysm, and those with sustained monomorphic ventricular tachycardia; it has little, if any, role in patients with diffuse cardiomyopathy. However, with the advent of the ICD and radiofrequency ablation, this type of surgery is rarely performed.

### Transplantation

Cardiac transplantation may be an option for patients with cardiomyopathy and heart failure who have experienced serious life-threatening ventricular tachyarrhythmias. In such patients, the ICD may be used as a bridge to transplantation.

### Implantable Cardioverter-Defibrillator Therapy in Hypertrophic Cardiomyopathy (see Chapter 25)

The most important concern in patients with hypertrophic cardiomyopathy is SCD resulting from a ventricular tachyarrhythmia. ICDs are the preferred therapy for such patients. No randomized trials have provided evidence of improved survival with an ICD as primary or prophylactic therapy in hypertrophic cardiomyopathy. However, support for their use comes from the known rate of SCD in patients at high risk and from observations of the high rate of appropriate ICD discharges in patients who have received a device for primary

prevention. For example, in one study of 128 patients receiving an ICD for primary or secondary prevention, the rate of appropriate device activation was 11% per year when it was used for secondary prevention of SCD and 5% per year when it was used for primary prevention.<sup>117</sup>

On the basis of data from several studies, a consensus statement from the ACC and ESC<sup>117</sup> identified several major risk factors for SCD in hypertrophic cardiomyopathy patients: a history of SCD or sustained ventricular tachycardia, a family history of premature SCD, unexplained syncope, severe left ventricular hypertrophy (maximum wall thickness > 30 mm), a hypotensive blood pressure response during exercise testing, and NSVT on ambulatory monitoring. According to the ACC/AHA/ESC guidelines, ICD insertion should be considered for primary prevention of SCD in patients with one or more of these high-risk features.

**Implantable Cardioverter-Defibrillator for Unexplained Syncope.** Syncope in patients with nonischemic cardiomyopathy and advanced heart failure may result from any of the well-established causes of syncope. However, when the syncope is of unknown origin, a ventricular tachyarrhythmia or a bradycardia resulting from a conduction abnormality such as complete heart block is often the cause. Regardless of the cause, syncope in such patients is associated with a high 1-year risk of SCD that is similar to that in patients who have experienced a ventricular tachyarrhythmia.<sup>118</sup> In one series, the mortality rate was 45% among patients with syncope, in comparison with 12% among those without syncope.

Although no hard data are available, it is believed that the ICD is the most effective therapy in these patients. In one study, investigators evaluated 147 patients with nonischemic cardiomyopathy, unexplained syncope, and no history of sustained ventricular tachyarrhythmia or SCD.<sup>119</sup> The actuarial survival rate at 2 years was higher among the 25 patients treated with an ICD (85%) than among the 122 patients managed with conventional medical therapy (67%); of those receiving an ICD, 40% experienced an appropriate shock. Another study also revealed that in patients with cardiomyopathy, unexplained syncope, and no electrophysiological abnormalities, empirical ICD therapy improved long-term outcome and the hazard ratio for the risk of an event in the ICD recipients, in comparison with patients treated with conventional therapy, was 0.18. Appropriate ICD shocks occurred in 26% of patients at 2 years.

In contrast, SCD-HeFT, which included 472 patients with a history of syncope before or after randomization, revealed that the ICD did not protect against SCD in comparison with amiodarone or placebo (hazard ratios = 1.54, 1.33, and 1.39, respectively; in the test for differences,  $P = .86$ ).<sup>120</sup>

The ACC/AHA/ESC guidelines suggest that, according to expert opinion, an ICD can be beneficial and is a reasonable approach to therapy in patients with cardiomyopathy and unexplained syncope.

## Recommendation for Treatment of Ventricular Tachyarrhythmias

Patients with heart failure and ventricular arrhythmia should be treated aggressively with drugs proven to be effective for therapy of heart failure, including a  $\beta$ -blocker, an ACE inhibitor, an ARB in selected patients, a statin, and an aldosterone antagonist in selected patients.

### *Patients with a History of a Ventricular Tachyarrhythmia (Ventricular Tachycardia or Sudden Cardiac Death)*

According to the current ACC/AHA/ESC guidelines, the ICD is the recommended approach for preventing recurrent ventricular arrhythmia in patients with cardiomyopathy of any origin and heart failure who have survived SCD caused by

ventricular fibrillation or ventricular tachycardia or who have sustained ventricular tachycardia. For patients with very severe left ventricular dysfunction (LVEF < 20%) in whom the risk of mortality from progressive heart failure is high, the benefit of an ICD is questionable. Among patients with very poor systolic function, advances in the therapy of heart failure have improved survival, partly as a result of a lower rate of death from nonarrhythmic causes. However, the ACC/AHA/ESC guidelines do not include recommendations based on the LVEF. Nevertheless, the ICD is considered a preferred approach in these patients, unless there are significant comorbid conditions that would affect survival; in such patients, antiarrhythmic therapy is generally preferred. Amiodarone therapy may, however, be a reasonable option for initial therapy in patients with ventricular tachycardia; the ICD can be reserved for patients who have recurrent ventricular tachycardia (which is often slower and better tolerated hemodynamically) despite amiodarone therapy.

Although the randomized studies have shown that amiodarone and the ICD were equally effective in patients with an LVEF higher than 35%, the use of an ICD is preferred in these patients, especially when the patient has experienced SCD.

Antiarrhythmic therapy with sotalol or amiodarone is often used as adjunctive therapy for the patient who has other symptomatic arrhythmias, such as NSVT or atrial fibrillation, or who has recurrent episodes of ventricular tachyarrhythmias that result in symptoms or frequent ICD discharges. Antiarrhythmic therapy is also recommended for those patients not considered candidates for an ICD. Radiofrequency ablation is also an adjunctive therapy for patients with ischemic cardiomyopathy who have frequent episodes of sustained monomorphic ventricular tachycardia that results in ICD discharges.

### *Prophylactic Therapy in Patients at High Risk with Cardiomyopathy*

According to the current ACC/AHA/ESC guidelines, the ICD is the recommended approach in patients who have survived myocardial infarction by at least 40 days, have an LVEF of 30% or lower (ischemic cardiomyopathy), have NYHA functional class II or III heart failure, are receiving chronic optimal medical therapy, and have reasonable expectation of survival with a good functional status for more than 1 year.

The ICD is also indicated in patients with nonischemic cardiomyopathy who have had an LVEF of 35% or lower for at least 9 months, have NYHA functional class II or III heart failure, are receiving chronic optimal medical therapy, and have reasonable expectation of survival with a good functional status for more than 1 year.

Although LVEF is currently the only criterion for prophylactic ICD use in the primary prevention of SCD in patients with an ischemic or nonischemic cardiomyopathy, data about other clinical factors will help in risk stratification to identify patients at high risk who will benefit from ICD implantation.

Antiarrhythmic drugs, primarily amiodarone or sotalol, are preferred for patients who are not deemed to be candidates for an ICD. These drugs are useful as adjunctive therapy to treat atrial fibrillation, NSVT, or sustained ventricular tachycardia that are associated with symptoms or result in ICD discharges. Radiofrequency ablation is useful for patients with ischemic cardiomyopathy who experience frequent ICD discharges because of sustained ventricular tachycardia.

### *Patients with Hypertrophic Cardiomyopathy (see Chapter 25)*

According to the current ACC/AHA/ESC guidelines, the ICD is the recommended approach for secondary prevention in patients with a hypertrophic cardiomyopathy who survive an episode of sustained ventricular tachycardia or SCD, who are receiving chronic optimal medical therapy, and who have reasonable expectation of survival with a good functional status for more than 1 year.

The ICD can be effective as primary prevention of SCD in patients with hypertrophic cardiomyopathy who are thought to be high risk; such patients are generally defined as those who have one or more of the high-risk features (i.e., a family history of premature SCD, unexplained syncope, severe left ventricular hypertrophy with a maximum wall thickness >30 mm, a hypotensive blood pressure response during exercise testing, or NSVT on ambulatory monitoring).

It is also believed that amiodarone can also be effective secondary therapy for patients with hypertrophic cardiomyopathy and a history of sustained ventricular tachycardia or ventricular fibrillation, if an ICD is not feasible.

### Patients with Unexplained Syncope

Among patients with cardiomyopathy and heart failure who experience syncope of undetermined origin, the rate of mortality, often the result of SCD, is high; it is similar to the incidence in patients with a sustained ventricular arrhythmias. There is a growing consensus that these patients should receive an ICD.

## Future Directions, 799

The rate of 3-year survival from 1975 to 1981, before the routine use of cyclosporine, was 40%; in comparison, from 1982 to 1994, the era of the early use of cyclosporine, that rate was 70%.<sup>2</sup> The number of heart transplantation procedures worldwide has declined somewhat from the peak of approximately 4500 per year in 1994, which perhaps reflects better medical and device therapies for heart failure and a better understanding of prognostic indicators.<sup>3</sup> Nonetheless, the number of potential organ donors cannot meet the demand created by growing waiting lists for heart transplants. As a result, other modalities for the treatment of stage D (chronic, progressive, and refractory) heart failure have been created and are being assessed in clinical trials (see Chapter 61).<sup>4</sup> More recently, for many patients referred for heart transplantation, one, if not more, of the alternative therapeutic options has usually failed,<sup>5</sup> and the patients are becoming progressively older and sicker, with increasing numbers of medical comorbid conditions. Likewise, the selection criteria for donors have expanded to increase the number of organs available.<sup>6</sup> As a result of these changes, the patients selected for heart transplantation are increasingly those with more acute disease, and, simultaneously, the available organs have been of poorer quality.<sup>1,7</sup>

Cardiac transplantation is the treatment of choice for eligible patients with refractory heart failure. Nevertheless, the survival benefit of cardiac transplantation in advanced heart failure, in comparison with conventional treatment, has never been tested in a prospective randomized trial. Norman E. Shumway and colleagues developed surgical techniques for the procedure as early as 1966, and Christiana Barnard performed the first clinical human cardiac transplantation in 1967.<sup>1</sup> By the 1980s, when a review panel was convened, the U.S. Health Care Financing Administration (HCFA) had concluded that heart transplantation was no longer experimental. Accordingly, in 1986, the HCFA issued proposed regulations for reimbursement of Medicare-eligible patients undergoing heart transplantation in centers that met HCFA-specified standards of experience and performance.

Many advances have occurred in the management of cardiac transplant recipients since the mid-1980s, including new immunosuppression modalities, therapies for chronic rejection, and improved operative and cardiac preservation techniques. As a result, the rate and length of survival have been enhanced over the same time period.

been developed to help with this critical analysis.<sup>8,9</sup> It is important for referring physicians to understand the potential benefits that cardiac transplantation might confer on a recipient, as well as comorbid conditions that might portend an unsatisfactory outcome. A risk-benefit assessment for each patient is ultimately what transplantation committees perform in their deliberations.

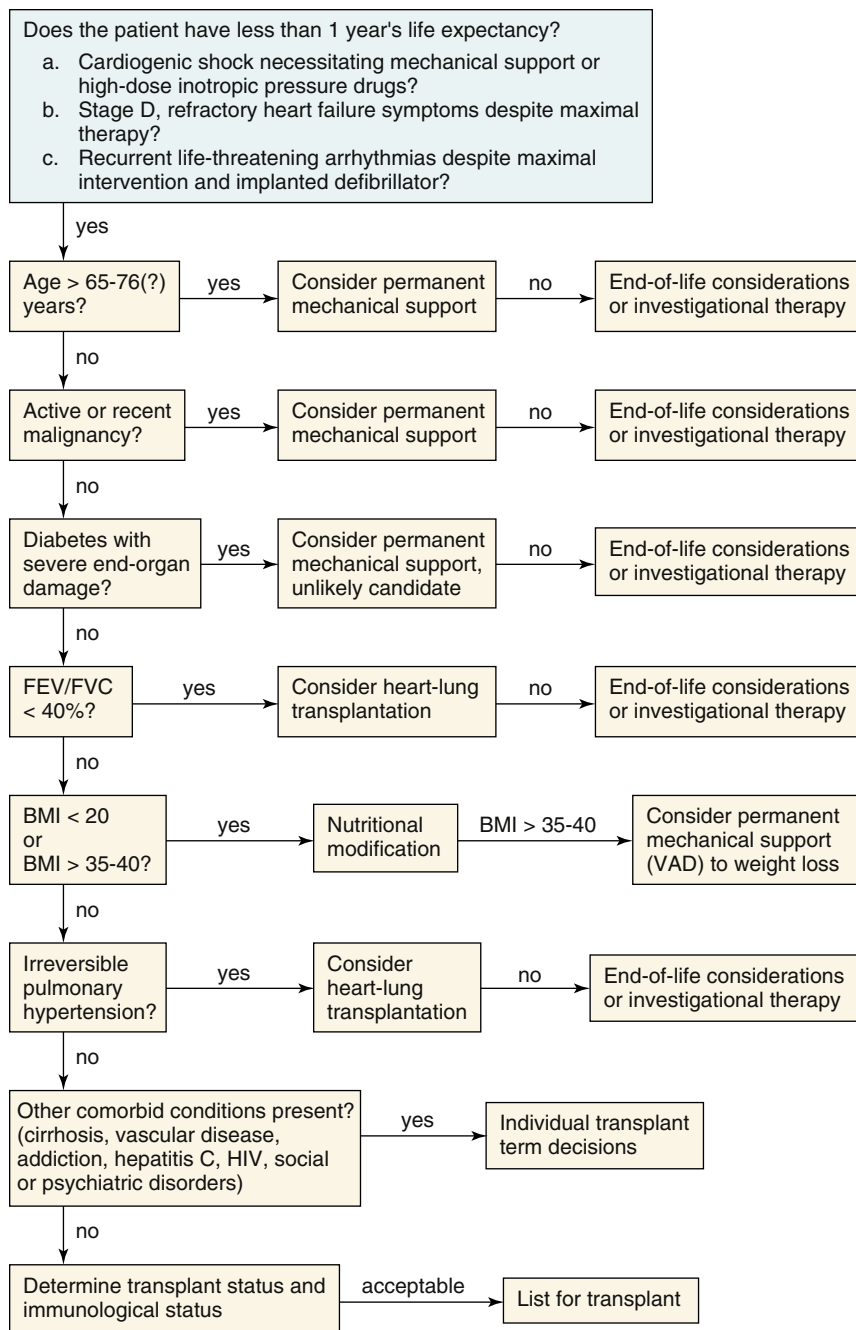

## Evaluation of the Potential Recipient

Figure 54-1 outlines the questions that must be answered to evaluate a potential patient for cardiac transplantation. The usual candidates are patients whose life expectancy is estimated to be less than 1 year. Typically, patients for consideration have one of several conditions: (1) cardiogenic shock that necessitates mechanical support or high-dose inotropic or vasopressor drugs (in which case, the course of disease is clearly irreversible); (2) stage D heart failure symptoms despite optimal therapy<sup>10</sup>; (3) recurrent life-threatening arrhythmias despite maximal interventions, including implanted defibrillators; or, in rare cases, (4) refractory angina without potential for revascularization.<sup>4</sup> Adult patients with repaired congenital heart disease are developing progressive heart failure and are being increasingly considered for heart transplantation.<sup>11</sup> Several models have been proposed to assist in the risk stratification of patients with heart failure through the use of both invasive and noninvasive methods.<sup>8,9</sup> The most potent predictor of outcome in ambulatory patients with heart failure is a test of symptom-limited metabolic stress to calculate peak oxygen consumption ( $\text{VO}_2$ ) (see Chapter 57).<sup>12</sup> A peak  $\text{VO}_2$  of less than 12 mL/kg/min is indicative of a poor prognosis, with a survival rate that is lower than that for transplantation.<sup>13</sup> Ideally, this information is organized in a score that also accounts for other important prognostic information, such as systemic blood pressure, results of biological assays (such as blood natriuretic peptide), renal function, and frequency of hospitalization.<sup>14,15</sup> Nonambulatory patients who require continuous intravenous inotropic support from which they cannot be weaned or those who require mechanical support to maintain adequate cardiac index are more obviously

## PATIENT POPULATION

### Which Patients Need to Be Considered for Transplantation?

The purpose of performing a heart transplantation for an individual patient is to prolong life and to improve the overall quality of life. No single prognostic algorithm enables clinicians to accurately predict impending morbidity or mortality in an individual patient, although multiple scoring systems have

**FIGURE 54-1** Flowchart depicting evaluation of a patient for cardiac transplantation. BMI, body mass index; FEV, forced expiratory volume; FVC, forced vital capacity; HIV, human immunodeficiency virus; VAD, ventricular assist device.

at risk for a poor outcome without transplantation; however, they often manifest signs and symptoms of end-organ failure of the pulmonary, hepatic, and renal systems, which may signal an ominous prognosis even with a transplant procedure.

Each patient must then undergo an extensive medical and psychosocial evaluation by the transplantation team to detect contraindications to transplantation and to further determine prognosis, the urgency of transplantation, and immunological status. There are a number of relative contraindications to heart transplantation; one of the most debated and variable among centers is the upper age limit for consideration. In general, patients older than 65 years are ineligible; more often, such patients undergo high-risk reparative surgery, implantation of permanent cardiac assist devices, or investigational therapies, such as cell transplantation, or they may receive hearts from an alternative list of less-than-optimal donors.<sup>16</sup> However, one heart transplantation guideline indicated that the maximum age for eligibility could be as high as 70 years;

therefore, individual centers must determine their own age cutoff.<sup>17,18</sup> The presence of an active or recent malignancy or of diabetes with severe end-organ damage limits life expectancy after transplantation, and these are common reasons why potential recipients are ineligible. Significant lung disease complicates postoperative management and precludes the possibility of normal physical functioning; extremes of weight, as measured by body mass index, have also been shown to worsen posttransplantation prognosis.<sup>4</sup> Patients with advanced heart failure and renal dysfunction are generally ineligible for heart transplantation because abnormal renal function increases morbidity after transplantation. Thus, it is important to clearly distinguish patients with potentially reversible renal failure from patients in whom renal dysfunction is associated with advanced, irreversible end-stage renal disease. At many transplantation centers, combined heart-kidney transplantation procedures are performed in selected patients.<sup>19,20</sup>

Pulmonary arterial hypertension—whether accompanied by a pulmonary vascular resistance of greater than 6 Wood units that cannot be reduced by medical therapy or occurring after the placement of a ventricular assist device (VAD)—is considered an absolute contraindication to cardiac transplantation. In the setting of fixed pulmonary hypertension, the donor right ventricle often fails, which in many cases leads to early postoperative mortality.<sup>21</sup> In some centers, individual patients with irreversible pulmonary pressures may be considered for a combined heart-lung transplantation procedure. Other comorbid conditions may negatively affect a transplantation team's decision to further consider a potential recipient; these conditions include hepatitis C or cirrhosis, peripheral or cerebral vascular disease, advanced neuropathy, human immunodeficiency virus (HIV) status, addictions to alcohol or illicit drugs, and social or psychiatric disorders. Appropriate counseling of the patient who is ineligible for heart transplantation should include end-of-life preparation and discussions about possible investigational approaches.<sup>22</sup>

Each patient undergoes immunological evaluation, which is increasingly sophisticated, to determine ABO blood type; antibody screening; testing for panel reactive antibody (PRA); and human leukocyte antigen (HLA) typing. The presence and levels of anti-HLA antibodies is determined by cytotoxic testing in which the recipient's serum is incubated with lymphocytes from 30 to 60 individuals that represent a wide range of HLA antigens. The PRA value is expressed as a percentage of cell panel members that undergo cytolysis and is considered positive if more than 10% of the cell panel members undergo cytolysis. The PRA test can identify the presence of circulating anti-HLA antibody but not the specificity or strength of antibody. Enzyme-linked immunosorbent assay (ELISA) and flow cytometry can also determine PRA and are more sensitive than the cytotoxic test.<sup>23</sup>

The most common cause of sensitization, or elevated PRA levels, is pregnancy; however, sensitization can also occur with transfusions, prior transplantation, or insertion of a VAD. Patients with a PRA exceeding 10% usually must undergo prospective crossmatching in order to identify a prospective donor. This involves testing the recipient's serum with donor cells, in the presence of complement, to see whether cytotoxicity occurs. Cell destruction portends an unacceptably increased potential for either acute rejection or more chronic, recurrent rejections. Highly sensitized patients—those with high circulating levels of preformed antibodies—often have to wait long periods before a suitable donor can be found.

Newer and more sensitive immunological techniques have further quantified the type and number of circulating antibodies in patients waiting for transplantation and have challenged transplantation teams in knowing which potential donors are acceptable. Moreover, prospective crossmatching techniques can be done only for donors and recipients in a single geographical region, and teams must increasingly travel outside a region for donors; this makes it difficult to obtain donor organs for their sensitized waiting patients. Virtual crossmatching methods are now being used with some success, in which flow cytometry-based, single-antigen bead assays enable the clear identification of antibody specificities. Prospective donors with these antigens can be avoided, and a compatible donor can be selected without the need for prospective crossmatching. This increases the number of donor matches outside the geographical area of the local organ procurement organization.<sup>24,25</sup>

## Management of the Patient Waiting for Cardiac Transplantation

In the United States, solid organ transplantation is regulated, audited, and facilitated by the government. The United Network for Organ Sharing (UNOS) is the national organization

that maintains organ transplant waiting lists and allocates identified donor organs; it is organized by regions throughout the country and integrated closely with local organ procurement organizations. Donor hearts are assigned to recipients according to a priority status that is standardized nationally. The priority status is based on the recipient's level of medical urgency, blood type, body size, and duration of time at a particular status level. Patients awaiting heart transplantation are assigned a risk status according to the level of medical support they require. Patients who can be maintained safely and successfully outside the hospital are assigned the status of lowest priority, status 2. Intermediate priority is given to patients who require hospitalization and some continuous inotropic support or who require ongoing VAD therapy (status 1B). The highest priority (status 1A) is assigned to patients who require high-dose, continuous, inotropic infusions or mechanical support, such as an intra-aortic balloon pump (IABP), ventilator, or VAD therapy. Such critically ill patients must be located in an intensive care unit and undergoing continuous hemodynamic monitoring with Swan-Ganz catheters. Patients with VADs in place who are waiting for transplantation are given an automatic 30-day status 1A listing, with the timing at the discretion of the center. Thereafter, if the function of the VAD is normal, the patient is reassigned to status 1B. Donor hearts are offered geographically (by the location of the donor) and sequentially (to patients with the highest priority and the appropriate blood type). This process has been facilitated by a computerized system that requires transplantation teams to have online access at all times. Nevertheless, speed and timing are critical aspects of optimal donor allocation, because potential donors often exist in an unstable hemodynamic environment that may affect the viability of the donor heart. In addition, transportation of donor hearts is generally limited by a “cold ischemic” time (the duration of organ viability between harvest and implantation) of approximately 4 hours.

Pretransplantation waiting times in the 11 UNOS donor regions vary considerably, as do the challenges to individual transplantation teams in managing waiting recipients throughout the United States. The ability of potential recipients to be listed for and receive an organ transplant is influenced by a number of different factors, including candidate gender, size and blood group, presensitization status, source of health insurance or lack thereof, type of cardiac disease, proximity to a transplantation center, and even the number of other transplantation centers in the region. Information about these and many other parameters of the United States transplantation program are available to the public on a variety of websites, including the official UNOS website (<http://www.unos.org/>), on which site-specific data may also be compared nationally or by city or region. Since about 2000, an increasing number of heart transplant recipients have been listed and undergone transplantation as status 1A or 1B, in comparison with the less urgent status of years past.<sup>26</sup> This fact probably reflects the increasing use of VADs as a bridging method in desperately ill patients before transplantation; earlier, similar patients would have died. Mechanical support devices often allow patients to be managed successfully as outpatients while they await transplantation, but the implantation of the device qualifies the recipient to at least a status 1B or more urgent. There is considerable debate about the outcome of patients with VADs, in comparison with patients who undergo transplantation without a prior VAD, with strong arguments on both sides.<sup>27</sup> Nevertheless, the available data from the Organ Procurement and Transplantation Network (OPTN) and from the Scientific Registry of Transplant Recipients (SRTR) website ([www.ustransplant.org](http://www.ustransplant.org)) suggest that overall survival is no different for patients who undergo transplantation as status 1A, 1B, or 2, as illustrated in Figure 54-2.

**FIGURE 54-2** Percentages of patients surviving 1, 3, and 5 years after heart transplantation, in the United States, according to listing status. (Adapted from the information on the Scientific Registry of Transplant Recipients website, National Transplant Statistics [<http://www.ustransplant.org>]; accessed March 14, 2010.)

Patients waiting for transplantation must be regularly reevaluated for the possibility of worsening status, which would necessitate a change in priority; the development of a new comorbid condition that would preclude transplantation; or significant clinical improvement that would warrant a reconsideration of the listing. An analysis of the OPTN/SRTR data suggests that the overall death rate among patients waiting for heart transplantation has fallen from 220 to 142 patients per 1000 patient-years at risk.<sup>26</sup> In addition, all transplantation teams acknowledge that some patients are removed from the waiting list each year because of marked clinical improvement, despite the great care in patient selection.<sup>28</sup>

## THE CARDIAC TRANSPLANTATION PROCEDURE

### The Cardiac Donor

In view of increasing organ demand, efficacious donor management and meticulous selection are crucial in maintaining excellent transplantation outcomes. Organ procurement representatives have become highly skilled in the rapid but thorough evaluation of potential donors, often screening for multiple organ harvests from a single donor. Obviously, any medical history about the donor is crucial, including any relevant cardiovascular disorders before brain death. All donors are screened for communicable diseases, including viral disorders such as hepatitis and HIV infection. In contrast to blood bank donation, donors with behavioral risk factors are not barred from contributing to the organ supply. Accordingly, clinicians have increasingly debated the risk associated with transplantation and how much of the donor-associated risk should be conveyed to the potential recipient.<sup>29</sup> Specific information that is relevant for the assessment of cardiac donor suitability also includes the presence or absence of thoracic trauma, donor hemodynamic stability, pressor and inotropic requirements, duration of cardiac arrest, the need for cardiopulmonary resuscitation, and number of hypotensive episodes and the method by which hypotension was managed. Echocardiography is an invaluable screening method to evaluate potential donors. Some potential donors undergo hemodynamic deterioration caused by brain death, which

necessitates inotropic or pressor infusions and substantial fluid administration, with subsequent derangements in electrolytes and hemoglobin concentration. The resultant cardiovascular instability leads to suboptimal condition of some donor hearts and has compounded the problem of donor shortage. To increase the donor yield, recommendations have been published to improve the evaluation and successful use of potential cardiac donors.<sup>5,30</sup>

The acceptable “cold ischemia” time for cardiac transplantation is approximately 4 hours. Prolonged ischemic time has been shown to be a significant risk factor for mortality after cardiac transplantation, especially when coupled with other risk factors, such as older donor age. In the first two decades of heart transplantation, the upper limit of donor age was 35 years, but older donors are now used frequently; an age up to 60 years is considered safe by most centers.<sup>31</sup> It has become quite standard to perform cardiac catheterization on the older donor to further clarify the integrity of the coronary circulation. The final decision to accept a heart for transplantation is made at the time of harvesting, after direct examination of the heart for myocardial infarction, trauma, coronary calcification, left ventricular hypertrophy, or dilatation. The harvesting team communicates the decision to the recipient hospital’s transplantation team, so that the recipient may be prepared for surgery.

One of the main problems thought to be responsible for early graft failure after transplantation is inadequate myocardial protection during prolonged ischemic transport.<sup>1,32,33</sup> Current myocardial preservation techniques allow interventions to be made during five different phases of the transplantation procedure: donor cardiovascular management; protection during explantation; protection during transportation to the recipient center; protection during implantation; and protection during the immediate reperfusion period.<sup>34,35</sup> Optimal protection of donor hearts will, it is hoped, ultimately expand the potential donor pool and enhance early graft function. Moreover, endothelial injury that occurs during organ procurement, preservation, and reperfusion, as well as ongoing injury during the life span of the cardiac allograft, results in endothelial activation.<sup>36</sup> If protection strategies can successfully reduce ischemia-reperfusion damage, long-term heart transplantation outcomes may be improved by the protective effects on endothelial cells, which would reduce the subsequent development of cardiac allograft vasculopathy (CAV). This goal has spurred the development of new devices that are designed to further protect the harvested heart during transportation by continuous bloodless circulation or autologous blood-perfused systems.<sup>32</sup>

### Surgical Considerations

The two most common surgical approaches for the implantation of the donor heart are the biatrial and bicaval anastomoses (Figure 54-3). The biatrial anastomosis technique has long had a reputation for being simple, safe, and reproducible; four suture lines are made in the left atrium, pulmonary artery, aorta, and right atrium. The bicaval anastomosis technique was introduced in the early 1990s with the intentions to reduce right atrial size, to minimize distortion of the recipient heart, to preserve atrial conduction pathways, and to decrease tricuspid regurgitation. This alternative procedure entails five anastomoses: left atrium, pulmonary artery, aorta, inferior vena cava, and superior vena cava. Although there has been no prospective trial to establish the superiority of either technique, the bicaval technique is now performed more often in the United States, primarily because it appears to decrease the need for permanent pacemakers in transplant recipients.<sup>37-39</sup> Some surgeons have become increasingly interested in techniques to minimize subsequent tricuspid regurgitation and have described tricuspid annuloplasty performed simultaneously with the transplantation surgery.<sup>40</sup>

**FIGURE 54-3** Surgical techniques for cardiac transplantation. **A**, Standard Shumway (biatrial) technique of orthotopic heart transplantation. **B**, Bicaval technique of orthotopic heart transplantation. (Modified from Al Khalidi A, Robbins RC. New directions in cardiac transplantation. *Annu Rev Med* 2006;57:455)

Many transplantation candidates have had pacemaker or cardiac defibrillator devices implanted during the years leading up to their need for transplantation. These devices are typically removed surgically at the end of the transplantation operation, after the chest has been closed. Likewise, previous heart surgery—most commonly, coronary artery bypass graft procedures—lengthens the time it takes to prepare the recipient to receive the donor heart and increases the risk of bleeding during and after surgery. Just as the age at the time of transplantation has increased since 2000, so too has the number of patients who have undergone previous heart surgery. Of most importance is that the number of patients about to undergo transplantation with VADs in place has steadily increased, and so transplantation procedures are riskier and result in more bleeding.<sup>41-46</sup>

The most common reason for failure to wean a heart transplant recipient from cardiopulmonary bypass is right-sided heart failure, evidenced by a low cardiac output despite a rising central venous pressure. In the surgical field, the right heart chambers can be observed to dilate and contract poorly. Intraoperative transesophageal echocardiography (TEE) displays a dilated, poorly contracting right ventricle and an underfilled, vigorously contracting left ventricle. Right ventricular function may be enhanced with inotropic agents and pulmonary vasodilators, but the prognostic importance of preoperative pulmonary vascular resistance becomes obvious in these first few hours after surgery.<sup>47,48</sup>

## EARLY POSTOPERATIVE MANAGEMENT

### Cardiovascular Issues

In general, the management of the heart transplant recipient early after surgery does not differ substantially from that after other open-heart procedures, although the transplant recipient is generally debilitated after suffering severe heart failure for weeks or months before surgery. Cardiac transplant recipients often go into surgery with profoundly disturbed hemodynamics and significant renal insufficiency. Postoperative management has to be undertaken with close scrutiny of the urine output and renal function, because a rising creatinine level may necessitate a change in the immunosuppressive regimen. The resultant fluid overload may serve to further overdistend a struggling right ventricle. Many patients manifest generalized edema within the first week after surgery; however, it generally responds to intravenous diuretics. Vaso-motor alterations of the peripheral vasculature that result in tissue edema contribute to this occurrence.

Because the donor heart is denervated after surgical implantation, bradycardia is a frequent problem, and a direct-acting  $\beta$ -agonist drug should be available. Temporary pacing leads

are necessary for all recipients, because most are dependent on external pacemakers for a number of days after surgery; as many as 10% to 15% of transplant recipients require a permanent pacemaker.<sup>46</sup> Cardiac transplant recipients typically need chronotropic and inotropic support for a few days in the intensive care unit, after which time the infusions are weaned as tolerated. Many centers use isoproterenol for this purpose because of its lack of vasoconstrictive effects on the pulmonary vasculature. Inhaled agents have been used to achieve selective pulmonary vasodilation in cardiac transplant recipients, especially those with preoperative pulmonary hypertension. Inhaled nitric oxide is a potent vasodilator that has a selective effect on the pulmonary vasculature because of its rapid breakdown in the lung.<sup>47</sup> Administration of nitric oxide in heart transplant recipients with pulmonary hypertension has been shown to reduce pulmonary vascular resistance and improve right ventricular function. Iloprost, a carbacyclin analogue of prostaglandin  $I_2$ , can be aerosolized and has been administered in an inhaled form to treat severe pulmonary hypertension. The inhaled agents, delivered via the ventilator, are initiated in the operating room and continued until right ventricular function has stabilized.

### Immunosuppression

Cardiac transplantation centers throughout the world have individual approaches to the management of immunomodulation for transplant recipients so that the donor heart is not rejected. All centers adhere to the principle that no patient undergoing heart transplantation is at low risk for rejection. Instead, it is more appropriate to stratify patients as those at average risk and those at high risk for subsequent rejection. Before transplantation surgery, patients at high risk for rejection include those with preformed antibodies (e.g., sensitized patients), usually secondary to previous surgery that necessitated transfusions; pregnant patients; patients waiting on mechanical circulatory assist devices; and, possibly, African American patients.<sup>43</sup> In addition, it is useful to characterize patients as being at higher risk of developing important comorbid conditions after transplantation, including infection, acute renal failure, or worsening diabetes, because an immunosuppressive regimen may have to be modified accordingly. After transplantation, a risk profile may be additionally tailored according to the retrospective crossmatch information and cytomegalovirus status of the donor and recipient. An immunosuppression strategy is thus developed for each patient on the basis of their risk for rejection and their risk for developing important complications of the immunosuppressive drug therapy.<sup>1,49-52</sup> Nevertheless, most immunosuppressive regimens begin with the simultaneous use of three classes of drugs: glucocorticoids, calcineurin inhibitors, and antiproliferative agents. In a subset of patients, transplantation teams

### Induction Therapy in the Perioperative Period

Induction therapy is a heterogeneous application of perioperative antibody drugs used in combination with a foundational immunosuppressive regimen in solid-organ transplantation. The ultimate aim of induction is to inhibit only the T cells that respond to donor antigen. The aim of induction treatment is for the recipient to achieve immunological unresponsiveness to the transplant in the presence of a fully functioning immune system (donor-specific tolerance). Both polyclonal and monoclonal antibodies have been used for this form of therapy; their use depends on the institution and the country. Induction therapy is currently used in approximately 40% of heart transplant recipients.<sup>53-55</sup> Theoretically, induction agents should reduce the overall rate of rejection, but their primary benefit currently seems to be the delay of cellular rejection in the first 4 to 8 weeks of the early postoperative period, when renal dysfunction is most worrisome. Induction therapy may allow the less aggressive use of the calcineurin inhibitors, which would spare renal function initially, during the most vulnerable period.

Drugs used for induction include antithymocyte globulins (polyclonal antibodies) and the anti-CD3 antibody OKT3 and the interleukin-2 receptor antagonists daclizumab and basiliximab (monoclonal agents). OKT3 was widely used as induction in the past, but it has virtually vanished as an option because of the subsequent increased rejection rates and occurrence of lymphomas.<sup>56</sup> The antithymocyte globulins are currently used more commonly for the first 3 to 7 or even 14 days after transplantation, despite a paucity of efficacy data for the population of heart transplant recipients. The use of basiliximab has been explored in three trials: one in which the drug was compared with OKT3 induction<sup>57</sup> and two in which basiliximab was compared with placebo in a randomized design.<sup>58,59</sup> Although basiliximab was less toxic than OKT3, it did not alter outcome with regard to rejection, infection, or survival. In comparison with placebo, a significant delay in rejection occurred with basiliximab, but rates of late rejection may have increased. Basiliximab was found to be noninferior to rabbit antithymocyte globulin for the prevention of acute rejection in a trial of 35 patients.<sup>60</sup> Daclizumab, in comparison with no induction, reduced rejection without an attendant increase in mortality.<sup>61</sup> Thus, there may be some rationale for administering the induction agents to patients at high risk (e.g., those with preformed antibodies, renal dysfunction, or a worrisome retrospective crossmatch), but there are no compelling data as yet in the population of heart transplant recipients, and they are the subjects of considerable controversy.<sup>53,62,63</sup>

### Maintenance Immunosuppression

As mentioned previously, immunosuppressive regimens begin with the simultaneous use of three classes of drugs: glucocorticoids, calcineurin inhibitors, and antiproliferative agents. In the immediate postoperative period, they are given parenterally, with a quick transition to oral formulations. *Corticosteroids* are nonspecific anti-inflammatory agents that work primarily by lymphocyte depletion. Patients receive high doses of initially intravenous and then oral steroids that are gradually tapered over the next 6 months; the goal is often to withdraw steroid therapy completely. At many centers, steroids are given several hours before the transplantation surgery. Side effects include cushingoid appearance, hypertension, dyslipidemia, weight gain with central obesity, peptic ulcer formation and gastrointestinal bleeding, pancreatitis, personality changes, cataract formation, hyperglycemia progressing to steroid-induced diabetes, and osteoporosis with avascular necrosis of bone. The well-appreciated adverse

profile of the corticosteroids has prompted the development of a number of innovative strategies to eliminate them as early as possible after the transplantation surgery. Corticosteroids are also usually the drug of first choice to treat acute rejection.<sup>64,65</sup>

There are two *calcineurin inhibitors*: cyclosporine and tacrolimus. Their main mechanism of action involves binding to specific proteins to form complexes that block the action of calcineurin, a key participant in T-cell activation. The calcineurin inhibitors serve to block the signal transduction pathways responsible for T- and B-cell activation and therefore act specifically on the immune system and do not affect other rapidly proliferating cells. Critical and often limiting adverse effects include nephrotoxicity, in as many as 40% to 70% of patients, and hypertension with the development of left ventricular hypertrophy; both drugs cause approximately equivalent incidences of these untoward events.<sup>64,66</sup> Hirsutism, gingival hyperplasia, and hyperlipidemia are more frequent with cyclosporine, and diabetes and neuropathy are more frequent with tacrolimus.<sup>60</sup> The incidences of deep venous thrombosis, tremor, headache, convulsions, and paresthesias of the limbs are also increased with both drugs.<sup>64,65</sup> There are target therapeutic levels for both drugs; these goals are also adjusted over the subsequent months and years after transplantation. Therapeutic levels have been typically calculated with trough blood samples, but it has been shown that cyclosporine concentration 2 hours after administration (C2) is a more accurate predictor of total cyclosporine exposure.<sup>67</sup> It remains to be demonstrated whether the short- or long-term efficacy of cyclosporine in heart transplant will be further improved by monitoring the 2-hour cyclosporine concentration. In the United States, tacrolimus is now available in generic formulations; therefore, this drug tends to be the calcineurin inhibitor of choice in most centers.<sup>68,69</sup> As discussed later, progressive renal insufficiency is a major limitation of the calcineurin inhibitors, and investigators continue to explore methods to minimize their use or withdraw it altogether.<sup>62,66</sup>

*Antiproliferative agents* either directly or indirectly inhibit the expansion of alloactivated T- and B-cell clones. In this class, azathioprine was the earliest agent used, and it served as the mainstay of immunosuppression even before the routine use of cyclosporine. In the 2000s, mycophenolate mofetil has replaced azathioprine as the first-line antiproliferative drug; several randomized trials have demonstrated its superiority to azathioprine.<sup>70-73</sup> Mycophenolate mofetil is hydrolyzed to mycophenolic acid, which inhibits de novo purine syntheses. The major adverse effect of both azathioprine and mycophenolate mofetil is leukopenia; the use of mycophenolate mofetil can be limited by debilitating diarrhea or nausea. It is likely that the combination of mycophenolate mofetil and tacrolimus potentiates their individual adverse effects.

Sirolimus (often called *rapamycin*) and everolimus are two newer agents that block activation of T cells after autocrine stimulation by interleukin-2. They also are known to inhibit proliferation of endothelial cells and fibroblasts. Their action complements that of calcineurin inhibitors, and both sirolimus and everolimus have been used as maintenance immunosuppressive agents, as alternatives to standard immunosuppressive agents, and as rescue drugs for rejection. Sirolimus, a mammalian target of rapamycin (mTOR) inhibitor, has been shown to slow the progression of CAV with established disease,<sup>74-76</sup> and everolimus has been demonstrated to reduce both acute rejection and CAV.<sup>77</sup> In one randomized trial, sirolimus, in comparison with azathioprine, when added to cyclosporine and steroids, decreased by half the number of patients with acute rejection, which resulted in less subsequent development of CAV.<sup>72,73</sup> Because the drugs inhibit the proliferation of fibroblasts, they may cause

significant difficulties with wound healing, and most centers do not use them as initial therapy immediately after the transplantation surgery. The drugs have also been associated with the development of significant pericardial effusions. Sirolimus has been increasingly utilized to replace the calcineurin inhibitors as a strategy to improve renal dysfunction or to reverse left ventricular hypertrophy.<sup>66,78,79</sup>

The long-standing use of the maintenance combination of cyclosporine, azathioprine, and steroids has been challenged in a number of trials. Tacrolimus plus mycophenolate mofetil and tacrolimus plus sirolimus were compared with cyclosporine plus mycophenolate mofetil in a multicenter trial.<sup>71</sup> The overall rate of 1-year survival did not differ among the three regimens, but there was statistically less significant rejection with or without hemodynamic compromise with tacrolimus plus mycophenolate mofetil than with cyclosporine plus mycophenolate mofetil. Overall, patients taking tacrolimus plus mycophenolate mofetil had better renal function and triglyceride levels at 1 year. This trial has been pivotal in promoting tacrolimus as the primary calcineurin inhibitor in use worldwide. Researchers in later studies explored the use of converting a calcineurin inhibitor to sirolimus or everolimus for a renal-sparing effect.<sup>80</sup> Unfortunately, many of these newer approaches are being implemented without the benefit of rigorous, controlled trials.

### Other Potential Perioperative Management Issues

In addition to the common postoperative problems encountered after heart surgery, the transplant recipient is frequently debilitated and may be malnourished, particularly if he or she has not been supported by a VAD. Issues concerning exercise rehabilitation and nutrition can be time consuming for the transplantation team and challenging for the patient and family. Depression in patients with chronic heart failure is a regular occurrence and is not immediately alleviated by the transplantation procedure.<sup>81-83</sup> In addition, marked emotional lability is common in recipients and is aggravated by the high-dose steroids used. As a result, successful heart transplantation teams must focus on more than the physical needs of the new transplant recipient. On occasion, the stress of the wait for transplantation often depletes the family of financial resources and emotional resiliency. On the other hand, patients are often rehabilitated much faster if they were allowed time to recover from the heart failure syndrome by the use of VAD support before receiving the transplant. It is critical that a transplantation center have dedicated physical therapists, nutritionists, and social workers or psychologists who can act in concert to address these noncardiovascular issues.

## CHRONIC MANAGEMENT OF THE CARDIAC TRANSPLANT RECIPIENT

### Rejection

Rejection involves cell- or antibody-mediated cardiac injury that results from the recognition of the cardiac allograft as nonself. This process is categorized into three major types of rejection, according to histological and immunological criteria: hyperacute, acute, and chronic.<sup>49,84-87</sup> *Hyperacute rejection* results when an abrupt loss of allograft function occurs within minutes to hours after circulation is reestablished in the donor heart; it is rare in modern-day transplantation. The phenomenon is mediated by preexisting antibodies to allogeneic antigens on the vascular endothelial cells of the donor organ, which is now avoided with current HLA typing techniques. These antibodies fix complement that promotes

intravascular thrombosis. Subsequently, the graft vasculature is occluded rapidly, and swift and overwhelming failure of the cardiac graft occurs.

Acute cellular rejection or *cell-mediated rejection* is a mononuclear inflammatory response, predominantly lymphocytic, that is directed against the donor heart, most commonly occurs from the first week to several years after transplantation, and occurs in up to 40% of patients during the first year after surgery. The key event in both the initiation and the coordination of the rejection response is T-cell activation, moderated by interleukin-2, a cytokine. Interleukin-2 is produced by CD4 cells and, to a lesser extent, by CD8 cells and exerts both an autocrine and a paracrine response. Unlike renal and liver transplants, cardiac transplants have no reliable serological markers for rejection. Therefore, the endomyocardial biopsy remains the “gold standard” for the diagnosis of acute rejection. Biopsy is performed via a transjugular approach weekly and then every other week for several months; monthly biopsy continues for 6 to 12 months in many programs and for years thereafter in some. Cell-mediated rejection is graded according to a universally agreed-upon system that is periodically reviewed (Table 54-1).<sup>88</sup>

Risk factors for early rejection include younger recipient age, female gender, female donor, cytomegalovirus-positive serological status, prior infections, African American recipient race, and number of HLA mismatches.<sup>43,89</sup> Of most importance is that patients who fail to take or tolerate their immunosuppressant drugs, especially early in the postoperative course, are at very high risk for severe or recurrent cellular rejection. The occurrence of one or more episodes of treated rejections during the first year is a risk factor for both 5-year mortality and development of transplant coronary disease.<sup>90</sup> Likewise, treatment for acute rejection in the first 6 months after transplantation contributes to a slower overall rehabilitation of the patient.

The aggressiveness of treatment for cell-mediated rejection depends on the biopsy grade, clinical correlation, patient risk factors, rejection history, length of time after transplantation, and whether target levels of the immunosuppressant drugs are achieved. For example, an asymptomatic, early moderate rejection in a patient soon after transplantation who has achieved at least target levels of immunosuppressants or who has one or more risk factors for early rejection would be treated more aggressively than a patient at low risk for rejection with no history of cell-mediated rejection.

Another form of acute rejection is acute humoral rejection, or antibody-mediated rejection (AMR), which occurs days to weeks after transplantation and is initiated by antibodies rather than by T cells. The alloantibodies are directed against donor HLA or endothelial cell antigens. AMR is a serious complication after heart transplantation and manifests as graft dysfunction or hemodynamic abnormalities in the absence of the appearance of cellular rejection on biopsy samples. AMR is now recognized as a distinct clinical entity, and strict histopathological and immunological criteria for its diagnosis have been established (Table 54-2).<sup>88,91</sup> Further testing, including immunofluorescent staining of specially prepared myocardial tissue, is often necessary to elucidate the presence of AMR and is an important consideration in the evaluation of the transplant recipient with left ventricular dysfunction. The pathological markers of AMR identifiable in endomyocardial biopsy tissue include deposits of immunoglobulin M, immunoglobulin G, or complement in the microvasculature or myocytes. Antibodies with specificity for non-HLA antigens on the graft may also be present in the circulation, and their presence should support the diagnosis of AMR. Patients at greatest risk for AMR are women, patients with a high PRA screen value, and patients with a positive crossmatch. It is estimated that significant AMR occurs in

**TABLE 54–1 Current and Previous Grading Systems for Cell-Mediated Rejection in Heart Transplantation**

2004		1990	
Grade 0 R	No rejection	Grade 0	No rejection
Grade 1 R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage	Grade 1, mild • A: Focal • B: Diffuse	Focal perivascular and/or interstitial infiltrate without myocyte damage Diffuse infiltrate without myocyte damage
Grade 2 R, moderate	Two or more foci of infiltrate with associated myocyte damage	Grade 2, moderate (focal)	One focus of infiltrate with associated myocyte damage
Grade 3 R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema ± hemorrhage ± vasculitis	Grade 3, moderate • A: Focal • B: Diffuse Grade 4, severe	Multifocal infiltrate with myocyte damage Diffuse infiltrate with myocyte damage Diffuse, polymorphous infiltrate with extensive myocyte damage ± hemorrhage + vasculitis

about 7% of patients, but that number may be as high as 20%. Because antibody assays are becoming more precise, AMR will probably be recognized more often, with a correlating need for newer treatment algorithms.<sup>84,92,93</sup>

**Chronic rejection**, or late graft failure, is an irreversible, gradual deterioration of graft function that occurs in many allografts months to years after transplantation. Current concepts suggest that donor heart dysfunction in the chronic stages of maintenance immunosuppression is related to chronic rejection, is mediated by antibodies, or is a result of progressive graft loss from ischemia. The last process is characterized by intimal thickening and fibrosis that lead to luminal occlusion of the graft vasculature; it is often referred to as “CAV”, or transplant coronary artery disease. An approach to managing nonspecific graft dysfunction (Figure 54-4) is focused primarily on the diagnosis of AMR, as opposed to the presence of CAV.<sup>94</sup>

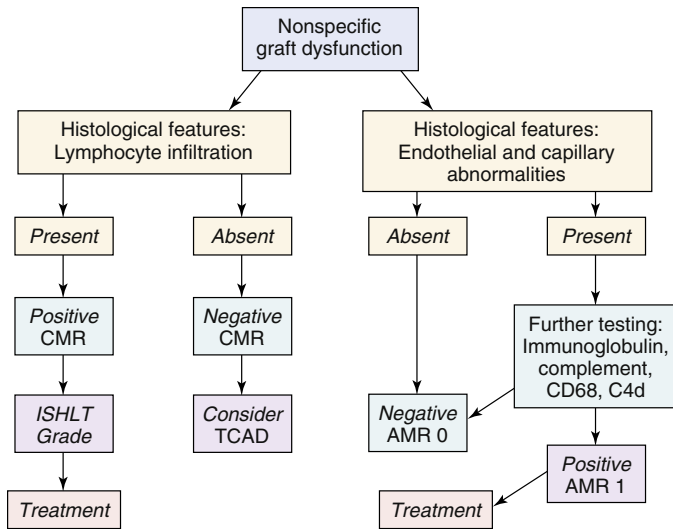

Attention has also focused on noninvasive methods to detect rejection. Gene expression assays have been developed by identifying a number of candidate gene markers from a pool of more than 25,000 genes of interest through the use of gene-chip array technology. Subsequently, real-time polymerase chain reaction (PCR) technologies are used in the peripheral blood to identify a pattern of gene activation that may be correlated with allograft rejection. One such assay is available for clinical use, but it is not yet clear how

the information obtained can be best used in a wide range of transplant recipients.<sup>95</sup>

## Infection

Despite the advances in immunosuppressive management, a major untoward consequence remains the occurrence of life-threatening infections. Infections cause approximately 20% of deaths within the first year after transplantation and continue to be a common cause of morbidity and mortality throughout the recipient's life. The most common infections in the first month after surgery are nosocomial, bacterial, and fungal infections related to mechanical ventilation, catheters, and the surgical site. Mortality rates are highest for fungal infections, followed by those for protozoal, bacterial, and viral infections. *Aspergillus* and *Candida* species account for the most common fungal infections after heart transplantation. In addition, a higher number of infections of any type during the first month after transplantation increases the risk of a subsequent fatal cytomegalovirus infection, a rejection (because immunosuppression frequently has to be decreased in order to treat the infection), or a prolonged hospital stay. Viral infections, especially cytomegalovirus, can enhance immunosuppression, which results in additional opportunistic infections. Accordingly, each heart transplantation team must develop a prophylactic regimen against cytomegalovirus, *Pneumocystis*

State-of-the-art strategies for immunosuppression. *Curr Opin Organ Transplant* 2007;12:536-42.)

*carinii*, herpes simplex virus, and species causing oral candidiasis that is to be used during the first 6 to 12 months after transplantation. Prophylactic intravenous ganciclovir or oral valganciclovir is generally given for variable amounts of time in the cytomegalovirus-seronegative recipient of a heart from a cytomegalovirus-seropositive donor. Optimal prophylaxis regimens and timing have not been completely standardized, and some of the decisions to be made about prophylaxis are outlined in Table 54-3.<sup>96</sup> The necessity of routine prophylaxis, however, has withstood the test of time. The regimen increases substantially the number of medications taken and potential drug interactions the recipient may experience. Some of the important drug interactions are listed in Table 54-4.<sup>64,65,97</sup>

## Medical Complications and Comorbid Conditions

The complications after heart transplantation reflect, in part, the premorbid status of the majority of transplant recipients who have vascular disease and other significant medical conditions. After 5 years, more than 90% of recipients have hypertension, at least 80% have hyperlipidemia, and more than 30% of patients have diabetes (Table 54-5).<sup>7</sup> Each year after transplantation, a larger number of patients develop clinically significant CAV, which is the major limitation of survival after transplantation. Almost 30% of recipients have CAV by 5 years, and at least half do so at 10 years. Likewise, progressive renal insufficiency is an insidious problem that has been addressed only since about 2007 by substitution protocols to limit the administration of calcineurin inhibitors.<sup>78,98</sup>

### Malignancy

The magnitude of overimmunosuppression in many transplant recipients is illustrated by the prediction of a 30% to 40% incidence of neoplasia in transplant recipients since 1980. The risk of fatal malignancy increases progressively in the years after transplantation, and there is a substantially higher risk in immunosuppressed patients than in the normal population. Posttransplantation lymphoproliferative disease and lung cancer are the most common fatal malignancies (Table 54-6).<sup>7</sup>

Risk factors for malignancy are multifactorial and include impaired immunoregulation, a synergistic effect with other carcinogens such as nicotine or ultraviolet light exposure, and oncogenic causes such as the Epstein-Barr virus and

papillomavirus. The cumulative amount of immunosuppression is positively correlated with risk of malignancy. The incidences of lymphoproliferative disease, skin and lip cancers, and Kaposi's sarcoma are particularly high. Malignancies account for 24% of deaths after 5 years. Accordingly, as illustrated in Table 54-4, transplantation teams must ensure that the transplant recipient is adequately screened on a regular basis for the development of cancer.<sup>99,100</sup>

### Diabetes

Patients who develop new-onset diabetes mellitus after transplantation are at increased risk for morbidity and mortality. Accumulating evidence suggests that long-term outcomes,

**TABLE 54–4** Commonly Used Drugs and Potential Drug Interactions with Immunosuppressants

Drug	Potential Interaction
Acyclovir	Increased nephrotoxicity with calcineurin inhibitors
Allopurinol	Increased bone marrow suppression with azathioprine
Amlodipine or felodipine	Increased levels of calcineurin inhibitor
Antacids	Decreased levels of mycophenolate mofetil
Antidepressants	Increased levels of calcineurin inhibitor
Cimetidine	Increased levels of calcineurin inhibitor
Calcineurin inhibitors	Increased levels of mycophenolate mofetil
Clotrimazole	Increased levels of calcineurin inhibitor
Colchicine	Increased toxicity of colchicine
Diltiazem	Increased level of calcineurin inhibitor; increased neurotoxicity
Erythromycin or clarithromycin	Increased level of calcineurin inhibitor; prolonged QT intervals
Ganciclovir or valganciclovir	Increased nephrotoxicity with calcineurin inhibitors; leukopenia
Iron	Decreased levels of mycophenolate mofetil
Ketoconazole	Increased levels of calcineurin inhibitor
Phenobarbital	Decreased levels of calcineurin inhibitor
Phenytoin	Decreased levels of calcineurin inhibitor, increased levels of phenytoin
Primidone	Decreased levels of calcineurin inhibitor
Rifampin	Decreased levels of calcineurin inhibitor
Statin drugs	Increased risk for myopathy/rhabdomyolysis
St. John's wort	Decreased levels of calcineurin inhibitor levels
Target of rapamycin inhibitors	Increased nephrotoxicity with calcineurin inhibitors
Trimethoprim-sulfamethoxazole	Increased nephrotoxicity with calcineurin inhibitors
Verapamil	Increased levels of calcineurin inhibitor

including patient survival and graft survival, may be adversely affected. New-onset diabetes is characterized by decreased B-cell insulin secretion and increased insulin resistance secondary to the effects of immunosuppression. Many cases of new-onset diabetes are attributed to the high-dose steroids used early after transplantation surgery, but it is now appreciated that the calcineurin inhibitors play an important role as well. Impaired B-cell function appears to be the primary mechanism underlying the induction of diabetes by calcineurin inhibitors.<sup>101,102</sup>

The risk factors for the development of diabetes after transplantation include obesity, increased age, family history of diabetes, abnormal glucose tolerance, and African American or Hispanic descent. Changing trends in the demographics of transplant recipients, such as increased age and increased body mass index, suggest that current patients may be at greater risk of new-onset diabetes than were earlier patients. In one study, transplant recipients older than 45 years were 2.9 times more likely to become diabetic after transplantation.<sup>102</sup> Higher body mass index increases risk of insulin resistance, and steroids can cause glucose intolerance, insulin resistance,

and frank hyperglycemia. African American patients are more likely to develop new-onset diabetes mellitus regardless of the immunosuppression used, but they are particularly susceptible after treatment with tacrolimus.<sup>64,97</sup> Unfortunately, there are very poor data about specific drugs to be used in the management of patients with new-onset diabetes after cardiac transplantation.

### Hypertension

The excess risk of hypertension is related primarily to the use of calcineurin inhibitors, both because of direct effects of the drugs on the kidney and because of the associated renal insufficiency that is also highly prevalent. The incidence of hypertension may be lower with tacrolimus than with cyclosporine.<sup>103</sup> Blood pressure elevation in this population is characterized by a disturbed circadian rhythm without the normal nocturnal fall in blood pressure and with a greater 24-hour hypertensive burden. Posttransplantation hypertension is difficult to control and often necessitates a combination of several antihypertensive agents.

### Renal Insufficiency

In a large registry of almost 70,000 recipients of nonrenal solid organ transplants, the risk of developing chronic renal failure was 16% at 10 years.<sup>104</sup> Various causes have been postulated for early renal insufficiency associated with calcineurin inhibitors, including renal arteriolar vasoconstriction directly mediated by calcineurin inhibitors, increased levels of endothelin-1 (a potent vasoconstrictor), and decreased nitric oxide production and alterations in the kidney's ability to adjust to changes in serum tonicity. Until the early 2000s, renal insufficiency, once present, progressed inexorably to renal failure. A number of new trials are in progress to evaluate the effects of substituting an mTOR inhibitor (sirolimus or everolimus) for a calcineurin inhibitor on renal function and on rejection episodes.<sup>78,98</sup>

### Hyperlipidemia

Hyperlipidemia occurs as commonly in transplant recipients as in the general population. The concern has been that in many studies, hyperlipidemia has been associated with the development of CAV, cerebrovascular, and peripheral vascular disease, and the attendant morbidity and mortality of these vascular disorders. Typically, total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels increase by 3 months after transplantation and then generally fall somewhat after the first year. A number of drugs commonly used after transplantation contribute to the hyperlipidemia observed. Corticosteroids may lead to insulin resistance, increased synthesis of free fatty acids, and increased production of very low density lipoprotein. Cyclosporine increases serum LDL cholesterol and binds to the LDL receptor, which decreases its availability to absorb cholesterol from the bloodstream; tacrolimus probably causes less hyperlipidemia. Sirolimus and mycophenolate mofetil also have unfavorable effects on lipid levels. Sirolimus in escalating doses has been shown to result in prominent elevation in triglyceride levels.<sup>64,97</sup>

Lipid-lowering therapy with any statin or with 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor was strongly associated with a marked improvement in 1-year survival in the Heart Transplant Lipid registry.<sup>105</sup> In heart transplant recipients, pravastatin and simvastatin have been associated with outcome benefits in survival, severity of rejection, and CAV,<sup>43,106</sup> whereas studies in kidney transplantation have not supported this finding. However, no long-term trials or data in this population have demonstrated improved outcomes with lowering LDL cholesterol levels to a specific target with more potent or higher dose statin therapy. Statins are metabolized differently, some by the cytochrome

**TABLE 54–5 Morbidity After Heart Transplantation for Adults\***

Outcome	Within 5 Years		Within 10 Years	
	Percentage with Known Response	Total N with Known Response	Percentage with Known Response	Total N with Known Response

cypheptadine (CYP) 3A4 and some by CYP2C9, and others are metabolized by a non-CYP mechanism in the liver. Thus, caution must be used in administration of statin drugs beyond the doses used in the randomized trials of simvastatin and pravastatin.<sup>97</sup> Transplantation teams must develop a coherent strategy about the goal and target doses of statins in their transplant recipients.

### Cardiac Allograft Vasculopathy

The development of CAV remains the most disheartening long-term complication of heart transplantation; the annual incidence rate is 5% to 10%. The prognosis of heart transplant recipients is largely determined by the occurrence of CAV; after the first postoperative year, CAV becomes increasingly prevalent as a cause of death. CAV can develop as early as 3 months after transplantation and is detected angiographically in 20% of grafts at 1 year and in 40% to 50% at 5 years.<sup>107,108</sup> In contrast to eccentric lesions seen in atheromatous disease, CAV results from neointimal proliferation of vascular smooth muscle cells, so that it is a generalized process. Typically, the condition is characterized by concentric narrowing that affects the entire length of the coronary tree, from the epicardial to intramyocardial segments, which leads to rapid tapering, pruning, and obliteration of third-order branch vessels. The majority of affected patients do not experience anginal symptoms because of denervation of coronary arteries. The first clinical manifestation of CAV may include myocardial ischemia and infarction, heart failure, ventricular arrhythmia, or sudden cardiac death.

The causes of CAV are multifactorial. The risk of CAV increases as the number of HLA mismatches and the number and duration of rejection episodes increase. Various nonimmunological factors have been associated with development of CAV, including cytomegalovirus infection of the recipient, donor or recipient factors (e.g., age, gender, pretransplantation diagnosis), and factors related to surgery (ischemia-reperfusion injury). Classic risk factors for vascular disease such as smoking, obesity, diabetes, dyslipidemia, and hypertension also increase the risk for CAV.

In an effort to detect the development of CAV, transplantation teams must devise an approach to screen for the disease and, when it is found, control its progression. The usefulness of coronary angiography is limited by the fact that CAV produces concentric lesions that affect the distal and small vessels, often before becoming apparent in the main epicardial vessels. Intravascular ultrasonography is currently the most sensitive imaging technique for studying early CAV. Intravascular ultrasonography provides quantitative information about vessel wall structure and lumen dimensions. An increase in intimal thickness of at least 0.5 mm in the first year after transplantation is a reliable indicator of both CAV development and 5-year mortality.<sup>109,110</sup> However, the increased invasiveness and cost of intravascular ultrasonography preclude its widespread application. Dobutamine stress echocardiography has high sensitivity (83-95%) and specificity (between 53% and 91%) in comparison with angiographic CAV and even greater specificity than intravascular ultrasonography in

detecting disease.<sup>111</sup> Most transplantation centers perform one of these screening tests on an annual basis to assess the risk of new CAV.

The only definitive treatment of CAV is a second heart transplantation procedure. Other approaches, such as implantation of coronary stents and angioplasty, may have high restenosis rates and are unlikely to be effective because of the diffuse nature of the process.<sup>112,113</sup> Another approach to the prevention of CAV is the use of pravastatin and simvastatin. These drugs effectively repress the induction of major histocompatibility complex class II (MHC-II) expression by interferon- $\gamma$  and thereby inhibit T-cell proliferation. In addition, statins have a direct influence on the expression of genes for growth factors that are essential for the proliferation of smooth muscle cells. Randomized controlled trials have shown that both drugs result in significantly lower cholesterol levels, significantly improved survival rates, significantly fewer severe rejections, and a significantly lower incidence of CAV.<sup>110,114</sup> It is not clear whether other statin drugs have the same benefit in this population.

Researchers have increasingly examined the efficacy of sirolimus and of everolimus in preventing the development or progression of CAV in heart transplant recipients. The precise role of the two drugs in maintenance immunosuppression has not yet been determined, but they are frequently used and hold the promise of reducing coronary intimal thickening once CAV has been detected.<sup>107</sup>

#### New Health Problems

Patients waiting for a heart transplant should have an updated review of immunizations, and yearly influenza vaccines should be encouraged thereafter, along with the periodic pneumococcal vaccine.<sup>115</sup> Vaccines with live viral particles must be avoided by immunocompromised transplant recipients. In general, a comprehensive visit is scheduled at the anniversary of the transplantation procedure so that annual issues may be reviewed, beyond the typical cardiovascular problems addressed so frequently in the first year. These include thorough skin and eye examinations and recommended screening examinations such as mammography, colonoscopy, and rectal and pelvic examinations, according to guidelines. This is the opportune time to reinforce the necessity of regular physical exercise, maintenance of ideal body weight, abstinence from tobacco, and moderation with alcohol. The annual examination is also the occasion when many transplantation teams look more carefully for the presence of CAV.

In many centers, recipients are prescribed daily aspirin to prevent further vascular disease, but no randomized trials have evaluated the benefits of antiplatelet therapy in heart transplant recipients. Likewise, most recipients are given vitamins, stool softeners, iron supplements, and proton pump inhibitors early after surgery, primarily on the basis of empirical findings. These are part of the decisions that must be made on a programmatic basis for the transplant recipient (see Table 54-4).

The development of osteoporosis is a major problem in the population of transplant recipients, and vertebral fractures are common and result in marked debilitation; prophylaxis with calcium and vitamin D is usually initiated. At least 50% of patients before transplantation have evidence of osteopenia, and osteoporosis is common among patients with advanced heart failure.<sup>116</sup> Glucocorticoids given after transplantation surgery are a major contributor to additional bone loss; most bone loss occurs in the first 6 to 12 months.

Depression, a common finding in patients with heart failure, occurs in up to 25% of transplant recipients and can interfere remarkably with a satisfactory recovery. A number of antidepressants may be prescribed, but the potential for adverse drug interactions must be considered (see Table 54-5).

The management of gout may also be difficult because of drug interactions. Colchicine may increase the risk of myoneuropathy, and nonsteroidal anti-inflammatory drugs often cause worsening renal insufficiency and hyperkalemia. Allopurinol and azathioprine administered together can cause life-threatening neutropenia. Thus, transplant recipients must be instructed to discuss any new medicines prescribed to them with the transplantation team before they take these medicines.<sup>64,97,117</sup>

Physicians outside the transplantation center may be reluctant to care for the heart transplant recipient, which complicates the comprehensive management of these patients. Ideally, primary care physicians could provide a very important and early intervention that might be life-saving. The most common errors made by referring physicians who are unaware of normal transplantation procedures are the prescriptions of new drugs that result in adverse drug interactions (see Table 54-5). Both calcineurin inhibitors are metabolized in the liver by the cytochrome P-450 enzyme system. The activity of this system is influenced by hepatic dysfunction. Inducers of CYP3A4 include amiodarone, rifampin, and phenytoin; these drugs have the potential to lower the levels of calcineurin inhibitors. Agents that inhibit CYP3A4, and also raise levels of the immunosuppression regimen, include antifungals, macrolide antibacterials, calcium channel antagonists, and grapefruit juice.<sup>117</sup>

Physicians must use a higher index of suspicion when evaluating the possibility of infection in a transplant recipient, who must always be considered an immunocompromised host. Physicians unaccustomed to caring for infection-prone transplant recipients may inadvertently miss an important manifestation of an infectious disease, especially early in the posttransplantation course. Again, communication with the transplantation team should be fostered as a strategy to prevent these and countless other problems.

## OUTCOMES AFTER HEART TRANSPLANTATION

### Survival

Figure 54-5 depicts the latest data from the International Society for Heart and Lung Transplantation regarding overall transplantation survival.<sup>7</sup> During the first year after transplantation, early causes of death are graft failure, infection, and rejection, with an overall 1-year survival rate of 87%. Interestingly, although worldwide approaches to the management of cardiac transplant recipients are substantially different from center to center, the outcomes are surprisingly similar. The 5-, 10-, and 15-year rates of survival after heart transplantation were very comparable in two centers: one in Nantes, France,<sup>100</sup> and one in Utrecht, The Netherlands (Figure 54-6).<sup>118</sup> Indeed, this phenomenon of similar outcomes despite marked differences in programmatic management may be regarded as a testament to the overall antirejection strategy. Nonspecific graft failure accounted for 41% of deaths during the first 30 days after transplantation, whereas noncytomegalovirus infection was the primary cause of death during the first year. After 5 years, CAV and late graft failure (31% together), malignancy (24%), and noncytomegalovirus infection (10%) were the most prominent causes of death.<sup>18,44,119</sup>

### Functional Outcomes

By the first year after transplantation surgery, 90% of surviving patients report no functional limitations, and approximately 35% return to work.<sup>120</sup> These statistics may change

**FIGURE 54-5** Overall survival after heart transplantation among 74,267 first-time recipients; the 10-year survival rate was at least 50%. (From Hertz MI, Aurora P, Christie JD, et al. Registry of the International Society for Heart and Lung Transplantation: a quarter century of thoracic transplantation. *J Heart Lung Transplant* 2008;27:937-942.)

**FIGURE 54-6** Overall rates of survival 5, 10, and 15 years after heart transplantation in Nantes, France, and Utrecht, The Netherlands. Note that the outcomes in the two countries are similar. (Data from Roussel JC, Baron O, Perigaud C, et al. Outcome of heart transplants 15 to 20 years ago: graft survival, post-transplant morbidity, and risk factors for mortality. *J Heart Lung Transplant* 2008;27:486-493; and Tjang YS, van der Heijden GJ, Tenderich G, et al. Survival analysis in heart transplantation: results from an analysis of 1290 cases in a single center. *Eur J Cardiothorac Surg* 2008;33:856-861.)

as the demographics of cardiac transplant recipients evolve. There are numerous challenges for optimal functional outcomes, not the least of which are nonreimbursement for cardiac rehabilitation programs by many third-party payers in the United States and the reluctance of many U.S. employers to hire transplantation survivors. Adapting to life after transplantation involves a variety of pretransplantation factors, including the patient's duration of illness, personality, intelligence, social support, and financial well-being.

The heart transplantation procedure markedly reduces cardiac filling pressures observed in the recipient before transplantation and augments cardiac output. During exercise, maximal cardiac output may be abnormal, as a result of denervation, limited atrial function, decreased myocardial compliance from rejection or ischemic injury, and donor-recipient size mismatch.<sup>121</sup> Much of this hemodynamic abnormality may be normalized with regular exercise.<sup>122,123</sup> Immediately after surgery, a restrictive hemodynamic pattern is frequently observed that gradually improves over a few days to weeks. Approximately 10% to 15% of recipients develop a chronic restrictive-type response during exercise that may produce fatigue and breathlessness. In the absence of parasympathetic innervation that normally lowers the heart rate,

the resting heart rate of a recipient is typically 90 to 115 beats per minute. Likewise,  $\beta$ -blockers may further impair exercise response in transplant recipients and should not be first-line therapy for hypertension in this population.

## FUTURE DIRECTIONS

Heart transplantation is one of multiple competing therapeutic options for treating advanced heart failure, including “destination” or permanent mechanical circulatory support (see Chapter 56). As newer therapies, such as cell transplantation (see Chapter 51) and better permanent mechanical devices, become available, the role of heart transplantation will need to be redefined as the therapy of choice. Moreover, the cost effectiveness of the transplantation procedure will decrease if 40% to 50% of patients require a VAD preoperatively. Organ allocation may need to be reconsidered in this era of rapid HLA typing and virtual crossmatching.

An ideal immunosuppressive regimen for cardiac transplantation will prevent cellular rejection, retard the development of CAV, have no nephrotoxicity, and produce negligible morbidity with regard to lymphoproliferative disease and opportunistic infections. The development of renal-sparing strategies in transplant recipients is one of the most significant therapeutic challenges. This and other modifications of the standard regimen must be explored in future trials. Trial networks to investigate some of these newer ideas or therapies must be established to facilitate research in this fragile population.

In the United States, there is now an acknowledged secondary subspecialty in medicine specifically for cardiologists who want to acquire expertise in the care of the heart transplant recipient.<sup>124</sup> Surgical training has allowed for the increased skill required to manage the wide array of mechanical circulatory support devices used to sustain the patient with advanced heart failure. Mechanisms to fund the prolonged training of these transplantation specialists, and other transplantation personnel, must be found in an increasingly impoverished health care system.

## Conclusions, 814

not yet achieved their goal as a readily available alternative to transplantation for advanced heart failure (see Chapter 56). However, the advent of axial flow LVADs as bridges to transplantation has markedly improved outcomes for transplant recipients. Ongoing trials with new-generation LVADs for chronic or “destination therapy” are expected to demonstrate improved outcomes and result in more widespread use (see Chapter 56). As the numbers of patients suffering from advanced heart failure continue to grow and the availability and feasibility of cardiac transplantation and assist devices may not meet that growing demand, a substantial number of patients with heart failure will probably become candidates for and derive benefit from heart failure surgery.

Because heart failure is a continuous disease process with ongoing detrimental reverse remodeling of the ventricles, insights into its pathophysiological features have led to major advances in surgical therapies (see Chapter 15). Contemporary surgical techniques and devices are attempts to restore the geometry of the failing ventricle and thereby arrest or reverse the adverse remodeling processes. As a result, cardiac function and subsequent outcomes have improved. Major advances in pharmacotherapy and imaging modalities have helped the surgical team select patients who will benefit most from surgical treatment of advanced heart failure. The management of chronic heart failure yields the best results through a combined medical and surgical approach, both of which are possible with a multidisciplinary team.

In this chapter, current and evolving surgical strategies for treating congestive heart failure are reviewed, with a focus on three major areas: revascularization

for ischemic heart disease, operations for valvular lesions, and ventricular remodeling surgery. Of course, patients’ needs in these three areas often overlap; for example, a patient with ischemic cardiomyopathy may undergo coronary artery bypass, mitral valve repair, and left ventricular (LV) reconstruction of scarred dyskinetic anterior infarcted segments.

## CORONARY REVASCLARIZATION FOR ISCHEMIC CARDIOMYOPATHY

### Definition and Epidemiology

Ischemic cardiomyopathy is currently defined as significantly impaired (LV) dysfunction (left ventricular ejection fraction [LVEF]  $\leq 35\%$  to  $40\%$ ) that results from coronary artery disease.<sup>1</sup> Ischemic cardiomyopathy is considered to be the most common cause of heart failure; it currently affects 2.5 million people in the United States, the annual incidence is 40,000 new cases, and the annual mortality rate is 200,000 (see Chapter 22).<sup>2</sup> Because of aging and increased cardiovascular risk profiles of the population in the United States, the population-attributable risk has been estimated to be as high as 68% among men and 56% among women.<sup>3</sup> In addition, according to a review of almost 2000 patients with symptomatic heart failure and LVEF lower than 40%, patients with ischemic cardiomyopathy had significantly worse outcomes than those with nonischemic cardiomyopathy.<sup>1</sup> In contrast, patients with single-vessel disease who had no history of myocardial infarction or revascularization had a prognosis similar to that in patients with nonischemic cardiomyopathy.

Older data from the Framingham Heart Study suggested that the prevalence of heart failure after a myocardial infarction is 14% at 5 years and 22% at 10 years.<sup>4</sup> However, more recent data showed this prevalence to be much higher, ranging from 10% at 2 years to more than 40% at 6.5 years after myocardial infarction.<sup>5,6</sup> Improved early revascularization, intensive care strategies, and heart failure therapies (medications and

devices, such as cardiac resynchronization therapy [CRT] and implantable cardioverter-defibrillator [ICD]) have increased survival of patients admitted with extensive myocardial infarcts; as a result, the number of late presentations of congestive heart failure has increased. The development of heart failure late after myocardial infarction is related to a variety of factors, including the size and location of the infarct, the presence of ischemic mitral regurgitation (IMR), and perhaps inflammatory status, as assessed by serum C-reactive protein level.<sup>5-7</sup> In addition, the risk of developing heart failure is also increased two to three times in patients with continuous angina, which suggests that myocardial ischemia contributes to the progressive LV dysfunction.<sup>8</sup> Therefore, strategies must be in place to detect and treat heart failure and ongoing, potentially reversible ischemia in patients who might benefit from coronary revascularization.

## Pathophysiology of Ischemic Cardiomyopathy

The mechanism most commonly involved in myocardial dysfunction secondary to ischemic cardiomyopathy is the loss of myocytes, which eventually leads to progressive reverse remodeling of the heart (see also Chapters 6 and 23).<sup>9</sup> The LV remodeling process after myocardial infarction is complex, involving myocyte stretch and slippage, a phenomenon that also occurs in the adjacent remote viable myocardium.<sup>10</sup> Ischemia-induced cellular changes include loss of myofibrils and disorganization of the structural proteins within the myocyte. In addition, extracellular changes, including fibrosis and alterations in the fiber orientation, cause changes in the geometrical shape of the heart.<sup>11</sup> Eventually, these processes lead to a progressive dilation of the ventricles with a subsequent increase in wall tension and impairment of systolic and diastolic function. Thus, the progressive loss of viable myocardium over time after the myocardial infarction is a continuous process that ultimately might be accompanied by the clinical heart failure syndrome.<sup>12</sup> However, restoration of myocardial blood flow in addition to surgical restoration of LV chamber geometry (section on left ventricular reconstruction surgery) might reverse this detrimental process.

Insights into the myocardial ischemia-induced changes on a cellular level help physicians to better determine which patients will benefit most from revascularization strategies (see also Chapter 23). Although transient ischemia can lead to a period of prolonged dysfunction even after the restoration of flow ("stunning"), persistent but asymptomatic ischemia might induce LV dysfunction ("hibernation") that can mimic nonischemic causes of heart failure. *Stunned myocardium* is used to describe a condition in which a short-term, total or near-total reduction of coronary blood flow produces an abnormality in regional LV wall motion of limited duration (hours or days) after reperfusion.<sup>13-15</sup> In contrast, *hibernating myocardium* is a state of persistently impaired myocardial and LV function at rest as a result of chronically reduced coronary blood flow that can be partially or completely restored to normal either by improving blood flow or by reducing oxygen demand.<sup>13-16</sup> If the hibernating myocardium is not treated in a timely manner, however, it may be associated with progressive cellular damage, recurrent myocardial ischemia, myocardial infarction, heart failure, and death.<sup>17</sup> Positron emission tomography (PET) has proved to be an excellent imaging modality for guiding selection of patients for revascularization strategies because it has shown that regions with abnormal wall motion may still be metabolically active and might therefore improve after revascularization.<sup>18</sup> Such regions are likely to appear hypokinetic, rather than akinetic or dyskinetic, during routine echocardiographic examination. In addition, the reduction in resting coronary blood flow in hibernating segments and the improvement after coronary intervention can be demonstrated by cardiovascular magnetic

resonance imaging (MRI).<sup>19</sup> Although in the clinical setting stunned myocardium is often superimposed on hibernation, or irreversible contractile dysfunction, earlier identification of hibernating myocardial regions with prompt myocardial revascularization is crucial in preventing and reversing the ongoing reverse remodeling process of the heart.

## Natural History of Ischemic Cardiomyopathy

The prognosis of patients after myocardial infarction depends on the extent of LV damage.<sup>20</sup> According to the Coronary Artery Surgery Study (CASS) registry, the 12-year survival rate among medically treated patients with LVEF lower than 35% was 21%, in comparison with 54% among patients with LVEF between 35% and 50%.<sup>21</sup> With current interventional techniques, survival rates have improved, especially with the addition of angiotensin-converting enzyme (ACE) inhibitors,  $\beta$ -blockers, statins, implantable CRT devices, and defibrillators to the armamentarium of heart failure therapy. However, one study demonstrated that after a mean follow-up period of 4.4 years, of the patients who had developed ischemic cardiomyopathy, 34% had died and 4.6% had undergone cardiac transplantation.<sup>22</sup> In those patients, outcomes were worse than in patients with an idiopathic or peripartum cardiomyopathy but considerably better than in patients with infiltrative, chemotherapy-induced, or human immunodeficiency virus (HIV)-induced cardiomyopathy (Figure 55-1).

## Selection of Appropriate Candidates for Revascularization

### Clinical Trials

No randomized clinical trial has been performed to evaluate the outcome of coronary artery bypass graft (CABG) surgery in patients with advanced ischemic cardiomyopathy (see also Chapter 23). However, in January 2002, a randomized, multicenter, international clinical trial, Surgical Treatment of Ischemic Heart Failure (STICH), was initiated to compare contemporary medical therapy plus CABG, medical therapy alone, and CABG with or without surgical ventricular restoration for patients with congestive heart failure and coronary heart disease. The STICH trial is sponsored by the National Heart, Lung, and Blood Institute as well as industry sponsors and has recruited 2212 patients with heart failure, LVEF lower than 35%, and coronary artery disease amenable to CABG at 127 clinical sites. The Hypothesis 1 group consists of 1212 patients, of whom 602 were randomly assigned to receive medical therapy alone and 610 were randomly assigned to receive medical therapies plus CABG. Follow-up assessment is ongoing, and the results have not yet been reported.

The other 1000 patients in the STICH trial had dominant anterior dyskinesia or akinesia of the left ventricle and had been assigned to receive surgery; they were further randomly assigned to undergo CABG surgery alone or CABG plus surgical ventricular restoration. These patients represent the Hypothesis 2 group.<sup>23</sup> Surgical ventricular reconstruction (SVR) reduced the end-systolic volume index by 19%, in comparison with a reduction of 6% with bypass surgery alone. New York Heart Association (NYHA) class of heart failure and 6-minute walk distance improved from baseline to a similar degree in the two groups in Hypothesis 2. However, no significant difference was observed in the primary outcome (death from any cause or hospitalization for cardiac causes), which occurred in 59% who were assigned to undergo CABG alone and in 58% who were assigned to undergo CABG with SVR ( $P = .90$ ). The addition of SVR to CABG reduced the LV volume, in comparison with CABG alone, but the seemingly beneficial ventricular remodeling was not associated with a greater improvement in symptoms or exercise tolerance or with a reduction in the rate of death or hospitalization for

**FIGURE 55-1** Outcomes of patients with cardiomyopathy, stratified by cause. HIV, human immunodeficiency virus. (From Felker GM, Thompson RE, Hare JM, et al. Underlying causes and long-term survival in patients with initially unexplained cardiomyopathy. *N Engl J Med* 2000;342:1077-1084.)

cardiac causes (see Figure 23-11). A disappointing finding was that the surgical strategies to reduce ventricular volume that have been examined in clinical trials (STICH, trials with the Acorn support device, trials with partial left ventriculectomy) have failed to provide the beneficial clinical outcomes that were anticipated.

The three major randomized clinical investigations of CABG versus medical management—the Veterans Administration Cooperative Study,<sup>24</sup> the European Coronary Surgery Study,<sup>25</sup> and CASS<sup>26</sup>—have excluded patients with heart failure or severe LV dysfunction. Such patients have been traditionally considered too “high risk” because of the severe LV dysfunction, and their conditions were deemed inoperable. This category of patients with end-stage ischemic cardiomyopathy accounts for 40% to 50% of heart transplantations performed.<sup>27</sup> Even with contemporary heart-failure treatment, a significant amount of these patients die while awaiting heart transplantation, and because of existing comorbid conditions, organ shortage, or both, others are too fragile to undergo transplantation.<sup>28</sup> In addition, survival of patients with viable ischemic myocardium is reduced when revascularization is not undertaken.<sup>29</sup> Therefore, each patient with ischemic cardiomyopathy must be carefully evaluated to determine the suitability for revascularization.

#### Clinical Factors

In the selection of candidates for revascularization, several clinical factors might play a role, including the presence of angina, suitability of target vessels for bypass grafting, heart failure symptoms, LV dimension, and the severity of hemodynamic compromise.<sup>30</sup> The absence of angina should not preclude consideration for surgical revascularization; however, there is little information about the percentage of patients with heart failure who have silent ischemia that might be ameliorated by revascularization.

#### Myocardial Viability

Patients with ischemic cardiomyopathy are heterogeneous with regard to adequacy of target vessels for revascularization, ischemic jeopardy, and myocardial viability (see also Chapters 36 and 23). Therefore, clinicians should use utmost care in preoperatively selecting patients who will benefit most from revascularization. Most researchers have found that revascularization of hibernating myocardium in patients with ischemic cardiomyopathy improves both survival and LV function in comparison with medical therapy alone, regardless of the

preoperative degree of LV dysfunction.<sup>18,31-36</sup> However, in many of these studies, the presence of angina was also a criterion for enrollment, which may have served as a clinical indicator of the extent of viability. Moreover, these types of studies have important limitations, including bias in selecting patients who undergo CABG, a lesser likelihood that negative findings will be published, and—because contemporary standard medical therapies (e.g., statins) are not used and internal mammary artery grafts are underused—uncertainty of applicability to current practice. Nevertheless, revascularization should be considered, because augmentation of coronary flow to viable ischemic or hibernating myocardium will improve LV function and survival. Several noninvasive imaging modalities may identify patients who have ischemic or hibernating myocardium amenable to revascularization surgery if adequate target vessels exist. The information concerning the myocardial viability that these modalities can provide differs because the different techniques depend on the inotropic reserve (dobutamine stress echocardiography [DSE]), demonstration of cell membrane integrity (thallium-201 imaging), preserved myocardial metabolism (PET with 2-[fluorine-18]-fluoro-2-deoxy-D-glucose [<sup>18</sup>FDG]), or the absence of scar tissue (gadolinium-enhanced MRI) in areas of dysfunctional myocardium.

DSE has been useful in the preoperative prediction of viable myocardium; it has an overall specificity of 91% and sensitivity of 68% for prediction of segmental recovery (see also Chapter 36).<sup>37</sup> DSE is used to examine the inotropic reserve of dysfunctional but viable myocardium. Viable myocardium exhibits improved regional contractile function (inotropic reserve), as assessed by simultaneous transthoracic echocardiography, in response to dobutamine. Segmental wall motion is monitored during infusion of increasing doses of dobutamine. Augmentation of segmental wall motion beginning at a low dose and continuing during higher doses of dobutamine (uniphasic response) is suggestive of myocardial stunning. However, augmentation at low doses followed by a reduction in function at higher doses (biphasic response) is indicative of ischemia and hibernation. Of importance is that the prevalence of contractile reserve among patients with ischemic cardiomyopathy is independent of the angiographic extent and severity of coronary disease.<sup>38</sup> A contractile response to dobutamine appears to require at least 50% viable myocytes in a given segment and is correlated inversely with the extent of interstitial fibrosis observed on myocardial biopsy samples.<sup>39</sup>

In *single photon emission computed tomography* (SPECT) with thallium-201 scintigraphy, thallium-201 is used as a

perfusion tracer because it has a high (80%) first-pass myocardial extraction fraction across physiological ranges of myocardial blood flow (see also Chapter 36). The myocardial uptake is a process requiring cell membrane integrity, and this fraction is therefore indicative of regional perfusion, as well as myocardial viability. Several approaches have been used to optimize the information obtained from thallium-201 scintigraphy, mostly involving a baseline stress image and one or two delayed images (4-hour redistribution and 24-hour late-delayed imaging). Regional thallium-201 redistribution activity represents the extent of regional myocardial viability; therefore, thallium-201 scintigraphy after a single stress injection has become the standard imaging technique for determining such viability. The demonstration of reversible ischemia by the conventional 4-hour stress-redistribution protocol implies the presence of viable myocardium. However, up to 50% of segments that have fixed defects at 4 hours might nonetheless recover either perfusion or function after revascularization.<sup>40,41</sup> Therefore, several modifications of the 4-hour stress-redistribution protocol were developed to improve the accuracy of viability detection. Late (24-hour) redistribution or immediate reinjection of a second, smaller dose of thallium-201 after the redistribution images often enables visualization of segments in a significant number of perfusion defects that had been deemed fixed by imaging at only 4 hours. In comparison with DSE, myocardial perfusion scintigraphy can identify segments with fewer viable myocytes. In one series, for example, DSE and thallium-201 scintigraphy showed equivalent sensitivity among segments with more than 75% viable myocytes (78% vs. 87%), but DSE was much less sensitive among segments with 25% to 50% viable myocytes (15% vs. 82%).<sup>42</sup> However, in comparison with thallium-201 scintigraphy, DSE was found to have greater specificity and positive predictive value in forecasting functional recovery after revascularization.<sup>43</sup>

PET is often considered the gold standard for evaluating myocardial perfusion and viability (see also Chapter 36).<sup>44</sup> Its advantage is that it enables clinicians to assess perfusion and metabolism simultaneously. PET requires the use of positron-emitting radionuclides, which are incorporated into physiologically active molecules. Ischemia shifts myocyte metabolism from fatty acids to glucose. Thus, uptake of a glucose analogue, <sup>18</sup>FDG, by myocytes in an area of dysfunctional myocardium indicates metabolic activity and, thus, viability. Regional perfusion can be assessed simultaneously with an agent that remains in the vascular space, thereby demonstrating blood flow (such as nitrogen-13 ammonia or rubidium-82). As a result, PET has the potential to differentiate between normal, stunned, hibernating, and necrotic myocardium. The presence of enhanced <sup>18</sup>FDG uptake in regions of decreased blood flow (known as “PET mismatch”) is diagnostic for hibernating myocardium, and a concordant reduction in both metabolism and flow (“PET match”) is thought to represent predominantly necrotic myocardium. Regional dysfunction in the presence of normal perfusion is indicative of stunning. Of importance is that myocardial segments with significant reductions in both blood flow and <sup>18</sup>FDG uptake have only a 20% chance of functional improvement after revascularization, whereas dysfunctional hibernating territories have approximately an 85% chance of functional improvement after revascularization.<sup>18,45-47</sup> The greater the number of viable myocardial segments, the greater the likelihood that revascularization will improve global LV function and consequently improve heart failure symptoms and survival.

Contrast medium-enhanced *cardiac magnetic resonance (CMR) imaging* can be used to establish the presence of hibernating myocardium (see also Chapter 36). Regions of myocardium that exhibit late (or delayed) enhancement 10 minutes after the injection of gadolinium-diethylenetriaminepenta-acetic

acid (Gd-DTPA) are areas of myocardial necrosis and irreversible injury; regions that fail to hyperenhance are viable. In addition, quantitative perfusion assessment can document the reduction in resting coronary blood flow in hibernating segments. The degree and transmural extent of enhancement with contrast-enhanced CMR imaging are inversely related to the potential of recovery of LV function after revascularization.<sup>48,49</sup>

Magnetic resonance myocardial tagging is another CMR method that quantifies local myocardial segment shortening throughout the LV myocardium and across the LV wall thickness. This method can be combined with low-dose dobutamine infusion to quantify the amount of myocardial viability, on the basis of end-diastolic wall thickness combined with dobutamine-induced systolic wall thickening; together, these methods may provide a better prediction of LV functional recovery. For example, end-diastolic wall thickness of more than 10 mm preoperatively, in combination with dobutamine-induced systolic wall thickening of 2 mm or more in 50% or more of dysfunctional segments, is well correlated with postoperative improvement in function; however, only 4% of the segments with an end-diastolic wall thickness of less than 6 mm will improve.<sup>50</sup> In comparison with DSE, dobutamine CMR has higher sensitivity (86% vs. 74%) and specificity (86% vs. 70%), but it is more labor intensive and more technically challenging.<sup>51</sup> Unlike nuclear scintigraphy and DSE, which appear to have limited predictive accuracy if more severe systolic dysfunction is present, contrast-enhanced CMR imaging has greater accuracy in segments with the most severe dysfunction, which represents another advantage of this technique.<sup>52</sup> At the Cleveland Clinic, CMR imaging has an established role in detecting the extent of viable myocardium and areas of scarring that might be amenable to reperfusion or other operative strategies that necessitate cardiopulmonary bypass.

## Risk of Revascularization

The most effective way of stratifying operative risk for cardiac surgical patients is to use a risk prediction algorithm that incorporates multiple variables to derive a risk score. Two of the algorithms most widely used for this purpose in the United States are the one developed by the Society of Thoracic Surgeons and the European System for Cardiac Operative Risk Evaluation (EuroSCORE); <http://www.euroscore.org/calculator>.<sup>53-57</sup> Both algorithms incorporate patient age, sex, comorbid conditions, and the severity and acuity of cardiac disease, and both can accurately predict 30-day mortality. One limitation of such risk prediction algorithms is their dependence on the patient data from which they were derived; as the patient population changes, and as surgical technique changes, risk analyses may soon become outdated.<sup>58</sup>

The presence of LV dysfunction and heart failure remains one of the most important independent predictors of operative mortality and other major adverse events after CABG (Figure 55-2).<sup>59</sup> In a prospective observational study of more than 8600 patients undergoing CABG between 1992 and 1997, the rate of operative mortality varied: less than 2% of patients with LVEF higher than 40%, 4% of those with LVEF of 20% to 40%, and 8% of those with LVEF lower than 20%.<sup>60</sup> However, the Cleveland Clinic reported lower in-hospital mortality rates for patients with normal (1.5%), moderately impaired (2.5%), or severely impaired (3.2%) LV function when they reviewed more than 14,000 cases of patients who underwent isolated CABG between 1990 and 1999. In addition, the Cleveland Clinic also reported that the numbers of patients at high risk had increased, but the surgical morbidity rate, adjusted for preoperative risk score, had fallen significantly from 14.5% (in 1986) to 8.8% (in 1994;  $P < .001$ ).<sup>61</sup>

**FIGURE 55-2** Predictive model for outcomes after coronary artery bypass graft (CABG). (From Kolh P. Importance of risk stratification models in cardiac surgery. *Eur Heart J* 2006;27:768-769.)

Additional determinants of mortality and morbidity risk include advanced age, female gender, comorbid conditions (e.g., diabetes, clinical cerebrovascular disease, renal dysfunction, significant chronic lung disease), prior CABG, and need for emergency bypass surgery or concomitant valve surgery.<sup>62,63</sup> However, improved surgical techniques with better myocardial protection and routine use of retrograde coronary sinus cardioplegia, together with a high level of experience and optimization of preoperative condition—all combined through a multidisciplinary approach—have reportedly improved outcomes.

## Benefits of Revascularization

In view of the advances in pharmacological treatments and the introduction of implantable CRT and ICD devices, it has been suggested that revascularization may not provide additional benefit for some patients with ischemic cardiomyopathy. However, unless the nonsurgical approaches can prevent further ischemic events from occurring and reverse the detrimental remodeling process, the presence of uncorrected coronary stenoses still threatens the survival of patients with ischemic cardiomyopathy. In addition, angina control seems to be best achieved by surgical revascularization in eligible patients. Surgically improving blood flow to hypoperfused but viable myocardium leads to functional improvement of the myocardium, with secondary effects of retarding or reversing ventricular remodeling, reducing the substrate for malignant ventricular arrhythmias, and ameliorating symptoms.

## Improvement in Symptoms of Congestive Heart Failure and in Functional Capacity

Several small-scale studies revealed marked improvement in symptoms after revascularization in patients with ischemic cardiomyopathy.<sup>64-67</sup> Besides reduction in angina, the improvement in NYHA functional class or heart failure symptoms is related to the amount of viable myocardium, which serves as a surrogate to predict positive reverse remodeling after CABG. For example, in one study, a blood flow–metabolism mismatch of more than 18% on PET was 76% sensitive and 78% specific in predicting a change in functional status after revascularization.<sup>64</sup> Another study showed a similarly significant improvement in functional capacity after revascularization, as reflected by the 34% increase in metabolic equivalents (from 5.6 to 7.5) in the group of patients with significant PET mismatch before revascularization.<sup>66</sup> Other investigators demonstrated a significant increase in peak oxygen consumption (15 to 22 mL/kg/min,  $P < .0001$ ) in a group of 34 patients with ischemic cardiomyopathy who underwent CABG.<sup>67</sup>

## Improvement of Left Ventricular Function

The improvement in LVEF after revascularization in patients with ischemic cardiomyopathy is typically related to the presence of myocardial viability. A review of 29 studies of 758 patients showed that LVEF increased 6% to 10% after revascularization when myocardium was viable, whereas no improvement in LVEF was noticed in the absence of viability.<sup>68</sup> After normal flow is restored in areas of hibernating myocardium, recovery of contractile function can take several days, weeks, or even months.<sup>32</sup> In addition, the improvement in LVEF can be associated with positive reverse LV remodeling, characterized by reductions in the LV end-systolic and end-diastolic dimensions with a less spherical shape of the ventricle.<sup>69,70</sup> The degree of improvement is significantly correlated with the number of segments that recover function after revascularization.<sup>69</sup> However, despite evidence of viability through noninvasive imaging techniques, late revascularization may not always result in measurable improvements in contractility.

After surgical revascularization in patients with ischemic cardiomyopathy, another predictor of potential improvement in LVEF is the LV end-diastolic dimension. Among patients in whom this dimension exceeds 7.0 cm (4.0 cm/m<sup>2</sup>), not only is the operative mortality rate higher but also the chances of positive reverse remodeling are smaller. The effect of LV enlargement on the improvement in LV function after surgery was illustrated in a review of 61 patients with ischemic heart disease, LVEF of 28%, all of whom had evidence of myocardial viability.<sup>71</sup> However, despite the presence of substantial viability, one third of the patients did not exhibit any improvement in LVEF or any reduction in ventricular volume. In contrast, the other two thirds of the patients, who did experience significant improvement in LVEF, all had smaller LV end-systolic volumes.<sup>71</sup>

There is some evidence that presurgical medical therapy with  $\beta$ -blockers can increase the likelihood that surgical revascularization will improve outcomes and reverse remodeling when myocardium is viable. In the Carvedilol Hibernation Reversible Ischaemia Trial, Marker of Success (CHRISTMAS), study, 387 patients with ischemic cardiomyopathy were treated with carvedilol or placebo. At 6 months, a significant linear relationship between the number of cardiac segments with hibernating myocardium at baseline and improvement in LVEF was evident with carvedilol therapy, whereas the placebo-treated patients did not have any improvement in LVEF.<sup>72</sup> It was hypothesized that  $\beta$ -blockade may improve the function of hibernating myocardium by reducing myocardial oxygen consumption and increasing diastolic perfusion, which ultimately led to improved reverse remodeling.<sup>72</sup>

### Improvement in Survival

Reports of small observational studies have suggested that improved survival after CABG may not require an improvement in LV function.<sup>36</sup> Initial results of large observational studies, such as CASS, and a post hoc analysis from the Studies of Left Ventricular Dysfunction (SOLVD) trial suggested that CABG improved outcomes in comparison with medical therapy alone in patients with coronary artery disease and LV dysfunction.<sup>26,73,74</sup> In those studies, however, myocardial viability was not evaluated.

Results of subsequent observational studies suggested that the survival benefit with revascularization in ischemic cardiomyopathy was limited to patients with viable myocardium<sup>31,37,75-77</sup> (Figure 55-3). The potential survival benefit derived from revascularization was best demonstrated in a meta-analysis of 24 nonrandomized viability studies involving 3088 patients with coronary artery disease and LV dysfunction (mean LVEF = 32%).<sup>31</sup> Among patients with myocardial viability, revascularization produced a significant 80% reduction in annual mortality rate (3.2% vs. 16% with medical therapy). In addition, a direct relationship between the severity of LV dysfunction and the magnitude of benefit was noted. However, no difference in annual mortality with revascularization was observed in patients without myocardial viability (annual mortality 7.7% vs. 6.2% with medical therapy).

Similar findings of improved survival after revascularization were documented in patients with ischemic cardiomyopathy and hibernating (viable) myocardium, assessed by PET.<sup>76,77</sup> The rate of cardiac mortality was significantly lower among patients who underwent revascularization than among medically treated patients (13% vs. 24%). Among medically treated patients, the risk of cardiac mortality was more than three times higher than among patients undergoing surgical therapy when the extent of mismatch was higher than 20%. With 20% or lower mismatch, in contrast, there was no increase in mortality among patients treated medically or surgically. Unfortunately, randomized prospective clinical trials with background contemporary medical and device therapies are lacking; it is hoped that the ongoing STICH trial will shed light on this issue in the subset of patients who undergo nuclear imaging studies.

### Summary

Surgical revascularization currently remains an important treatment option for ischemic cardiomyopathy. Improvements in surgical techniques, together with novel imaging modalities and risk stratification models, with the goal of revascularizing only viable myocardium, have led to improved short- and long-term outcomes in nonrandomized clinical trials.

## VALVE SURGERY FOR LEFT VENTRICULAR DYSFUNCTION (see Chapter 29)

Many patients with heart failure or LV dysfunction have clinically significant valvular lesions. It is estimated that almost 50% of patients with LVEF lower than 35% have grades 3 to 4+ mitral regurgitation, and 35% have grades 3 to 4+ tricuspid regurgitation (see also Chapter 29).<sup>78</sup> Severe mitral or tricuspid regurgitation has been linked to adverse outcomes and increased mortality.<sup>78,79</sup> Valvular disease also frequently causes heart failure, and surgical treatment of many valvular lesions is a well-accepted therapy, especially for the aortic valve. However, other combinations of valve disorders with LV dysfunction are more controversial, and many patients have been thought too sick to withstand surgery. Historically, clinicians were taught that mitral valve replacement in patients with LVEF lower than 40% should not be performed because of the high operative mortality rate.<sup>80</sup> However, at

**FIGURE 55-3** Mortality stratified according to the presence or absence of viability in the patients who underwent medical revascularization (solid bars) and those who underwent surgical revascularization (open bars). (From Kolh, P. (2006). Importance of risk stratification models in cardiac surgery. *Eur Heart J*. 27:768-769 and Underwood SR, Bax JJ, vom Dahl J, et al. Imaging techniques for the assessment of myocardial hibernation. Report of a Study Group of the European Society of Cardiology. *Eur Heart J* 2004;25:815-836.)

that time, the mitral valve was replaced with a ball-in-cage prosthesis, and, simultaneously, both papillary muscles and the entire subvalvular apparatus were removed. Nowadays, the importance of an intact valvular-ventricular interaction is recognized. Together with changing surgical opinion more in favor of mitral repairs instead of replacements, interest has resurged in the field of valvular surgery as part of the treatment strategy for LV dysfunction. This section focuses mainly on surgical options for valvular disease in patients with severe LV dysfunction; surgical treatment for valvular lesions without or with mild to moderate LV dysfunction is either well accepted or further addressed in Chapter 29.

## Functional Mitral Regurgitation in Patients with Severe Left Ventricular Dysfunction

### Pathophysiology

The integrity of the saddle-shaped mitral valve is sustained by coaptation of the anterior and posterior leaflets in the annular plane during ventricular systole, in a design that decreases leaflet, annular, and chordal strain.<sup>81</sup> Six components are responsible for an optimal valve function: the valve annulus, leaflets, chordae tendineae, papillary muscles, LV myocardium, and left atrium; any one of them can exhibit defects that lead to mitral valve dysfunction. In ischemic and nonischemic cardiomyopathy, functional mitral regurgitation usually results from geometric abnormalities of the left ventricle and leads to dysfunction of a morphologically normal mitral valve. Enlargement of the left ventricle causes functional mitral regurgitation through annular dilation, an increase in the interpapillary muscle distance, increased leaflet tethering (elongation and stretching of the chordae tendineae because of cardiac enlargement), and decreased closing forces from muscle weakness, in addition to asynchrony of papillary muscle contractile timing.<sup>81-83</sup> The ultimate result is failure of coaptation of the morphologically normal leaflets and central mitral regurgitation (Figure 55-4). There is clear overlap between functional mitral regurgitation and ischemic IMR, and the reports of functional mitral regurgitation resulting from heart failure include cases of patients with ischemic cardiomyopathy. However, the clinical features and management of IMR, including mitral regurgitation in association with myocardial infarction, are discussed separately.

**FIGURE 55-4** Pathophysiological features of functional mitral regurgitation. CT, chordae tendineae; MV, mitral valve; PM, papillary muscle. (From Bursi F, Enriquez-Sarano M, Nkomo VT, et al. Heart failure and death after myocardial infarction in the community: the emerging role of mitral regurgitation. *Circulation* 2005;111:295-301.)

### Nonsurgical Treatment Options

As with mitral regurgitation resulting from primary valve disease, functional mitral regurgitation imposes an important hemodynamic load on the left ventricle, which contributes to further eccentric hypertrophy and dilation, which increases the degree of mitral regurgitation and heart failure; thus, a vicious cycle exists.<sup>84,85</sup> Fortunately, the treatment of heart failure has evolved from symptom-directed therapy to treatments capable of altering the natural history of the disease and sometimes the attenuation of functional mitral regurgitation. Medical and surgical therapy and, for patients with an interventricular conduction delay, CRT may be beneficial. Pharmaceutical therapies include antagonists of neurohormonal activation, such as ACE inhibitors, aldosterone receptor blockers, and  $\beta$ -adrenergic blocking agents, which can reverse adverse ventricular remodeling in heart failure.<sup>86</sup> In addition, in selected patients with electrical dyssynchrony, CRT has led to impressive positive remodeling and to molecular changes that favorably affect outcomes.<sup>87,88</sup> Through these actions, those therapies may also reduce the degree of functional mitral regurgitation. However, patients with advanced heart failure commonly present with significant mitral regurgitation despite the use of these therapies and are therefore often referred for cardiovascular surgical treatment.

### Mitral Valve Repair

Traditionally, the risk associated with surgical correction of mitral regurgitation in the setting of severe LV dysfunction was considered prohibitive. Bolling and colleagues<sup>89</sup> were the first to demonstrate that this approach was feasible and could be conducted with reasonably low morbidity. They used an undersized annuloplasty repair, which effectively corrected functional mitral regurgitation in patients with heart failure. In more than 200 patients with cardiomyopathy, LVEF lower than 20%, and severe functional mitral regurgitation, mitral valve repair was associated with 1-, 2-, and 5-year actuarial survival rates of 82%, 71%, and 52%, respectively.<sup>90</sup> In addition, NYHA class improved for all patients, and most patients also demonstrated an improvement in LVEF, end-diastolic volume, and cardiac index, together with a reduction in sphericity index at the 24-month follow-up assessment.<sup>90</sup> These results were confirmed by a case series at the Cleveland Clinic in which

improved survival rates and positive effects on reverse remodeling were documented, in addition to reduced numbers of hospitalizations for heart failure during the follow-up period.<sup>91</sup>

The most convincing evidence of the safety and efficacy of mitral valve repair for functional mitral regurgitation was obtained in the mitral valve surgery condition of the prospective Acorn Clinical Trial.<sup>92</sup> This study of the CorCap device involved 193 patients receiving optimal medical management who had significant functional mitral regurgitation, mean LVEF of 24%, mean LV end-diastolic diameter of 7 cm, and NYHA class III or IV heart failure; most patients (94%) had idiopathic cardiomyopathy. The patients underwent mitral valve repair with an “undersized” mitral annuloplasty ring (84%) or replacement valve surgery (16%). The survival rates were 98.4% 30 days after surgery and 85.2% at 24 months, and there was progressive and sustained evidence of LV remodeling after mitral valve surgery. The important outcomes were that mitral regurgitation was successfully abolished and the mitral valve repair was durable; 88.4% of patients had grade 0 or 1 mitral regurgitation after 2 years, and reoperation was required by only 2% of patients.

A weakness of all the aforementioned studies was that they lacked a comparable control group of subjects who did not undergo surgery. The findings of these observational surgical series were subsequently challenged by Wu and associates.<sup>93</sup> In a propensity-matched, nonrandomized analysis, 126 patients who underwent mitral valve annuloplasty were compared with 293 who did not. Although both groups had similar degrees of severe functional mitral regurgitation, no net improvement in long-term survival (or in the combined endpoint of mortality or urgent transplantation) was evident in the patients who underwent surgery, regardless of cause of heart failure (either ischemic or nonischemic). This provocative but retrospective study lacked follow-up on indexes of ventricular structural remodeling, lacked analysis of symptom improvement, inadequately controlled medical therapy, and provided little information on durability of the repair.

Together, these experiences demonstrate that in patients with congestive heart failure and functional mitral regurgitation, mitral valve repair with an undersized complete rigid annuloplasty ring and without alteration of the subvalvular apparatus can be performed safely with low 30-day operative mortality rates (<2%); this operation probably also has positive effects on reverse remodeling, if it is performed by surgeons experienced in mitral valve repair. However, only a randomized trial can definitively determine whether the surgery is associated with a mortality-related benefit. The lack of proven long-term benefit of mitral valve repair of functional mitral regurgitation is therefore also reflected in published guidelines from major societies. The 2009 heart failure guidelines of the American College of Cardiology/American Heart Association (ACC/AHA)<sup>94</sup> noted that the effectiveness of mitral valve repair or replacement for severe secondary mitral regurgitation in refractory end-stage HF was “not established” (class IIb, level of evidence C), and it was “not generally recommended” by the 2006 practice guidelines of the Heart Failure Society of America.<sup>95</sup> Therefore, if mitral valve repair is considered as an alternative to transplantation, the patient should be informed that although symptoms are often improved, there is no clear evidence of a long-term mortality-related benefit. Also, factors that generally preclude mitral valve repair in patients with advanced heart failure include primary mitral valve disease not amenable to repair, severe aortic insufficiency, and long-standing mitral regurgitation antedating the onset of LV dysfunction with marked LV enlargement or the dependence on inotropic therapy.

## Ischemic Mitral Regurgitation in Patients with Severe Left Ventricular Dysfunction

### Pathophysiology

IMR is a complication occurring most often after a myocardial infarction with permanent damage to the papillary muscle or adjacent myocardium. In addition, it might occur with acute ischemia, but it typically disappears after the ischemia resolves. However, preexisting mitral regurgitation may become more severe in the presence of superimposed ischemia. Although IMR is, in rare cases, caused by a papillary muscle rupture, which always mandates urgent surgery, most affected patients have “functional” IMR, similarly to the functional mitral regurgitation in dilated cardiomyopathy, in which the papillary muscles, chordae, and valve leaflets are normal but there is poor coaptation of the leaflets, and restricted leaflet motion is frequently noted on echocardiography. However, there are two important differences between the conditions. First, in comparison with patients who have dilated cardiomyopathy, many patients with IMR are in need of CABG, and so clinicians often must decide whether the mitral valve should or should not be treated. Second, whereas the LV dilation in dilated cardiomyopathy is more spherical, patients with ischemic cardiomyopathy have one or more segments of hypokinesia, akinesia, or dyskinesia that lead to local LV remodeling, thereby altering the geometrical shape of the left ventricle in a different way. Many clinicians still use the term “papillary muscle dysfunction” to describe patients with IMR, but this is a misnomer because papillary muscle dysfunction alone does not explain the mechanism of IMR. The papillary muscle is dysfunctional because the LV wall—especially the posterolateral segment, on which it is inserted—is dysfunctional and the geometry of the ventricle is disturbed. Therefore, IMR is a more complex pathological process whose successful repair is also more challenging. These important questions related to IMR, including repair versus replacement and CABG alone versus CABG with mitral valve surgery, are being addressed in ongoing surgery network clinical trials sponsored by the National Heart, Lung, and Blood Institute: Comparing the Effectiveness of Repairing Versus Replacing the Heart’s Mitral Valve in People with Severe Chronic Ischemic Mitral Regurgitation (<http://clinicaltrials.gov/ct2/show/NCT00807040>) and Comparing the Effectiveness of a Mitral Valve Repair Procedure in Combination with Coronary Artery Bypass Grafting (CABG) Versus CABG Alone in People with Moderate Ischemic Mitral Regurgitation (<http://clinicaltrials.gov/ct2/show/NCT00806988>).

### Mitral Valve Repair

Patients with ischemic cardiomyopathy should be treated with the usual therapies for heart failure, including pharmaceutical agents and pacing therapies. However, medical therapy does not play a major role in the management of IMR itself. Among patients who have IMR in association with an acute myocardial infarction, reperfusion can sometimes reduce localized LV remodeling and prevent or treat IMR, especially in acute situations. However, the optimal surgical treatment of IMR long after the myocardial infarction is a matter of controversy, and there is wide variation in practice among cardiovascular surgeons. Much of this controversy stems from the lack of good data addressing this issue. Although it is believed that mitral valve repair is preferred over mitral valve replacement, there have been no randomized trials in which mitral valve repair has been compared with replacement with CABG or in which CABG alone has been compared with CABG plus mitral valve repair. The ongoing clinical trials of the Cardiothoracic Surgical Trials Network (<http://www.ctsurgery.net/currenttrials.html>) and future results will provide the necessary evidence.

Observational series have yielded conflicting results about the effect of late revascularization with or without mitral valve surgery for the reduction of IMR. According to a review in which CABG was performed in 136 patients with moderate to severe IMR, 40% continued to have moderate to severe (grade 3+ to 4+) mitral regurgitation, 51% had some improvement to mild (grade 2+) mitral regurgitation, and 9% even experienced a total disappearance of mitral regurgitation.<sup>96</sup> In addition, another group reported that among patients with moderate to severe IMR, mitral valve surgery at the time of CABG may not improve either symptom status or survival in comparison with CABG alone.<sup>97</sup> The Cleveland Clinic reported the largest series so far in which CABG plus mitral valve annuloplasty ( $n = 290$ ) was compared with CABG alone ( $n = 100$ ) for patients with ischemic cardiomyopathy and moderate or severe functional IMR.<sup>98</sup> Groups were propensity-matched according to demographics, extent of coronary disease, regional wall motion, and findings on quantitative echocardiography. The 1-, 5-, and 10-year survival rates were 88%, 75%, and 47% after CABG alone and 92%, 74%, and 39% after CABG with mitral valve annuloplasty ( $P = .6$ ) (Figure 55-5). However, patients undergoing CABG alone were more likely to have grade 3+ or 4+ postoperative mitral regurgitation than were those undergoing CABG with mitral valve annuloplasty (48% vs. 12% at 1 year;  $P < .0001$ ) (Figure 55-6). Nevertheless, the NYHA functional class substantially improved in both groups ( $P < .001$ ) and remained improved at 5 years. The authors therefore concluded that although CABG with mitral valve annuloplasty reduces postoperative IMR and improves early symptoms in comparison with CABG alone, it does not improve long-term functional status or survival in patients with severe functional IMR. They hypothesized that mitral valve annuloplasty alone, without addressing the underlying ventricular disease, was probably insufficient to improve long-term clinical outcomes. Therefore, although revascularization with mitral valve repair probably does improve symptoms and reduces IMR more than does CABG alone in patients with ischemic cardiomyopathy, no data confirm that long-term outcomes are better.

## Tricuspid Valve Surgery in Patients with Severe Left Ventricular Dysfunction

Tricuspid regurgitation is a very common abnormality and frequently not addressed during heart failure surgery. Regardless of cause, tricuspid regurgitation is associated with decreased survival.<sup>85,99</sup> In heart failure, the type of tricuspid regurgitation is almost always functional, being caused by dilation of the right ventricle and the tricuspid annulus as a result of high pulmonary artery pressures induced by left-sided heart failure. It leads to backward flow of blood into the right atrium during systole; when the tricuspid regurgitation is only mild or moderate, this has no major hemodynamic consequences because the right atrium is very compliant. However, when tricuspid regurgitation is severe, right atrial and central venous pressure rises, which results in signs and symptoms of right-sided heart failure and eventually a reduced forward cardiac output.

There is a preconceived notion that correction of high pulmonary artery pressures can result in improvement in tricuspid regurgitation, even if severe, if the regurgitation is functional and intrinsic valvular disease is not present. However, data from the Cleveland Clinic show that in 845 patients with moderate or severe tricuspid regurgitation who underwent isolated mitral valve surgery, more than half still had moderate or severe tricuspid regurgitation, which had a tendency to increase even more over time; this outcome suggests that the patients would have benefited from concomitant tricuspid valve surgery (see McCarthy,<sup>100</sup> p. 164). In addition, results of observational studies suggest that after

**FIGURE 55-5** Outcomes after coronary artery bypass graft (CABG) or CABG with mitral valve (MV) annuloplasty in patients with ischemic cardiomyopathy and ischemic mitral regurgitation. Numbers in parentheses represent number at risk. (From the Multicenter Postinfarction Study Group. Risk stratification and survival after myocardial infarction. *N Engl J Med* 1983;309:331-336.)

**FIGURE 55-6** Moderate to severe mitral regurgitation (MR) after coronary artery bypass graft (CABG) or CABG with mitral valve (MV) annuloplasty in patients with ischemic cardiomyopathy and ischemic mitral regurgitation. (From the Multicenter Postinfarction Study Group. Risk stratification and survival after myocardial infarction. *N Engl J Med* 1983;309:331-336.)

successful tricuspid regurgitation surgery, the right ventricle will remodel, with subsequent improvement in its function in most patients; however, 10% to 20% of patients have persistent moderate to severe tricuspid regurgitation soon after surgery.<sup>101,102</sup>

## Aortic Valve Surgery in Patients with Severe Left Ventricular Dysfunction

### Aortic Valve Stenosis

The results of valve replacement in patients with normal ventricular function are similar to those in patients with mild or moderately reduced LV function. Moreover, the reduced LVEF, which is secondary to the excessive afterload, is often immediately corrected by valve replacement.<sup>103,104</sup> In comparison,

patients with severely reduced ventricular function (LVEF = 25% to 35%) often may not experience complete resolution of symptoms after valve replacement. However, survival is still improved in this setting, although surgery is associated with a high operative mortality rate (9%).<sup>105</sup>

Only if the ventricular function is extremely reduced (in general, <25%) do uncertainties arise in the selection of patients who might benefit from surgery. These patients might not be able to generate a high gradient across the aortic valve despite significant valve narrowing (see also Chapter 29) and require further diagnostic testing. Some patients with low-gradient aortic valve stenosis have true severe aortic valve stenosis, whereas others have pseudo-aortic valve stenosis, in which the transvalvular pressure gradient is low because of the combination of moderate aortic valve stenosis and low cardiac output. True stenosis is distinguished from pseudo-aortic valve stenosis through evaluation of echocardiographic changes in hemodynamic and structural measurements in response to dobutamine, which normally augments cardiac output. In pseudo-aortic valve stenosis, the aortic valve area usually increases as ventricular function improves, whereas in true aortic valve stenosis, this area does not increase. In addition, patients with contractile reserve in response to dobutamine have a much better outcome after surgery. Although patients with low-gradient, true aortic valve stenosis have high perioperative and postoperative mortality rates, surgery is still recommended because valve replacement is associated with better outcomes than is continued medical therapy.<sup>106</sup> Indeed, the 1- and 4-year survival rates were markedly improved among patients who underwent surgery (82% and 78%), in comparison with those among patients who received medical therapy (41% and 15%;  $P < .0001$ ).<sup>106</sup>

Some critically ill patients with true aortic valve stenosis are hemodynamically too unstable and at too high a risk for mortality to undergo the operation. Such patients may be stabilized before surgery through judicious medical intervention or interventional procedures. The use of nitroprusside during continuous hemodynamic monitoring with a pulmonary artery catheter has been shown to lead to significant increases in cardiac index and significant reductions in mean arterial pressure and systemic vascular resistance in stabilizing patients, which makes subsequent aortic valve replacement surgery safer.<sup>107</sup> Percutaneous balloon valvotomy with or without placement of a valve prosthesis may reduce the aortic

valve gradient and can potentially improve symptoms as well. Although promising and the subject of intense investigation, these procedures are associated with high rates of morbidity and, in the case of valvotomy, only transient effectiveness.

### Aortic Valve Insufficiency

The volume load with subsequent LV dilation in patients with chronic aortic regurgitation is similar to the volume load of mitral regurgitation that can be affected by pharmacological therapy (vasodilators such as nifedipine and ACE inhibitors) and reversed by valve replacement. Evaluation of LV size and function is important because these parameters are not always correlated with symptoms.<sup>108,109</sup> However, the prognosis of patients with aortic regurgitation is determined largely by symptom status and by LV size and function.<sup>108,109</sup> An LV end-systolic volume higher than 60 mL/m<sup>2</sup>, an LV end-systolic dimension larger than 50 mm, or an LVEF lower than 50% usually indicates serious depression of LV systolic function with adverse outcomes if not surgically corrected. Surgical correction of the regurgitant lesion usually produces at least some improvement in symptoms, regardless of the functional state of the ventricle.<sup>110,111</sup> In addition, although earlier studies indicated a high risk of mortality among patients with severely depressed LVEF, current data indicate that early and 5-year survival rates would be similar to those in patients with better LV function<sup>112</sup> (see McCarthy,<sup>100</sup> p. 167). Moreover, much of the reported poor results with aortic valve replacement for aortic insufficiency (see also Chapter 29) and severe LV impairment occurred when myocardial protection was less sophisticated and when valve prostheses (such as the Starr-Edwards mechanical valve) had high gradients, which substantially decreased the possibility of late LV recovery.

Because of the improved outcomes, aortic valve surgery for aortic valve stenosis or aortic regurgitation can be considered for many patients with severe LV dysfunction, often with excellent outcomes that obviate the need for cardiac transplantation. Some centers have experience with aortic valve repair, but most still replace the aortic valve with either a mechanical or bioprosthetic valve. The choice between these valves was discussed in detail in the 2008 ACC/AHA guidelines, which recommended that patient age, ability to tolerate warfarin, and patient preference should all be taken into account.<sup>113</sup> The guidelines advocate that patients with a projected long life span generally receive a mechanical valve because of far greater durability and improved patient survival 15 years after surgery. Traditional indications for a bioprosthesis are patients who cannot or will not tolerate warfarin, those whose compliance is uncertain, and patients aged 65 years or older, because valve durability is less of a concern.

## LEFT VENTRICULAR RECONSTRUCTION SURGERY

SVR, or volume reduction, is the active surgical attempt to restore the shape of the pathologically remodeled ventricle to one that is physiologically superior. It has long been recognized that SVR alone can improve cardiac function and patient functional status.<sup>114</sup> In the setting of systolic heart failure, the heart enlarges to maintain stroke volume, but at the expense of several physiological and mechanical disadvantages: increased myocardial wall stress, subendocardial hypoperfusion and ischemia, increased myocardial oxygen consumption, afterload mismatch, and activation of compensatory neurohormonal mechanisms. Changes in size and geometry lead to progressive LV dysfunction and worsening heart failure. Sometimes it is possible to surgically remove or exclude portions of the dysfunctional myocardium, infarcted

territories, or both to return the LV cavity to a smaller chamber with more normal geometry and physiological properties. Reduction of internal cavity dimensions on the basis of Laplace's law help reduce end-systolic and end-diastolic wall stress, which results in reduced myocardial oxygen consumption, and helps improve myocardial efficiency, which has been shown to ameliorate the heart failure symptoms and improve outcomes.<sup>115-117</sup> The surgical remodeling has beneficial effects on areas of the left ventricle remote from the scar, which results in improved performance of the lateral wall in the case of surgical anterior LV reconstruction.<sup>115</sup> As discussed earlier, the randomized, prospective STICH trial did not demonstrate a benefit when SVR was performed with CABG (see Figure 23-11).<sup>23</sup> Many clinicians firmly believe, however, that properly selected patients may benefit from SVR. The theory and data that support the use of SVR are reviewed as follows.

Four developments have affected the current surgical LV reconstruction for ischemic cardiomyopathy. First, classic ventricular aneurysms are much less common now because of the use of aggressive percutaneous coronary interventions, the use of thrombolytic agents, and the evidence-based use of neurohormonal blocking agents after myocardial infarction.<sup>118-123</sup> Second, the technique of ventricular reconstruction has evolved from linear repair involving the free wall to a more complete infarct exclusion that includes repair of the scarred septum.<sup>124-127</sup> Third, the concept of reconstruction for dyskinetic LV segments has been extended to include akinetic, scarred, but nonaneurysmal areas of the LV.<sup>128-131</sup> Fourth, cryoablation can be used to treat foci of tachyarrhythmias, and SVR procedures are typically combined with CABG and valvular surgeries. The surgeon must exhibit extreme care to ensure that the LV cavity is not too small after SVR and that the mitral valve remains competent. On occasion, the patient must go back on cardiopulmonary bypass to increase the LV volume or to undergo repair of the mitral valve after SVR. Hence, transesophageal echocardiography plays a very important role in the surgical management of patients undergoing SVR.

### Indications for Remodeling Surgery in Ischemic Cardiomyopathy

The classic indications have included congestive heart failure, embolism originating from a thrombus contained in the aneurysm, and persistent malignant ventricular arrhythmias, despite optimal medical therapy. However, many patients undergo remodeling surgery only because the surgeon is committed and experienced in this technically challenging cardiac operation. In the Cleveland Clinic experience, a thin-walled aneurysm that collapses with venting of the aorta or left atrium must be present, most often in the vicinity of the left anterior descending coronary artery. If diffuse scar is mixed with muscle in all three coronary artery territories, often no reconstruction is undertaken because there is no discrete area to resect. As explained previously, viability studies are only 80% to 90% accurate; therefore, areas that are found to be thick-walled muscle intraoperatively are not resected, even though the "scar" was indicated on the viability study. All efforts are undertaken to optimally revascularize areas with preserved wall thickness. Most often, reconstruction is performed for a true dyskinetic aneurysm, although transmural scar in a thin-walled akinetic segment might be resected as well. As noted, opinions about this conflict in view of the reported STICH results that show lack of benefit. Dor<sup>117</sup> proposed similar indications for ventricular reconstructive surgery in asymptomatic patients who had suffered previous anteroapical myocardial infarction and had dilated left ventricle (end-diastolic volume index > 100 mL/m<sup>2</sup>), LVEF lower than 20%, LV regional dyskinesia or akinesis affecting more than 30% of the ventricular perimeter, and symptoms of

812 angina, heart failure, or arrhythmias or inducible ischemia on provocative tests. Relative contraindications are systolic pulmonary artery pressure higher than 60 mm Hg, severe right ventricular dysfunction, and regional dyskinesia or akinesis without dilation of the ventricle.<sup>117</sup>

CH 55

At the Cleveland Clinic, remodeling surgery is not performed in patients with stage D inotrope-dependent heart failure because these patients will not benefit from the procedure; they should be considered instead for cardiac transplantation or LVAD if it is clinically appropriate (see Chapter 56). In addition, physicians at the Cleveland Clinic believe it is prudent that before remodeling surgery, these patients are screened for cardiac transplantation or an LVAD. Regions of dyskinesia or scar that are imaged preoperatively are akinetic regions composed of islands of myocardium admixed with scar that is not of full thickness. These mottled areas are not resected and often do not improve when revascularized; as a result, the postoperative course is challenging, and mechanical support and transplantation are often needed.

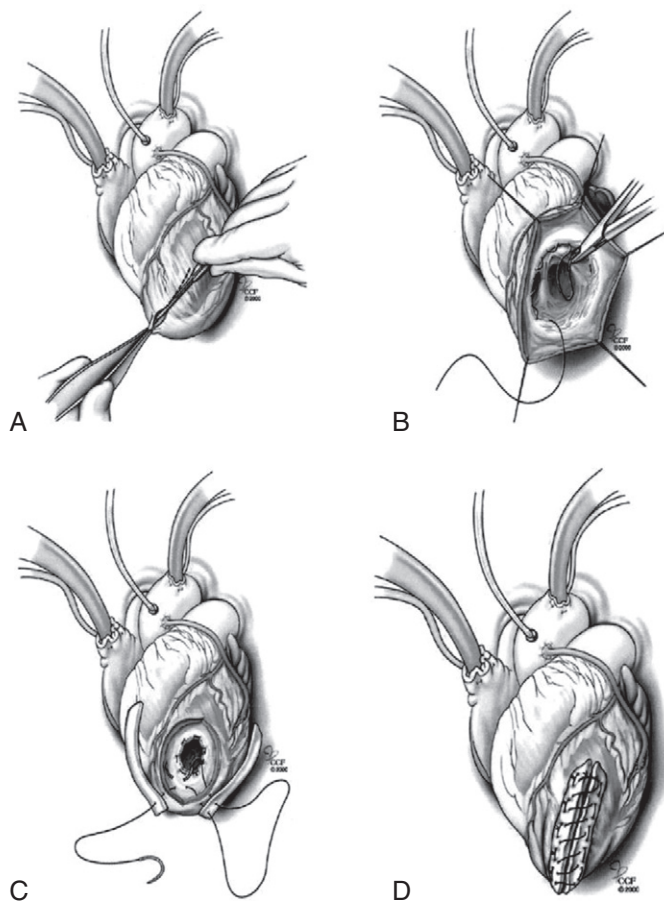

## Techniques for Remodeling Surgery in Ischemic Cardiomyopathy

### Dor Procedure

The Dor procedure, also called “endoventricular circular patch plasty,” is indicated only when an aneurysm has formed after a myocardial infarction.<sup>132</sup> A purse-string suture is created around a nonviable scarred aneurysm (Figure 55-7). Then the aneurysm is excluded, and the residual defect is covered by a patch made from polyester (Dacron), pericardium, or an autologous tissue flap. The remaining aneurysmal scar is then closed over the outside of the patch to give additional stability to the repair. The result is restored “normal” LV chamber geometry and improved LV function. The operation shortens the long axis but leaves the short axis length unchanged, which produces an increase in ventricular diastolic sphericity, whereas the systolic shape becomes more elliptical.<sup>133</sup> According to a multicenter report, among 662 patients who underwent the SVR procedure, the overall hospital mortality rate was 7.7% (4.9% with CABG alone vs. 8.1% with CABG and mitral valve repair).<sup>134</sup> An improvement in LVEF (from  $29.7\% \pm 11.3\%$  to  $40.0\% \pm 12.3\%$ ) with a reduction in end-systolic volume (from  $96 \pm 63$  mL/m<sup>2</sup> to  $62 \pm 39$  mL/m<sup>2</sup>;  $P < .05$ ) was observed.<sup>134</sup> At 3 years, the survival rate was  $89.4\% \pm 1.3\%$ , and 88.7% avoided readmission to the hospital for heart failure.<sup>134</sup> The STICH trial did not demonstrate a reduction in hospitalizations for all causes or for cardiac causes at a median follow-up interval of 48 months.<sup>23</sup>

### Cleveland Clinic Approach

At the Cleveland Clinic, most (89%) of the patients who undergo remodeling surgery for ischemic cardiomyopathy also undergo CABG, and almost 50% undergo concomitant mitral valve surgery, especially if the regurgitation is grade 2+ or higher.<sup>135</sup> The operation is performed through a full sternotomy on cardiopulmonary bypass. After the coronary grafts are established, the mitral valve is repaired, and a modified maze procedure is performed if the patient has a history of atrial fibrillation. The left atrial appendage is closed or resected to prevent future embolism. The LV scar is opened 2 cm lateral to the left anterior descending artery, any underlying LV thrombus is removed, and sutures are placed to retract the thin LV walls and thereby facilitate exposure of the septum, the papillary muscles, and the border zone of the infarcted and normal-appearing myocardium. Subsequently, the aneurysm or scarred area is resected subendocardially, and cryolesions are applied along the entire border zone in patients with a history of ventricular arrhythmias. With the

**FIGURE 55-7** Left ventricular reconstruction. **A**, The incision for left ventricular reconstruction is typically 2 cm left of the left anterior descending (LAD) artery and extends 3 to 5 cm parallel to the LAD artery. This is routinely performed while the heart is beating and empty. **B**, Reconstruction begins with a purse-string suture placed at the border zone of the infarction, slightly into the scar. **C**, When the second purse-string suture is tied, the neck of the aneurysm is usually 1 to 3 cm in diameter. In rare cases, a patch is used because of heavy calcium deposit on the septum that cannot be removed safely or because of concern that the remaining left ventricular cavity will be very small and contribute to diastolic dysfunction. Two strips of felt are positioned on either side of the ventriculotomy. These are sewn in place with horizontal mattress sutures. The mattress sutures should extend all the way down to the purse-string sutures. In this way, the cavity between the aneurysm neck and the left ventricular free wall is obliterated, and the chances of bleeding are minimized. **D**, The ventriculotomy is oversewn superficially in two layers as a final hemostatic safeguard. (From McGee, E. C., Gillinov, A. M., McCarthy, P. M. (2006) Reverse ventricular remodeling: mechanical options. *Curr Opin Cardiol* 21:215-220.)

heart beating, a first purse-string suture is placed in the border zone, and each bite is placed deep in the scarred tissue. This suture is then tightened to create a “neck.” In contrast to the DOR procedure, a patch is not routinely sewed over this opening because the dyskinetic or akinetic area will simply be replaced with another akinetic area; a patch is used only when the LV cavity would be too small. Therefore, an intra-ventricular balloon filled to a known volume of 60 mL/m<sup>2</sup> is inserted to ensure that the residual chamber size is adequate. Thus, in 95% of patients, this opening is closed simply by a second purse-string suture a few millimeters above the first suture. The resulting “neck” is less than 1 cm in length but is often completely obliterated once the sutures are tightened. Finally, two strips of felt are then placed on the epicardial surface, and horizontal mattress sutures passing through the free wall of the left ventricle are applied to approximate the border zone between normal and infarcted myocardium. The

ventricular cavity beneath the purse-string sutures are almost completely surrounded by normal myocardium. This technique can be viewed at <http://cvbook.nmh.org> (Figure 12). In case of a broad QRS complex, LV epicardial leads are often placed for later biventricular pacing if clinically indicated.

A cohort of 220 consecutive patients from the Cleveland Clinic underwent SVR between July 1997 and July 2003; the indication for surgery was heart failure, and 66% of the patients had NYHA functional class III or IV symptoms.<sup>135</sup> The mean preoperative LVEF was 22%, and the mean LV end-diastolic diameter was 6.4 cm. The mean age was  $61.4 \pm 9.0$  years, and 80% of the patients were male. The majority (86%) of patients underwent concomitant CABG, and 49% underwent mitral valve surgery. The 30-day mortality rate was 1%, and survival rates were 92% at 1 year, 90% at 3 years, and 80% at 5 years. Of the survivors for whom data on NYHA functional class were available, 85% had NYHA functional class I or II symptoms. Mortality was predicted by reduced preoperative LVEF ( $<20\%$ ), body mass index of  $24 \text{ kg/m}^2$  or lower, QRS duration of 130 msec or longer, and a postoperative requirement for renal replacement therapy. Mean LVEF improved to  $24.7\% \pm 8.86\%$  ( $P < .01$ ), and LV volumes were also significantly reduced. The investigators concluded that in selected patients with heart failure, SVR, in conjunction with revascularization and valve surgery, yields excellent survival rates, improves symptoms, and improves LVEF and LV dimensions.<sup>135</sup>

The aforementioned STICH trial is the first prospective, randomized clinical trial in which medical therapy only, medical therapy with CABG, and medical therapy with CABG and remodeling surgery are compared; it is hoped that the results will clarify which procedure should be performed in which patients with ischemic cardiomyopathy. The initial results from STICH, published in 2009 with data from a cohort of 1000 patients, did not show benefit when SVR was added to CABG versus CABG alone; however, the results of the entire cohort must be available before the role of medical therapy versus combined medical and surgical therapies can be assessed. Individual cardiac surgeons and cardiothoracic centers that have extensive experience and good outcomes with SVR will probably continue to apply this procedure in patients with dyskinetic segments that meet their proven selection criteria.

## Indications for Remodeling Surgery in Dilated Cardiomyopathy

Patients with idiopathic dilated cardiomyopathy and extreme ventricular dilation with advanced heart failure are referred for cardiac transplantation. Randal Batista, a Brazilian cardiac surgeon, popularized a radical technique of *partial left ventriculectomy* to restore the dilated ventricle to a near-normal size and shape.<sup>136,137</sup> Batista's procedure involved the removal of a section of the LV free wall, between both papillary muscles, extending from the apex to the mitral annulus. The remaining free edges were reapproximated and stitched together. The mitral valve and subvalvular apparatus were preserved, repaired, or replaced, depending on the amount of tissue removed. Several global centers, including some in the United States, published their experience with Batista's procedure. All survivors demonstrated an initial increase in LVEF, reduction in heart size, and improvement in clinical functional status up to 6 months.<sup>137-140</sup> However, despite the initial apparent clinical success, at 1 and 3 years after surgery, survival rate was limited to 80% and 60% and freedom from symptomatic heart failure was only 49% and 26%, respectively.<sup>141,142</sup> In addition, one third of the patients did not experience any benefit, and up to another third were in even worse condition after the surgery, which eventually precluded the widespread use of remodeling surgery in dilated cardiomyopathy.<sup>141,142</sup> In addition, the procedure was associated with high incidence of late fatal arrhythmias.<sup>141,142</sup> As a

consequence, Batista's procedure is no longer considered an appropriate option for patients with advanced heart failure, and both the 2009 practice guidelines of the ACC/AHA and the 2006 practice guidelines of the Heart Failure Society of America noted that partial left ventriculectomy is not recommended for nonischemic cardiomyopathy.<sup>94,95</sup>

Another historical surgical therapy for dilated cardiomyopathy, referred to as "dynamic cardiomyoplasty," in which the latissimus dorsi muscle is wrapped around the heart and paced during ventricular systole, initially garnered great interest.<sup>143</sup> This arrangement was originally thought to act as an auxiliary pump for the failing left ventricle, aiming to improve cardiac output and functional status. Symptomatic improvement occurred after cardiomyoplasty, although the mechanism of benefit was not clear. A large randomized clinical trial of cardiomyoplasty was started. However, only patients with NYHA class III heart failure were considered suitable for recruitment, because the rate of surgical mortality was deemed too high for patients with more advanced heart failure (30% for class IV). The study was terminated prematurely because of lagging randomization and marginal overall clinical improvement. In addition, it appeared that patients who could survive the operation did not need it, and those who needed it could not survive it.<sup>144,145</sup> For these reasons, cardiomyoplasty is not a viable surgical strategy for the management of heart failure.

## Device Therapies for Dilated Cardiomyopathy

The cardiomyoplasty experience has led to other novel approaches to heart failure, inasmuch as postoperative observations suggested that some patients benefited from the diastolic "girdling" effect of the muscle wrap and that progressive LV dilation could be slowed.<sup>146</sup> Several devices to prevent further LV dilation have been developed.

### Acorn Device

The Acorn CorCap device is a compliant polyester mesh jacket placed around the ventricles of the heart. It does not interfere with diastolic function but acts as an external constraint device, thereby preventing further dilation of the heart (Figure 55-8). Animal studies and small human case series demonstrated

FIGURE 55-8 CorCap cardiac support device.

**FIGURE 55-9** Myosplint device. AoV, aortic valve; LV, left ventricle; MV, mitral valve; RV, right ventricle.

positive effects on reverse remodeling and improvement in symptoms. Therefore, in a multicenter randomized clinical trial, CorCap was compared with medical therapy, and CorCap with mitral valve repair was compared with mitral valve repair alone.<sup>146</sup> The results were favorable for CorCap: 38% of patients receiving the device demonstrated improvement in heart failure status, in comparison with 27% of those who did not receive the CorCap.<sup>147</sup> Moreover, mitral valve repair was associated with progressive reductions in LV volumes and mass and with increases in LVEF and sphericity index, all consistent with reverse remodeling.<sup>92</sup> Recurrence of clinically significant mitral regurgitation was uncommon. Quality of life, exercise performance, and NYHA functional class were all improved. The addition of the CorCap cardiac support device led to greater decreases in volumes, a more elliptical shape, and a trend for a reduction in major cardiac procedures and improvement in quality of life than did mitral valve repair alone. Furthermore, the beneficial effects on LV remodeling were sustained at long term, after 3 years of follow-up.<sup>148</sup>

These findings indicate that there might be additional benefit with the CorCap cardiac support device over mitral valve surgery alone in patients with nonischemic cardiomyopathy. Because of the improvement in LV structure and function, along with a low operative mortality rate (<2%), the device is in use in Europe; it has not yet, however, obtained approval in the United States. The Acorn CorCap is undergoing nonrandomized evaluation in the United States in selected patients with reduced LVEF who are undergoing mitral valve repair.

#### Myocor Myosplint

The Myocor Myosplint device (Figure 55-9) is also aimed at inhibiting LV remodeling. The device consists of a trans-ventricular splint with epicardial pads that are adjusted to decrease the LV radius, which causes the left ventricle to become smaller and more energetically efficient, with decreased wall tension (by the law of Laplace). The trans-ventricular splints are placed on the beating heart without cardiopulmonary bypass, typically from the lateral left ventricle through the posterior interventricular septum. After the splints are tightened, the final shape of the ventricle is bilobular. Animal and small human case series also showed positive effects on remodeling and symptoms.<sup>149</sup> Myocor also developed a new product, Coapsys, that is designed to achieve off-pump mitral valve repair along with some ventricular volume reduction. The device includes a single trans-ventricular splint and pads on the outer surface of the left ventricle. Under continuous echocardiographic monitoring, the pads are tightened until mitral regurgitation is reduced

and eventually eliminated. One pad on the left ventricle is positioned at the level of the mitral valve apparatus and pulls the posterior annulus toward the anterior leaflet during tightening. The other pad on the LV free wall changes the ventricular shape during tightening. In humans who had Myosplint placement (immediately before heart transplantation), an acute reduction in LV end-diastolic and end-systolic volumes was similar to that observed in animal experiments.<sup>150</sup> A safety and feasibility study—the Evaluation of a Surgical Treatment for Off-pump Repair of the Mitral Valve (RESTOR-MV) trial—is currently under way.<sup>151</sup>

## CONCLUSIONS

Surgical treatments for heart failure are still relatively rare, in view of the large population at risk. Modern techniques yield low rates of perioperative morbidity and mortality and have led to improved long-term ventricular function and outcomes. Many patients referred for transplantation can now be treated with other surgical options that may delay or even preclude the need for cardiac transplantation.<sup>152</sup> For patients who have severe LV dysfunction but a considerable amount of viable myocardial tissue, coronary bypass surgery should be the first option. Mitral valve repair for severe LV dysfunction appears to be effective for symptomatic relief and might improve survival, especially if combined with therapies that also directly address LV remodeling. Direct ventricular reconstruction for ischemic cardiomyopathy with resection of delineated areas of dyskinetic scarring carries moderate rates of perioperative mortality and may lead to improved outcomes. Patients with nonischemic cardiomyopathy might benefit from alternative device strategies aimed at halting or reversing the detrimental remodeling process. Several ongoing prospective clinical trials are expected to provide more evidence to further define the role of surgery in both dilated and ischemic cardiomyopathy.

who have severe heart failure.<sup>15</sup> As mechanical devices become smaller and easier to implant, the indications for their use may broaden to include patients with less severe heart failure.

The history of MCS systems is reviewed briefly in this chapter. Devices currently used for short-term support in patients with reversible cardiogenic shock, as well as systems used for longer-term bridging to transplantation, are described. After a review of the capabilities and complications of MCS, the focus is on new applications, such as bridging to myocardial improvement and device implantation for permanent use, which are being studied in initial clinical trials. Last, the newest devices being tested and the promising future of MCS are discussed.

Congestive heart failure is a common cause of premature disability and death. For cases in which conventional medical therapy fails to alleviate the symptoms of end-stage heart failure, mechanical circulatory support (MCS) is increasingly used. Since the 1960s, this approach has become an effective means of saving many patients who would otherwise die of heart failure. Short-term MCS may be used to maintain patients who develop acute, reversible heart failure, such as heart failure that occurs after a myocardial infarction or cardiovascular surgery. Longer-term MCS may be used in patients with severe acute or chronic heart failure, including those awaiting heart transplantation (see Chapter 54).

Indeed, the clinical application of MCS has progressed because of advances in cardiac transplantation, which is the only available definitive treatment for refractory end-stage heart failure. In transplantation candidates, MCS can maintain hemodynamic stability and preserve life until a suitable donor heart becomes available. Prolonged (>30-day) support, particularly with an implantable left ventricular assist device (LVAD), not only allows these patients to survive but often reverses cardiac and end-organ dysfunction; as a result, the risk of perioperative complications is reduced,<sup>1-3</sup> and the results of transplantation are optimized.<sup>4</sup> In addition, mechanical devices are being studied for permanent cardiac replacement and for bridging to myocardial recovery.<sup>5-14</sup> According to the Institute of Medicine, long-term MCS could annually benefit 35,000 to 70,000 Americans

clinical use of this technology, by Gibbon in 1953, resulted in successful correction of an atrial septal defect.<sup>16</sup> Unfortunately, all of Gibbon's subsequent cardiopulmonary bypass cases ended in clinical failure, causing him to abandon the heart-lung machine. Further development of this device was achieved by Lillehei, at the University of Minnesota, and by Kirklin, at the Mayo Clinic. Early reports by Spencer and coworkers<sup>17</sup> emphasized the recovery of patients after cardiectomy who could not be weaned from cardiopulmonary bypass initially; in these cases, mechanical support was simply continued until the heart recovered.

The success of MCS in patients after cardiectomy paved the way for research efforts designed to allow more prolonged support of cardiac function. A prototype pump created for this purpose was used successfully by DeBakey and associates<sup>18</sup> in 1963, in a patient who had a cardiac arrest after undergoing aortic valve replacement. The pump worked well and supported the circulation for 4 days, but the patient had already suffered an irreversible neurological injury. The first successful case of prolonged left ventricular support was achieved by DeBakey<sup>19</sup> in 1966. The patient was supported by the pump for 10 days, after which the device was removed, and the patient survived long term.

Meanwhile, the intra-aortic balloon pump (IABP) had been introduced by Mouloupoulos and colleagues,<sup>20</sup> who performed animal experiments with this device in 1961. The IABP was not used clinically until 1967, when Kantrowitz and associates<sup>21</sup> implanted it in a patient with cardiogenic shock. The IABP is currently the most common form of mechanical support, sustaining more than 80,000 patients per year, some of whom receive the device as a bridge to cardiac transplantation.

In 1964, acting on the advice of DeBakey, the National Heart and Lung Institute established its Artificial Heart Program. Research into an implantable total artificial heart (TAH)—more properly termed a “biventricular replacement device”—began at Baylor College of Medicine during the same decade. This pump was first implanted in a human being in 1969, when Cooley and his team<sup>22</sup>

## HISTORY

In the mid-twentieth century, development of the cardiopulmonary bypass machine by John H. Gibbon Jr., C. Walton Lillehei, John W. Kirklin, and other investigators enabled direct anatomical repair of the diseased heart. The first

used it to perform the first clinical bridge-to-transplantation operation. The pneumatically driven, diaphragm-type, dual-ventricular pump was positioned orthotopically, replacing the native ventricles. It functioned well, sustaining the patient for 64 hours until a donor heart could be transplanted. In 1981, a second TAH, developed by Tetsuzo Akutsu at the Texas Heart Institute, was implanted as a bridge to transplantation.

In 1982, DeVries<sup>23</sup> performed the first of five TAH implantations intended to serve as permanent cardiac replacements. In these cases, the TAH was the Jarvik-7 model, designed by Robert Jarvik. Although the device was able to support the total circulation for weeks to months, patients had to remain hospitalized and tethered to a power supply and control consoles. In addition, the patients were plagued by device-related complications, particularly infection and stroke, and only two of the patients survived for more than a year.<sup>24</sup>

Because heart transplantation and TAH technology were failing to fulfill their initial promise, clinical efforts were redirected toward producing long-term implantable LVADs. In the 1970s, the institute responsible for the Artificial Heart Program achieved bureau status and became the National Heart, Lung, and Blood Institute (NHLBI). Research involving MCS began to be performed under the auspices of the Devices and Technology Branch of the Division of Heart and Vascular Diseases. In the mid-1970s, after extensive animal and in vitro tests of device safety and reliability, the NHLBI challenged physicians, engineers, and private companies to develop a fully implantable device for the long-term support of patients with heart failure.

The first NHLBI-sponsored device was an intra-abdominally positioned LVAD for treating postcardiotomy shock. In 1975, the Texas Heart Institute conducted the first clinical tests of this single-chambered implantable pump. Three years later, it was used as a bridge to transplantation in a patient who had developed stone heart syndrome after undergoing valve replacement.<sup>25</sup> The LVAD supported the patient's circulation for 5 days until a donor heart became available. In 1984, a different NHLBI-sponsored implantable LVAD was successfully used as a bridge to transplantation by Philip E. Oyer at Stanford University.

The ultimate goal, however, was to produce an LVAD that could provide long-term support or destination therapy. In the 1980s, investigators at the Texas Heart Institute began using the HeartMate, a fully implantable LVAD. Originally produced by Thermo Cardiosystems, Inc. (Woburn, Massachusetts), this pump was later acquired by Thoratec Corporation (Pleasanton, California). The HeartMate was first implanted as a bridge to transplantation in 1986. It had previously undergone 10 years of experimental testing. Although the initial model was pneumatically powered, an electrically driven model also became available, and it was first implanted as a portable LVAD in 1991. Both versions were later approved by the U.S. Food and Drug Administration (FDA) for commercial use to bridge patients to transplantation; the vented electric version is currently approved for long-term support or destination therapy in the United States.

Today, cardiologists and cardiovascular surgeons can choose from a wide range of MCS systems, depending on the desired degree of support, length of support, extent of postoperative mobility, and other factors (Table 56-1). Despite numerous design modifications and refinements, an ideal system has not yet evolved. Nevertheless, current systems can maintain many patients with end-stage heart failure, offering hope where none had previously existed.

## SHORT-TERM CIRCULATORY SUPPORT

Short-term MCS is an important strategy for controlling acute, reversible heart failure that manifests as cardiogenic shock, which otherwise often results in mortality.<sup>26-30</sup> Often, shock

is caused by an acute myocardial infarction involving more than 40% of the left ventricular mass<sup>31</sup>; in such cases, MCS can support the patient's circulation until his or her condition improves enough for myocardial revascularization to be undertaken.

Acute coronary occlusion is usually managed with an aggressive interventional procedure in the cardiac catheterization laboratory. Patients at particularly high risk, however, may benefit from emergency IABP or temporary cardiopulmonary bypass before the intervention is undertaken.

Temporary MCS may be necessary postoperatively to wean high-risk surgical patients from cardiopulmonary bypass; in these cases, mechanical assistance may also allow the preservation of adequate ventricular function. Moreover, when a patient has acute myocarditis or posttransplantation allograft dysfunction, short-term MCS often enables complete recovery.

## Intra-aortic Balloon Pump

The IABP is the most widely used MCS system in the world today. The 40- to 60-mL polyurethane balloon is attached to the tip of a catheter, which is inserted percutaneously into the common femoral artery and then advanced in to the descending thoracic aorta<sup>20,21</sup> (Figure 56-1). Alternatively, if iliofemoral vascular disease is present, the balloon may be inserted into the abdominal aorta via a retroperitoneal approach or into the aortic arch via the subclavian artery.

The pump's action depends on several unique but fairly simple physiological principles. At the start of diastole, the balloon inflates, augmenting coronary perfusion. At the beginning of systole, the balloon deflates; blood is ejected from the left ventricle, increasing the cardiac output by as much as 40% and decreasing the left ventricular stroke work and myocardial oxygen requirements.<sup>32</sup> In this manner, the balloon supports the heart indirectly. Although designed to provide short-term MCS, the IABP has occasionally supported heart transplantation candidates for several weeks. Clinical scenarios for use of this device include preoperative implantation in patients who undergo cardiac surgery with severely impaired left ventricular function or coronary perfusion (as in severe left main coronary artery disease); bridging to transplantation or long-term MCS in patients with intractable heart failure of any cause and impending major organ failure after unsuccessful medical therapy; and intraoperative implantation in patients who experience difficulty in weaning from cardiopulmonary bypass. The IABP has been used with some success in resuscitating patients with heart failure who have had a cardiac arrest.

The device's limitations include an inability to completely unload the left ventricle. Adequate IABP function depends on appropriate timing of the balloon cycle and is suboptimal in the presence of arrhythmias. Moreover, patients with IABPs must remain in their hospital beds. Potential sequelae include peripheral vascular hemorrhagic or thromboembolic complications, which may necessitate surgical intervention.<sup>33,34</sup> The IABP cannot be used in the presence of significant atherosclerotic or aneurysmal disease of the thoracic aorta or significant aortic regurgitation.

## Abiomed Biventricular System 5000

The Abiomed Biventricular System (BVS) 5000 (Abiomed Cardiovascular, Inc., Danvers, Massachusetts) was developed to provide short-term univentricular or biventricular support for patients with potentially reversible ventricular function. This pump is most commonly used in patients with postcardiotomy shock, but it has also been used successfully for treating acute myocarditis and for bridging to transplantation.<sup>1,35</sup> In this externally positioned system, pulsatile flow is provided by one or two disposable, dual-chambered blood

BSA, body surface area; BTT, bridge to transplantation; DT, destination therapy; FDA, U.S. Food and Drug Administration; IDE, investigational device exemption; L, left; N/A, not applicable; PCR, postcardiotomy recovery; R, right. <sup>a</sup>“Short” indicates <30 days; “Intermediate” indicates 30 days or more but that use is not intended to be permanent; “Long” indicates permanent use as an alternative to a heart transplant. <sup>b</sup>Dollar signs refer to the cost relative to the cost of the other listed devices.

**FIGURE 56-1** Illustration of intra-aortic balloon pump in the body. (Copyright 1997, Texas Heart Institute, Houston, TX.)

pumps controlled by a single console (Figure 56-2).<sup>36</sup> Within each pump, one-way flow is assured by two trileaflet valves: one between the ventricular and atrial chambers and the other in the ventricular outflow tract. Polyurethane (Angioflex) is used for the blood-contacting surfaces. A pneumatic, microprocessor-controlled drive console automatically initiates ejection when the pump is filled (stroke volume, 82 mL). The pump fills passively and ejects actively, yielding flows of up to 5 L/min. During weaning, the flow rate is decreased manually by means of a control knob.

The superiority of pulsatile MCS has not yet been proved, but some experts believe that pulsatile systems such as the Abiomed offer advantages over nonpulsatile pumps.<sup>37-42</sup> The FDA has approved the BVS 5000 for temporary use in patients with postcardiotomy shock. This pump is widely used for temporarily supporting patients with life-threatening heart failure. It is also used as a bridge to implantation of a long-term LVAD or as a bridge to transplantation. Because of the pump's high thrombogenic potential, full anticoagulation is necessary.

### Abiomed AB5000

The Abiomed AB5000 Circulatory Support System (Abiomed Cardiovascular, Inc.) was approved by the FDA as an adjunct to the BVS 5000 for short to intermediate support as a bridge to recovery. The same cannulas used in the BVS 5000 blood pump are used in this paracorporeal ventricular assist device, which can facilitate the transition from the BVS to the AB5000 device when longer-term support is desired. The AB5000 is powered by a partial vacuum and partial pneumatic console.

### Bio-Medicus Bio-Pump

Another option for short-term univentricular or biventricular MCS is the Bio-Medicus Bio-Pump (Bio-Medicus/Medtronic, Eden Prairie, Minnesota), an extracorporeal, centrifugal device available in two disposable models: an 80-mL model for adults (maximal flow, 10 L/min) and a 48-mL model for children. In this pump, rotating acrylic cones generate continuous flow according to the constrained vortex principle (Figure 56-3). The pump is magnetically coupled to an external motor and console.<sup>43</sup> It may be used to support either ventricle, or dual pumps may be used for biventricular support.

Clinicians have acquired considerable experience with the Bio-Pump because it is also used for cardiopulmonary bypass. Its advantages include simplicity, versatility, and cost effectiveness. Limitations include the need for specialized personnel to supervise the system. Moreover, durability problems preclude use of the Bio-Pump for more than 5 days, although this limit is occasionally exceeded. In any case, the pump component should be replaced every 48 to 96 hours. Despite heparin bonding, the circuit's electromagnetic elements are potential sites for thrombus or fibrin formation; therefore, systemic support with heparin is usually necessary unless post-operative hemorrhage becomes a problem. The externalized cannulas are also potential sites of infection.

### Levitronix CentriMag

The Levitronix CentriMag Blood Pumping System (Levitronix, Inc., Waltham, Massachusetts) is designed to provide short-term support for patients with severe, acute, but potentially reversible cardiac failure. The magnetically levitated impeller in this pump extends the longevity and reliability of the device (Figure 56-4). The Levitronix CentriMag has a 510(k) approval from the FDA for short-term circulatory support and is frequently used as a bridge to recovery or a bridge to treatment decision.<sup>44</sup>

### TandemHeart Percutaneous Transseptal Ventricular Assist Device

The TandemHeart Percutaneous Transseptal Ventricular Assist (PTVA) System (CardiacAssist, Inc., Pittsburgh, Pennsylvania) is a device approved by the FDA to provide temporary left ventricular support. It can be implanted in the catheterization laboratory or the operating room. An inflow cannula is inserted into the patient's left atrium through a standard transseptal puncture via a femoral venous sheath, and an outflow cannula is placed in the femoral artery (Figure 56-5). The extracorporeal centrifugal pump is connected to a controller that provides power, lubrication, and system monitoring.

### Impella Devices

The Impella 2.5 device (Abiomed Cardiovascular, Inc.) received a 510(k) approval from the FDA in 2008 to provide partial left ventricular support for up to 6 hours. The Impella 2.5 is inserted via the femoral artery, is advanced into the left ventricle in the catheterization laboratory, and provides up to 2.5 L of blood flow (Figure 56-6). The Placebo-controlled Randomized study of the selective A<sub>1</sub> adenosine receptor antagonist KW-3902 for patients hospitalized with acute HF and volume Overload to assess Treatment Effect on Congestion and renal function (PROTECT) I trial demonstrated the safety and feasibility of the Impella 2.5 in supporting patients who undergo high-risk percutaneous coronary intervention.<sup>45</sup> In the pivotal PROTECT II trial, which is under way, researchers are comparing the Impella 2.5 with the IABP for hemodynamic support while patients undergo high-risk

**FIGURE 56-2** Abiomed Biventricular System (BVS) 5000 blood pumps and control console. (Courtesy Abiomed, Danvers, MA.)

**FIGURE 56-3** Bio-Medicus Bio-Pump. (Courtesy Medtronic, Eden Prairie, MN.)

percutaneous coronary intervention. The Impella 2.5 device can provide up to 2.5 L of blood volume to the left ventricle via a percutaneous approach. When inserted into the ascending aorta intraoperatively, the Impella 2.5 can provide up to 5.0 L of flow to the left ventricle. In addition, the Impella 5.0 and the Impella LD (Left Direct) received 510(k) approval from the FDA in April 2009 to provide full left ventricular support for up to 6 hours. The Impella 5.0 is inserted through a surgically exposed femoral artery, whereas the Impella LD is inserted through a Hemashield graft that is sewn directly

**FIGURE 56-4** Levitronix CentriMag ventricular assist device. (Courtesy Levitronix, Waltham, MA.)

to the ascending aorta. Both the Impella 5.0 and the Impella LD can provide up to 5 L of flow.

## BRIDGING TO TRANSPLANTATION

The first three patients to receive implantable devices as bridges to transplantation (two TAHs—one in 1968 and one in 1981—and one LVAD in 1978) were treated at the Texas Heart Institute. These devices supported the patients until transplantation could be performed. However, all three patients subsequently died of overwhelming infection after transplantation.

**FIGURE 56-5** TandemHeart Percutaneous Transseptal Ventricular Assist (PTVA) System. (Courtesy CardiacAssist, Inc., Pittsburgh, PA.)

In the early 1980s, the introduction of the immunosuppressant drug cyclosporine, which spared the nonspecific immune system, allowed successful cardiac transplantation in patients otherwise “contaminated” by implantable devices. In the initial bridge-to-transplantation series, patients were confined to the hospital until transplantation occurred. Beginning in 1991, however, patients were allowed to live outside the hospital and even to return to work and other normal activities while receiving MCS. Bridging to transplantation was found to markedly increase posttransplantation survival in this high-risk group.<sup>1,2,4,46</sup> Once initiated, MSC tended to reverse the complex physiological abnormalities that characterize the body’s response to heart failure. Kidney and liver dysfunction were often reversed, and neurohormonal activation returned to normal levels.<sup>47</sup> As a result, patients were generally restored to New York Heart Association (NYHA) functional class I while awaiting transplantation. This is an important reason why long-term posttransplantation survival was enhanced in these otherwise more technically challenging patients.<sup>1,2,46</sup>

Bridging to transplantation is indicated for transplantation candidates who have symptoms of progressive heart failure despite maximal drug therapy, cardiac resynchronization therapy, or inotropic support. Because of longer wait times for

**FIGURE 56-6** Impella 2.5, 5.0, and LD devices. (Courtesy Abiomed, Danvers, MA.)

donor hearts and improved success with newer-generation LVADs, patients are often referred directly for LVAD implantation rather than being placed on IABP support in the intensive care unit. The selection criteria, which were approved by the FDA in 1994, include a pulmonary capillary wedge pressure higher than 20 mm Hg, a cardiac index of 2 L/min/m<sup>2</sup> or lower, and a systolic blood pressure of 80 mm Hg or lower. Outpatients with chronic heart failure who undergo routine right-sided heart catheterization while awaiting cardiac transplantation may meet these criteria. The following conditions render a patient ineligible for MCS: elevated, fixed pulmonary vascular resistance; irreversible renal or hepatic failure; respiratory failure; sepsis; and a severe neurological deficit. These conditions also render patients ineligible for cardiac transplantation. Marked pulmonary hypertension, which reflects minimal changes in the patient’s symptoms, can also develop in a patient with chronic heart failure. Therefore, hemodynamic values are routinely monitored in patients awaiting cardiac transplantation. Although patients older than 60 years and those who require mechanical ventilation for respiratory insufficiency are not necessarily excluded from receiving MCS, they are less likely to have a good outcome. Moreover, the first-generation pulsatile, long-term LVADs are too bulky to fit small patients (body surface area < 1.5 m<sup>2</sup>). The newer, continuous-flow LVADs have enabled smaller patients, including women, to benefit from MCS.<sup>48</sup>

When selecting an MCS device, the surgeon must consider the degree of support needed, the estimated duration of support, the invasiveness of the implantation procedure, and the patient’s need for postoperative mobility (see Table 56-1). For long-term bridging in patients with chronic heart failure, the approved devices are the Thoratec PVAD (Percutaneous Ventricular Assist Device) System, the Thoratec IVAD (Implantable Ventricular Assist Device), the CardioWest TAH, the Novacor Ventricular Assist System, the HeartMate XVE LVAD, and the HeartMate II LVAD.

### Thoratec Percutaneous Ventricular Assist Device System

The Thoratec PVAD System (Thoratec Corporation) has a flexible, seam-free, segmented pump sac within a rigid polycarbonate shell (Figure 56-7).<sup>49</sup> One-way blood flow is maintained by Björk-Shiley concavo-convex tilting-disk valves in the inlet and outlet tracts. The pump is pulsatile and pneumatically powered, with a maximal stroke volume of 65 mL

**FIGURE 56-7** Thoratec Percutaneous Ventricular Assist Device System. (From Thoratec Corporation, Pleasanton, CA.)

and a maximal output of 7 L/min. It can provide left, right, or biventricular assistance.

The Thoratec device is valuable for treating reversible cardiogenic shock<sup>50</sup> or for bridging to transplantation. When used as a bridging device in a multicenter study involving 154 patients,<sup>51</sup> the system provided left ventricular support in 22% of the cases and biventricular support in the other 78%. Successful transplantation was performed in 65% of the patients. One year after transplantation, the actuarial survival rate was 82%, which is similar to that of the general population of heart transplant recipients. The most common sequelae were hemorrhage (42%) and infection (36%). In another study, involving only postcardiotomy patients, 37% were weaned from the device, and the survival rate of the weaned patients was 57%. Perioperative myocardial infarction and renal failure were the most frequent complications in this series.<sup>52</sup>

As of January 2010, more than 5000 patients had been supported worldwide with the Thoratec PVAD or IVAD, according to the Thoratec Corporation's database. Of these pumps, 3011 were used as bridges to transplantation, 512 were used as postcardiotomy bridges to myocardial recovery, and 596 were used for other or adjunctive support. For bridging to transplantation, biventricular support was used in 1747 cases (58%), LVAD support in 1087 (36%), and right ventricular assist device support in 177 (6%). Of the patients requiring isolated LVAD support, 66% survived to receive a transplant, and 1% recovered function and were weaned from the device. Of the patients requiring biventricular support, 55% received a heart transplant, and 1% recovered ventricular function. Of patients who needed postcardiotomy support, 34% of those with isolated LVADs and 20% of those requiring biventricular VADs were successfully weaned from the device after myocardial recovery.

Because the pump sac may lead to thrombus formation, continuous anticoagulant therapy is necessary as soon as operative bleeding ceases to be a threat. Anticoagulation is achieved with a combination of dextran, dipyridamole, and heparin or warfarin.<sup>53,54</sup> After bleeding has resolved, it is important to use a combination of anticoagulant and antiplatelet therapy to avoid thrombus formation and stroke. Because of the presence of external blood pumps and the necessity for exteriorized cannulas, patients cannot move around freely.

**FIGURE 56-8** CardioWest total artificial heart. (Courtesy SynCardia Systems, Inc., Tucson, AZ.)

Despite this drawback, the Thoratec pump is widely used because of its safety, effectiveness, and versatility.

### CardioWest Total Artificial Heart

Originally called the Jarvik-7 (and later the Symbion) heart, the CardioWest TAH (SynCardia Systems, Inc., Tucson, Arizona) is implanted orthotopically in patients who need biventricular support (Figure 56-8).<sup>55</sup> The system features two pneumatic blood pumps, each with a semirigid, polyurethane polyester (Biomer) outer shell (Ethicon, Inc., Somerville, New Jersey), and a four-layer flexible Biomer diaphragm. One-way blood flow is ensured by a Medtronic-Hall tilting-disk valve in each pump's inflow and outflow tracts. Whereas the cuffed inflow cannulas are sewn to the atrial remnants of the native heart, the outflow cannulas are attached to the aorta and pulmonary artery by means of polyester (Dacron) grafts. The external pneumatic drive console is connected to the blood pumps by means of drivelines that exit through the patient's left flank. At the transcutaneous exit sites, the drivelines are overlaid with velour-covered silicone elastomer (Silastic; Dow Corning, Midland, Michigan) to ensure stability and encourage tissue ingrowth. During diastole, the pumps are passively filled with blood. In turn, during systole, an influx of air causes the diaphragm to advance and discharge blood. The most common potential problems associated with the CardioWest TAH are hemorrhage, thromboembolism, stroke, and infection.<sup>56</sup> Nevertheless, this system has been used for prolonged periods as a bridge to transplantation in patients with end-stage acute or chronic heart failure.<sup>57,58</sup>

In a nonrandomized prospective study, of the patients who received the CardioWest TAH as a bridge to transplantation, 79% survived until transplantation, in comparison with 46% of historical control patients who did not have a bridge to transplantation.<sup>59</sup> These data led to the approval of the CardioWest TAH as a bridge to transplantation by the FDA in 2004. A smaller, portable pneumatic driver, which allows patients to be discharged from the hospital, has received Conformité Européenne (CE) Marking approval and is available in Europe. SynCardia is developing a third-generation,

“wearable” driver, which will also facilitate discharge from the hospital and further improve quality of life.<sup>60</sup>

As of January August 2010, the CardioWest has been implanted in 860 patients worldwide, accounting for more than 300 patient years of life on the artificial heart (J. Cope-land, personal communication, August 6, 2010). Although originally designed as a permanent replacement heart, the CardioWest TAH is currently approved as a bridge to heart transplantation for patients dying of end-stage biventricular failure.

### Novacor Ventricular Assist System

The Novacor Ventricular Assist System (WorldHeart Corporation, Salt Lake City, Utah) is a pulsatile blood pump designed to attain the original NHLBI goal of destination therapy, as proposed in 1977.<sup>61</sup> This electrically driven, implantable blood pump (Figure 56-9) has a seamless polyurethane pump sac that, when actuated by dual pusher-plates, produces a maximum stroke volume of 70 mL. One-way blood flow is ensured by a 21-mm bioprosthetic valve in the inflow and outflow tracts. The system is currently powered by external batteries, allowing mobility of the patient. The pump is linked to its power source by means of a percutaneous drive-line, which also allows external venting.

In clinical bridge-to-transplantation trials performed since 1984, the Novacor device has enabled successful bridging to transplantation in about 60% of reported cases. Posttransplantation survival rates have been excellent.<sup>62,63</sup> The most frequent complications have been hemorrhage, infection, and thromboembolism.<sup>62</sup>

Robbins and coworkers<sup>64</sup> reported their experience with 53 patients who received Novacor devices for bridging to cardiac transplantation over a 16-year period. After a mean support period of  $56 \pm 76$  days, 66% of the patients underwent

successful transplantation. Complications included bleeding (43%), infection (30%), and embolic cerebrovascular events (24.5%).

A prospective, nonrandomized trial was conducted at 13 centers in the United States and Canada to assess the impact of support with the Novacor Left Ventricular Assist System (LVAS) on survival and quality of life in patients ineligible for cardiac transplantation who were inotrope-dependent.<sup>65</sup> The Investigation of Nontransplant-Eligible Patients Who Are Inotrope Dependent (INTREPID) trial enrolled 55 patients who could not be weaned from inotropic support. The patients receiving optimal medical therapy had lower mean serum sodium levels (128 vs. 134 mg/dL,  $P = .001$ ) and higher mean blood urea nitrogen levels (59 vs. 40 mg/dL,  $P = .02$ ) than did the patients who received the Novacor LVAS. In comparison with patients treated with optimal medical therapy, patients treated with the Novacor LVAS had superior survival rates at 6 months (46% vs. 22%,  $P = .03$ ) and 12 months (27% vs. 11%,  $P = .02$ ). Of the LVAS-treated patients, 85% had NYHA class I or II symptoms; in comparison with medically treated patients, Novacor recipients had lower rates of cardiovascular dysfunction ( $P < .0001$ ) and renal dysfunction ( $P = .0009$ ) but higher risks of bleeding ( $P = .008$ ), stroke ( $P = .06$ ), and infection ( $P = .54$ ). The favorable INTREPID trial results prompted WorldHeart to initiate the Randomized Evaluation of the Novacor LVAS In Non-Transplant Population (RELIANT) trial to establish that the Novacor LVAS was superior to optimal medical therapy and equivalent to the HeartMate XVE LVAD for destination therapy. The trial was subsequently halted because of slow enrollment and clinicians' preference for smaller, continuous-flow pumps. Use of the Novacor LVAS was discontinued in 2008.

### HeartMate XVE Left Ventricular Assist Device

The HeartMate LVAD (Thoratec Corporation) was initially developed with NHLBI support in response to the NHLBI's 1977 request for proposal. The *in vivo* laboratory experience and the initial clinical experience were obtained exclusively at the Texas Heart Institute. The system was first used clinically with a pneumatically powered pump that had an external console. This was a cost-saving approach, inasmuch as the initial patients were confined to the hospital. The original version of the HeartMate, however, was a vented-electric model (VE-LVAD). It was first used clinically, beginning in 1991, in patients expected to have a long wait for a donor heart.

The VE-LVAD and the implantable pneumatic version (IP-LVAD) have the same blood pump and similar operating principles. The blood pump is a flexible polyurethane diaphragm within a titanium alloy shell. The woven polyester (Dacron) inflow and outflow cannulas each contain a 25-mm caged porcine xenograft valve. The outflow cannula is extended by a 20-mm woven Dacron graft, which is trimmed to the proper length at implantation. To encourage the formation of a pseudo-neointimal lining and thereby minimize thromboembolism, all the blood-contacting surfaces except the valves are specially textured.<sup>66</sup> The titanium surfaces are covered with sintered titanium spheres, and the diaphragm is covered by fibrils that arise from its polyurethane base. The IP-LVAD pump weighs 570 g, and the VE-LVAD pump weighs 1150 g. Both devices produce a maximal effective stroke volume of 83 mL. Blood flows range up to 12 L/min for the IP-LVAD and 10 L/min for the VE-LVAD.

The HeartMate can greatly improve the clinical status of patients who receive bridges to transplantation.<sup>6,67,68</sup> Most patients who are in NYHA functional class IV before receiving the HeartMate return to class I after 3 to 4 weeks of support. Meanwhile, they can be rehabilitated physically. In cases involving prolonged MCS (>30 days), use of the HeartMate improves the outcome of transplantation.

**FIGURE 56-9** Novacor Ventricular Assist System. (Courtesy WorldHeart, Salt Lake City, UT.)

The IP-LVAD was the first implantable pump to be approved by the FDA (in 1994) for bridging to transplantation. The FDA based its approval on results of a study in which 75 IP-LVAD recipients were compared with 33 untreated control patients.<sup>4</sup> Transplantation was performed in 71% of the IP-LVAD recipients, of whom 91% survived after transplantation. In contrast, transplantation was performed in only 36% of the control patients, of whom 67% survived after transplantation.

The VE-LVAD (Figure 56-10) received FDA approval for commercial use in 1998. Because this model allows full patient mobility, it has been the device most commonly used for bridging to transplantation. In a prospective, multicenter trial,<sup>69</sup> 280 VE-LVAD recipients awaiting transplantation were compared with 48 control patients who did not receive ventricular assistance. The LVAD group was supported for an average of 112 days (range, 1 to 691 days), and 58% of these patients were enrolled in a hospital release program. Before a suitable donor heart could be found, 82 (29%) of the LVAD patients and 32 (67%) of the control patients died. Of the 280 LVAD recipients, 188 (67%) eventually underwent transplantation, and 10 (4%) had the device removed electively. One year after transplantation, the LVAD patients had a significantly better survival rate (84%) than did the control patients (63%;  $P = .0197$ ). Device-related complications included bleeding (11%), infection (40%), thromboembolic events (6%), and neurological dysfunction (5%).

**FIGURE 56-10** Components of the HeartMate vented-electric left ventricular assist device (LVAD). The inflow cannula is inserted into the apex of the left ventricle, and the outflow cannula is anastomosed to the ascending aorta. Blood returns from the lungs to the left side of the heart and exits through the left ventricular apex and across an inflow valve into the prosthetic pumping chamber. Blood is then actively pumped through an outflow valve into the ascending aorta. The pumping chamber is placed within the abdominal wall or peritoneal cavity. A percutaneous drive line carries the electrical cable and air vent to the battery packs (only the pack on the right side is shown) and electronic controls, which are worn on a shoulder holster and belt, respectively. (Modified from Rose EA, Gelijns AC, Moskowitz AJ, et al. Long-term mechanical left ventricular assistance for end-stage heart failure. *N Engl J Med* 2001;345:1435-1443, with permission, and from Naka Y, Rose EA. Assisted circulation in the treatment of heart failure. In Libby PL, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, ed 8, Philadelphia, 2008, Elsevier, pp 685-696.)

In 1998, researchers began a landmark study, the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH), designed to determine whether the VE-LVAD could offer permanent support for patients with severe heart failure who were ineligible for transplantation. Patients were randomly assigned to receive either MCS or continued medical therapy and were observed for 2 years. The results showed a reduction of 48% in the risk of death from any cause in the group that received LVADs, in comparison with those treated with medical therapy (relative risk = 0.52; 95% confidence interval, 0.34 to 0.78;  $P = .001$ ). Among the very ill patients with heart failure, the rates of survival at 1 year were 25% of those treated with medical therapy and 52% of those treated with the LVAD ( $P = .002$ ). At the end of the 2 years, the survival rates were 8% and 23%, respectively ( $P = .09$ ). Quality-of-life indicators were also more favorable for the LVAD-treated group (Figure 56-11).<sup>70</sup> As of January 2010, more than 6000 vented-electric HeartMate devices had been implanted worldwide, and the HeartMate XVE was the first LVAD to receive FDA approval for long-term support or destination therapy.

### HeartMate II Left Ventricular Assist Device

The HeartMate II (Thoratec Corporation) LVAD is a continuous-flow, rotary-pump device that is capable of delivering 6 to 12 L/min of flow. The pump consists of an internal axial-flow blood pump, a percutaneous lead that connects the pump to an external system driver, and a power source (Figure 56-12). One advantage of the HeartMate II LVAD is its smaller size, which allows it to be used in underserved populations, including women and adolescents.<sup>65,71</sup> Other benefits include the potential for long-term mechanical reliability, less noise, and greater comfort for patients.

The HeartMate II bridge-to-transplantation trial was a prospective, nonrandomized, multicenter trial enrolling 133 patients at 26 centers between March 2005 and May 2006. The researchers compared study patients with historical control groups by assessing objective performance criteria.<sup>4,69,72</sup> The primary endpoint was transplantation, cardiac recovery,

**FIGURE 56-11** Kaplan-Meier analysis of survival in the two treatment conditions of the Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial. OMM, optimal medical management; VE-LVAD, vented-electric left ventricular assist device. (Adapted from Park SJ, Tector A, Piccioni W, et al. Left ventricular assist devices as destination therapy: A new look at survival. *J Thorac Cardiovasc Surg* 2005;129:9-17, with permission and from Naka Y, Rose EA. Assisted circulation in the treatment of heart failure. In Libby PL, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, ed 8, Philadelphia, 2008, Elsevier, pp 685-696.)

**FIGURE 56-12** HeartMate II left ventricular assist device. (From Thoratec Corporation, Pleasanton, CA.)

or ongoing mechanical support while patients remained eligible for transplantation at 180 days (Figure 56-13). Secondary endpoints included functional status and quality of life. The primary endpoints were reached by 100 patients (75%), and the median duration of support was 126 days (range, 1 to 600 days). The survival rates during support were 75% at 6 months and 68% at 12 months. By 3 months after LVAD implantation, patients showed improvements in functional status and quality of life. Major adverse events included postoperative bleeding that necessitated surgery (31%), ischemic stroke (6%), hemorrhagic stroke (2%), transient ischemic attack (4%), right-sided heart failure (17%), infection unrelated to the device (28%), and percutaneous lead infection (14%).<sup>48</sup> This study showed that the continuous-flow HeartMate II LVAD provided effective hemodynamic support and improved both functional capacity and quality of life in patients awaiting transplantation. To date, more than 1000 patients worldwide have received the HeartMate II, which received FDA approval for use as a bridge to transplantation in 2009.

The Thoratec Corporation conducted a pivotal trial that compared the pulsatile HeartMate XVE (66 patients) to the continuous-flow HeartMate II (134 patients) for long-term support (ie, destination therapy).<sup>72a</sup> The trial enrolled patients in a 2:1 fashion; 2 patients received the HeartMate II for every 1 patient who received the HeartMate XVE. The primary composite end point was survival free from disabling stroke and from reoperation to repair or replace the device at 2 years. Secondary end points included survival, frequency of adverse events, the quality of life, and functional capacity. The primary composite end point was reached in more patients with continuous-flow devices than with pulsatile-flow devices (hazard ratio, 0.38; 95% confidence interval, 0.27-0.54;  $P < 0.001$ ), and patients with continuous-flow devices had superior actuarial survival rates at 2 years (58%

**FIGURE 56-13** Kaplan-Meier estimates of survival in patients who received pulsatile HeartMate XVE to the continuous-flow HeartMate II device as destination therapy. (From Slaughter, M. S., Rogers, J. G., Milano, C. A. et al. (2009). Advanced heart failure treated with continuous-flow left ventricular assist device. *N Engl J Med.* 361, 2241-2251.)

vs 24%,  $P = 0.008$ ) (Figure 56-13). Adverse events and device replacements were less frequent in patients with the continuous-flow device. The quality of life and functional capacity improved significantly in both groups. The HeartMate II was approved for use as destination therapy by the FDA in 2010.<sup>72b</sup> As of January 2010, more than 4000 HeartMate II LVADs have been inserted worldwide (Farrar, personal communication, August 6, 2010).

## PERIOPERATIVE COMPLICATIONS

The bridge-to-transplantation population is vulnerable to perioperative hemorrhage, sepsis, thromboembolism, renal failure, technical failure, and neurological sequelae.<sup>73,74</sup> The most common serious problems are hemorrhage and sepsis. Hemorrhage, which occurs in up to 60% of patients, results from liver dysfunction, the implantation procedure itself, and the blood trauma caused by cardiopulmonary bypass and blood-pump rheological characteristics.<sup>75,76</sup> Biventricular MCS is more likely to cause hemorrhage than is univentricular MCS.<sup>75</sup> Sepsis occurs in 30% to 40% of patients, resulting in significant morbidity.<sup>75,77-79</sup> Nevertheless, sepsis does not necessarily rule out successful cardiac transplantation.<sup>76,80,81</sup> Patients with comorbid conditions and hemorrhage are at the highest risk for sepsis.<sup>82,83</sup> Data from 195 LVAD patients enrolled in the Thoratec destination therapy registry between November 2001 and March 2005 were reviewed for risk factors for death in patients awaiting heart transplantation. According to univariate analysis, significant preoperative risk factors for 30-day mortality included reflections of the severity of heart failure. Patients were stratified into risk categories (extremely high, very high, high, moderate, and low risk) on the basis of a preoperative risk score.<sup>84</sup> The ultimate decision to proceed with VAD implantation can be made only after the patient has been thoroughly assessed and after all attempts have been made to optimize the patient's hemodynamics and end-organ function. Short-term MCS devices are often used in patients with recent shock and early multiorgan failure, who are at the highest risk for serious complications and death.

A common underlying cause of death in LVAD patients is right-sided heart failure, which decreases the preload of the left ventricle and, thus, of the device itself, compromising the cardiac output. This condition is often exacerbated by elevated pulmonary vascular resistance. Current therapy involves aggressive use of milrinone, nitric oxide,

nitroglycerin, or prostaglandin E<sub>1</sub>, all of which promote pulmonary vasodilation and improve left-sided blood flow. Often, right-sided heart failure occurs early after LVAD implantation and is precipitated by bleeding and the need for multiple transfusions. Preoperative fixed or hard-to-reverse elevated pulmonary vascular resistance increases the risk of right-sided heart failure after LVAD implantation. Despite medical therapy and the use of a right-sided VAD, treatment options are limited, and the rate of mortality from right-sided heart failure remains high.

## BRIDGING TO MYOCARDIAL IMPROVEMENT

The first patient reported to demonstrate long-term myocardial improvement with MCS was a 33-year-old man who received a HeartMate at the Texas Heart Institute in 1991. He died 503 days later, of a neurological thromboembolic complication, while still receiving MCS.<sup>2</sup> Before his death, the patient had a near-normal ejection fraction and evidence of physiological and anatomical myocardial recovery. Subsequently, positive results similar to these have been observed in HeartMate XVE and HeartMate II recipients, as well as in patients with other systems.<sup>6,85-87</sup> Most patients who undergo MCS before transplantation not only have improved hemodynamic, anatomical, and histological values<sup>47</sup> but also decreased levels of neurohormones such as plasma norepinephrine, which are abnormally elevated in heart failure.<sup>5</sup> On the basis of these observations, a number of patients have undergone LVAD removal after prolonged MCS led to meaningful long-term improvement in cardiac function. The number of such patients is small, but the potential clinical importance is considerable, inasmuch as most of these long-term patients show improvement.

To determine whether LVAD explantation is feasible, a method has been developed at the Texas Heart Institute to assess myocardial improvement through dobutamine stress echocardiography and invasive hemodynamic monitoring, with the LVAD off or providing only minimal support. Other centers have developed similar protocols to determine whether a patient can be weaned off LVAD support. With the use of the Texas Heart Institute method, 9 of 16 patients have had a favorable response, as indicated by improvements in the cardiac index, rate of rise of left ventricular pressure, ejection fraction, and left ventricular end-diastolic dimension as the dobutamine doses increased. The nine patients who had a favorable response underwent device explantation, and six have survived long term with good functional status. Because of the organ shortage and the difficulty of matching some patients with appropriate donors, this strategy may become very important in managing end-stage heart failure.

## BIOLOGICAL PROPERTIES OF VENTRICULAR UNLOADING

Intriguing reports suggest that mechanical unloading with an LVAD changes the structural and functional properties of the failing heart (see Chapter 8).<sup>88-91</sup> Improvements in structure, programmed cell death and survival, gene and protein expression, and cardiomyocyte function underlie the myocardial changes observed during LVAD support.

### Morphology

Mechanical unloading results in a 20% to 30% decrease in the myocyte volume, cell length, cell width, and cell length-to-thickness ratio, but the cell thickness does not change.<sup>92</sup> In addition, mechanical unloading decreases the nuclear size

and DNA content, which is suggestive of a reversal of nuclear hypertrophy and polyploidization.<sup>93</sup> In addition to changing cardiomyocyte structure, LVAD treatment alters the composition of the myocardial extracellular matrix. Whereas results of early studies suggested that a slight increase in myocardial fibrosis accompanies mechanical unloading,<sup>94,95</sup> more recent studies have revealed that LVAD treatment reduces fibrosis and collagen I and III content.<sup>96,97</sup> Thus, MCS reverses some of the histopathological findings in patients with end-stage cardiomyopathy.

## Programmed Cell Death and Cell Survival (see Chapter 6)

End-stage cardiomyopathy is associated with an increase in the rate of programmed cell death (apoptosis).<sup>98</sup> This loss of myocytes is believed to contribute to myocardial dysfunction. Mechanical unloading may improve cardiac function, as just noted, and may also decrease apoptosis. Comparison of myocardial samples obtained before and after LVAD treatment revealed a reversal of the decreased transcription of the antiapoptotic proteins Bcl-x(L) and FasExo-6Del.<sup>99</sup> This change was accompanied by an attenuation of DNA fragmentation. In addition, Uray and associates<sup>100</sup> found that transcription of human epidermal growth factor receptor 2 (Her2/neu), an antiapoptotic tyrosine kinase, increases with LVAD treatment. These findings suggest that mechanical unloading activates antiapoptotic pathways. In contrast, other researchers, using immunohistochemistry, have found that the levels of Bcl-2 and the repair-marker-protein proliferator cell nuclear antigen are increased at the time of device insertion and are decreased in most patients with mechanical unloading.<sup>101</sup> Reports concerning the cell-survival programming and the reentry of myocytes in the cell cycle have received much attention.<sup>102,103</sup> Cell-survival pathways (e.g., activation of protein kinase B) and cardiomyocyte hyperplasia counterbalance the myocyte loss induced by apoptosis and necrosis and may contribute to the improvement of cardiac function during mechanical unloading.

## Reversal of Dysfunctional Gene and Protein Expression (see Chapter 8)

Interest has focused on mediators and mechanisms of contractile dysfunction and their reversal with mechanical unloading. The results of a study that included 47 patients with NYHA class III or IV heart failure suggested that a 3-month regimen of soluble tumor necrosis factor (TNF) receptor (etanercept) improves the structure and function of the left ventricle.<sup>104</sup> Several multicenter trials have examined the role of TNF- $\alpha$  Antagonism in patients with end-stage cardiomyopathy. In two trials—Research into Etanercept Cytokine Antagonism in Ventricular Dysfunction (RENAISSANCE) and Randomized Etanercept North American Strategy to Study Antagonism of Cytokines (RECOVER)—the use of three dosages of etanercept, a fusion protein directed against TNF- $\alpha$ , has been evaluated in 2048 patients with heart failure. The studies were halted early because no benefit was seen with any dosage of etanercept.<sup>105</sup> In addition, a smaller study of 150 patients with moderate heart failure did not demonstrate clinical improvement in patients treated with infliximab, a chimeric monoclonal antibody that binds to TNF- $\alpha$ , despite a decrease in the inflammatory cytokines C-reactive protein and interleukin-6.<sup>106</sup> One important finding of these three trials was that the lowest dosage of anti-TNF- $\alpha$  therapy appeared to be safe; however, the optimal dose for potential benefit in patients with heart failure still needs to be established.<sup>105</sup> Interestingly, two studies have shown that increased myocardial levels of TNF- $\alpha$  gene and protein expression, seen

at device implantation, decrease with mechanical unloading.<sup>13,91</sup> These findings suggest that LVAD-related improvement of cardiac function is associated with a decreased content of myocardial TNF- $\alpha$ .

In addition to cytokines, several other genes and proteins are altered by mechanical unloading. For example, unloading of the heterotopically transplanted normal rat heart induces reactivation of fetal genes, as seen in pressure-induced hypertrophy.<sup>107</sup> Induction of the fetal gene program may be an adaptive response in favor of an energy-sparing metabolism. Other investigators have shown that dystrophin expression,  $\beta$ -tubulin protein content, and levels of the stress-inducible protein metallothionein become normal or nearly normal with LVAD support.<sup>108-110</sup> These changes in the genes and proteins of energy metabolism, the cytoskeleton, and cardioprotection may contribute to LVAD-related improvement in cardiac function.

### Improved Cardiomyocyte Function

In studies of isolated human cardiomyocytes, LVAD support increased the magnitude of contraction, shortened the time of peak contraction, and reduced the time to 50% relaxation.<sup>111</sup> In addition, responses to  $\beta$ -adrenergic stimulation were greater in myocytes isolated after LVAD support. In this context, Ogletree-Hughes and colleagues<sup>112</sup> found that mechanical unloading reverses the downregulation of  $\beta$ -adrenergic receptors and improves cardiac responsiveness to inotropic stimulation. Similar findings were reported by Heerd and coworkers,<sup>113</sup> who measured the isometric force-frequency relationship in isolated left ventricular trabeculae from failing hearts with and without LVAD support. These investigators verified that mechanical unloading improves the contractile force. Northern blot analysis (messenger RNA) showed upregulation of sarcoplasmic/endoplasmic reticulum calcium adenosine triphosphatase (SERCA) subtype 2a, the ryanodine receptor, and the sarcolemmal sodium-calcium exchanger, whereas Western blot analysis (protein) showed only increased SERCA subtype 2a protein content; consistent with the increased SERCA subtype 2a levels was the augmentation of calcium uptake by the sarcoplasmic reticulum in LVAD-treated hearts.<sup>113</sup> In the heterotopic abdominal mouse heart transplant model, Ritter and associates<sup>114</sup> showed that 5 days of unloading increases myocyte fractional shortening and the calcium homeostasis transient. Of four parameters (morphology, programmed cell death, dysfunctional gene and protein expression, and calcium homeostasis), calcium homeostasis consistently shows the most change in response to mechanical unloading. Recovery of left ventricular function during mechanical unloading has been reported by at least three groups, including one at the Texas Heart Institute.<sup>85,86,89,90,115</sup> However, these reports are anecdotal. Although there is evidence for improved function of the failing heart and organs, the mechanisms that underlie these phenomena are the subject of intense investigation.

The often-complete left ventricular unloading provided by the LVAD is allowing for new insights into the molecular and cellular biology of the failing heart and its response to hemodynamic forces. It is hoped that these insights will lead to optimal unloading strategies that can improve myocardial function and to many other medical or gene-based therapies that can aid the failing heart.

### ECONOMICS AND QUALITY-OF-LIFE ISSUES

Historically, the goal of MCS therapy has been successful bridging to transplantation. However, because of the concept of implanting support devices for permanent use, quality-of-life and long-term economic issues have become important.

To be successful for permanent use, an MCS device must reduce mortality, improve the patient's quality of life, and have a favorable economic effect. Results from the REMATCH trial, designed to assess these issues in patients with the HeartMate XVE LVAD, indicate that use of the LVAD as destination therapy may be a reasonable alternative to continued medical management in patients with medically refractory heart failure. Smaller studies have also yielded valuable insights. In the study by Grady and colleagues,<sup>116</sup> HeartMate XVE recipients who completed a questionnaire 1 to 2 weeks after LVAD implantation reported a significantly better quality of life, more satisfaction with health and functionality, and significantly less symptom-related distress than they had noted preoperatively. However, these patients also had significantly more self-care disability and dissatisfaction with their socioeconomic status. After LVAD implantation, exercise capacity improves slowly but substantially, and some patients are able to return to work.<sup>3</sup> Moskowitz and associates<sup>117</sup> found that patients undergoing bridging to transplantation had a substantially improved quality of life after LVAD implantation, although it was not as good as what they enjoyed after transplantation.

According to Dew and coworkers,<sup>118</sup> quality of life improves (much as it does in a transplant recipient) if the LVAD recipient is discharged home. The cost may also be substantially reduced by outpatient management. In investigations by Morales and associates,<sup>119</sup> who studied 44 HeartMate XVE patients, outpatient management yielded a substantial cost benefit; 30% of the patients were able to return to work or school. A patient's ability to resume productive activity confers a financial benefit to society that is difficult to measure. Because a growing percentage of the population is disabled by severe heart failure, this factor is becoming increasingly important in determining the economic aspects of long-term LVAD use.

### FUTURE DIRECTIONS

Tomorrow's blood pumps will be small, totally implantable devices that are more efficient, biocompatible, and reliable than today's models. The goal is to produce a durable device that requires no percutaneous elements and that can be implanted with minimal blood loss. Although still in the experimental stages, the following systems are showing considerable potential.

#### Jarvik 2000

The Jarvik 2000 is a miniature (90-g), continuous-flow LVAD that has only one moving part: the rotor (Figure 56-14). Like other continuous-flow pumps, it has diminutive blood-contacting surfaces and requires neither valves nor a compliance chamber. The device is small enough to fit some children and small adults. Also, it can be implanted through a lateral thoracotomy, without cardiopulmonary bypass.<sup>120</sup> This approach offers the theoretical advantages of less bleeding and lower operative risk, which are especially beneficial for patients who have undergone previous sternotomies. The device is positioned within the left ventricular apex, with the outflow graft attached to the descending or ascending thoracic aorta. Power is supplied through a small driveline that exits the abdominal wall. Once activated, the pump displaces up to 25 mL of blood and yields maximal flows of more than 11 L/min. In laboratory studies at the Texas Heart Institute, more than 25 calves have been supported by this pump for up to 240 days.<sup>121</sup> As of August 2010, this device has been implanted in 90 human patients at the Texas Heart Institute and in 422 patients worldwide. The first patient given lifetime use of the Jarvik 2000 in England was continuously supported for

**FIGURE 56-14** Jarvik 2000 left ventricular assist device. (Copyright 2000, Texas Heart Institute, Houston, TX.)

**FIGURE 56-15** MicroMed DeBakey ventricular assist device. (Courtesy MicroMed Cardiovascular, Inc., Houston, TX.)

7 years, 6 months, and 5 days, before dying of renal failure with a healthy heart. The overall results are very good; some deaths have been caused by multiple organ failure and right-sided heart failure in the very sick patients chosen to undergo implantation. Clinical studies are under way, and perioperative morbidity and mortality rates are lower than those for many other LVADs. Moreover, device reliability is unsurpassed: so far, there has not been a single failure of the pump mechanism. The level of hemolysis is clinically insignificant, and most patients regain normal renal, hepatic, and pulmonary function after device implantation. Because of this success, the Jarvik 2000 is likely to play a major role in a wide variety of clinical scenarios.<sup>122</sup>

**FIGURE 56-16** HeartWare left ventricular assist device. (Courtesy HeartWare, Miramar, FL.)

### MicroMed DeBakey VAD

The MicroMed DeBakey VAD is the result of collaboration among the DeBakey Heart Center, MicroMed Corporation, and the National Aeronautics and Space Administration (NASA). This axial-flow, nonpulsatile device was designed by a NASA engineer who received a heart transplant from Dr. DeBakey. The MicroMed DeBakey VAD is 3 inches long and 1 inch in diameter and weighs 53 g. It consists of an inflow cannula implanted in the left ventricular apex, a spinning impeller pump that contains a bearing, and an outflow cannula anastomosed to the ascending aorta (Figure 56-15). Outflow is monitored with a flow probe. The initial clinical results look promising, but significant regurgitation may result if the device stops. The risk of thrombosis and embolization appears to be high if sufficient anticoagulation is not achieved.<sup>116</sup> As of late 2002, the device had been implanted in 173 patients worldwide; 21 patients were supported for more than 6 months and one for more than 441 days. The overall experience is good, and design modifications are being made to reduce the risk of thrombosis.<sup>123-127</sup>

### HeartMate III

The HeartMate III (Thoratec Corporation) is being evaluated in animals. This pump has a transcutaneous energy transmission system that permits complete implantation and a magnetically suspended rotor that minimizes wear and may allow unparalleled longevity.

### MVAD by HeartWare

The miniature VAD (MVAD; HeartWare, Inc., Miramar, Florida) is a small pump with a wide-blade rotor design and a magnetically suspended impeller that generates axial blood flow (Figure 56-16). This design portends increased durability and longevity.<sup>128</sup> According to initial results from the HeartWare LVAS International Clinic Trial in Europe, 91% of patients survived 180 days after implantation.<sup>129</sup> A bridge-to-transplantation trial is under way in the United States.

**FIGURE 56-17** AbioCor total artificial heart. (Courtesy Abiomed, Danvers, MA.)

## Abiomed Total Artificial Heart

In an NHLBI-sponsored trial, the Texas Heart Institute and the Abiomed Corporation jointly tested the AbioCor TAH in hopes that it may eventually be used as a long-term cardiac substitute, a treatment for acute heart failure, and a bridge to transplantation. This biventricular pump is implanted orthotopically and relies on a flexible, hydraulically actuated membrane sac (Figure 56-17). The centrifugal pump is driven by a brushless direct-current motor that rotates at 6000 to 8000 rpm. The motor is powered by an internal battery, which is recharged by means of transcutaneous energy transmission. The direction of hydraulic flow can be easily reversed with a rotating valve. Because the valves and pumps are made of polyurethane, the pump is unusually quiet. The AbioCor was first implanted clinically in 2001, at the University of Kentucky, in a patient whose life expectancy was less than 30 days. In September 2006, the FDA approved a humanitarian device exemption for the AbioCor TAH after it was implanted in 14 patients. This study showed that the device is safe and benefits patients with severe heart failure for whom death is imminent. After initial clinical use, the atrial cage of the AbioCor TAH was redesigned to reduce the risk of thromboembolic events. To further refine and improve this technology, Abiomed will conduct a postmarket study of an additional 25 patients.

## CONCLUSION

Since the advent of MCS in the 1960s, extensive strides have been made in device technology, patient selection, and postoperative management. Long-term MCS is yielding insights into the biological processes of congestive heart failure and the effects of ventricular unloading. New applications, including bridging to myocardial improvement and permanent cardiac replacement, are becoming clinical realities. In clinical trials, LVAD implantation has produced survival rates at 1 year that rival those achieved with cardiac transplantation. The

improved patient outcomes with newer devices have encouraged earlier referral of patients with advanced heart failure for MCS. Although improvements are still needed in several areas, MCS is restoring an increasing number of patients with end-stage heart failure to productive, high-quality lives.

### Future Directions, 842

Until the middle of the 1970s, exercise testing was not routinely performed on patients with heart failure because of concerns about exacerbating symptoms, potential deleterious effects on ventricular function, and the possibility of severe cardiac dysrhythmias and arrest. For similar reasons, exercise training in patients with heart failure was actively shunned. In the late 1970s, studies began to demonstrate that exercise testing and training are safe in this population.<sup>1</sup> At the same time, the investigators noted the poor correlation between resting ventricular function and exercise capacity.<sup>2,3</sup> They decided patients with heart failure should no longer be excluded from diagnostic and prognostic exercise testing, nor should they be routinely advised to refrain from participating in exercise activities, including training. However, the effects of exercise training on symptoms and outcomes in heart failure patients remained unknown for many years.

Exercise intolerance, which is defined as the reduced ability to perform activities involving dynamic movement because of symptoms of dyspnea or fatigue, is the most common clinical symptom among patients with heart failure. The origin of exercise intolerance in patients with heart failure is multifactorial. Numerous investigations have identified potential mechanisms to explain the source of exercise intolerance. In this chapter, we review the potential mechanisms that underlie exercise intolerance in patients with heart failure and discuss the intricacies of exercise testing and training, with a focus on studies that have demonstrated the efficacy of exercise training in patients with heart failure.

capacity is the increase in heart rate associated with an increase in workload; increases in arteriovenous oxygen difference and stroke volume (LV end-diastolic volume multiplied times ejection fraction) contribute relatively little. Increases in stroke volume are accomplished by use of both the Frank-Starling mechanism to augment LV end-diastolic volume and more complete LV emptying to reduce end-systolic volume. The ventricles have inotropic reserve; when this is coupled to peripheral vasodilation during exercise, there is a greater degree of ventricular emptying. Age, gender, genetic profile, and level of conditioning may affect one or several components of the determinants of maximal exercise capacity.<sup>5</sup>

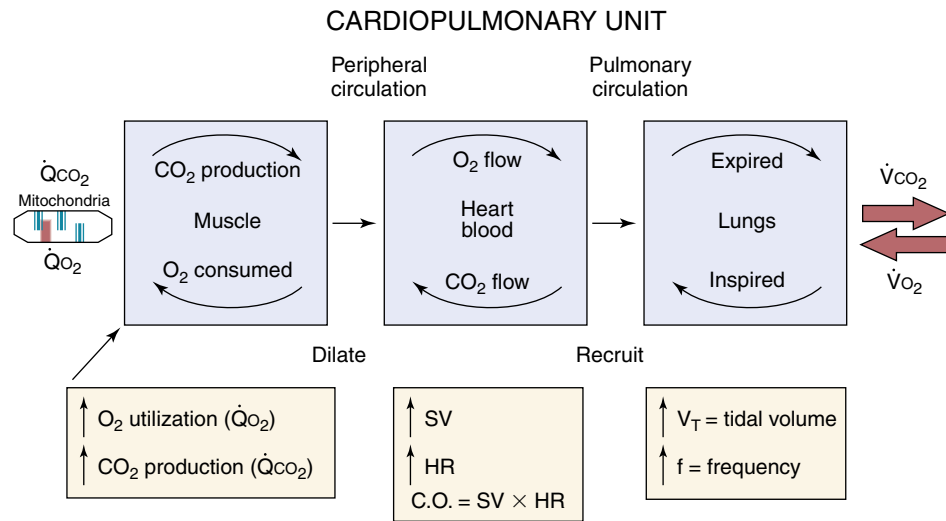

In patients with heart failure, the reduction in functional exercise capacity appears to result from a complicated combination of impairments in central and peripheral mechanisms, including impairments in cardiac output and blood flow to skeletal muscle, decreases in perfusion to active skeletal muscle as a result of decreases in capillary density, and intrinsic abnormalities in skeletal muscle themselves secondary.<sup>6-8</sup> In patients with heart failure, LV dilation, and reduced resting LV systolic function, stroke volume typically increases only modestly during exercise because of a blunted ability to increase both LV preload and ejection fraction.<sup>9</sup>

The reduced ability to augment LV end-diastolic volume is explained by the Frank-Starling mechanism: the fact that the already dilated LV is operating near its maximal volume and has thus exhausted most of its preload reserve. The failure to increase LV systolic emptying and thereby augment LV ejection fraction arises from a combination of impaired intrinsic contractility, reduced  $\beta$ -adrenergic responsiveness, elevated systemic vascular resistance caused by increased activity of the sympathetic and renin-angiotensin-aldosterone systems, and a blunted peripheral arterial vasodilator response to exercise.<sup>10</sup> Some of the peripheral vasoconstriction may also be associated with changes in muscle pH and accumulation of metabolites. In patients with ischemic cardiomyopathy, stroke volume may fall during exercise if myocardial ischemia develops as a result of

## MECHANISMS OF EXERCISE INTOLERANCE IN HEART FAILURE

### Cardiovascular

The capacity for performing aerobic exercise depends on the ability of the heart to augment its output to exercising muscle and the ability of skeletal muscle to use oxygen delivered via the circulation (Figure 57-1). Typically, cardiac output is increased four to six times in normal subjects exercising to maximal capacity.<sup>4</sup> The increase in cardiac output results primarily from a substantial increase in heart rate with a modest increase in stroke volume (Figure 57-2). In fact, in normal individuals, the primary determinant of maximal exercise

**FIGURE 57-1** Pluripotent stem cells from different sources can be expanded in vitro and differentiated into cardiac progenitor cells and mature cardiac cell types, thus enabling cell-replacement therapy or tissue engineering. CPC, Cardiac progenitor cell; ESC, embryonic stem cell; iPS cell, induced pluripotent stem cell; PSC, parthenogenetic stem cell; SGSC, spermatogonial stem cell. (From Wollert, K. C. and Drexler, H. C. (2010). Cell therapy for the treatment of coronary heart disease: a critical appraisal. *Nat. Rev. Cardiol.* 7, 204-215).

$$\dot{V}_{O_2} = \Delta(a - v)_{O_2} \times HR \times LVEDV \times EF$$

$$O_2 \text{ pulse} = \dot{V}_{O_2} / HR = \Delta(a - v)_{O_2} \times LVEDV \times EF$$

$\downarrow$   $\uparrow$   $\downarrow$   $\downarrow$   
 Surrogate for SV Central factors  
 Oxygen carrying capacity of the blood & peripheral (skeletal muscle) factors

**FIGURE 57-2** The Fick equation for oxygen consumption ( $\dot{V}_{O_2}$ ).  $\dot{V}_{O_2}$  = arteriovenous oxygen difference  $\times$  cardiac output; cardiac output represents heart rate (HR)  $\times$  left ventricular end-diastolic volume (LVEDV)  $\times$  ejection fraction (EF). The relation can be transformed to show that  $O_2$  pulse ( $\dot{V}_{O_2}/HR$ ) is a surrogate for stroke volume, if arteriovenous oxygen difference is assumed to be constant (LVEDV  $\times$  EF). Arteriovenous oxygen difference represents oxygen-carrying capacity of the blood (e.g., hemoglobin, red blood cell volume) and peripheral skeletal muscle factors.

excessive myocardial oxygen demand. Mitral regurgitation is often present during exercise in patients with heart failure and systolic dysfunction, as a result of dilation of the mitral annulus.<sup>11</sup> Such exercise-related mitral regurgitation reduces forward stroke volume but can be attenuated with vasodilators and diuretics.<sup>11</sup> Thus, in patients with heart failure, cardiac output is augmented primarily by heart rate increase because of the inherent limitations in stroke volume, as noted previously. Whereas maximal heart rate is usually reduced only mildly in patients with heart failure, blunting of heart rate reserve (i.e., the degree of heart rate augmentation above resting values) can be substantially blunted by current standard therapies for heart failure, such as  $\beta$ -adrenergic blockers and dual-chamber pacing. The chronotropic incompetence that results from such effects on acute exercise testing have been explored, but whether it influences the acquisition of an exercise training response is unknown.

### Peripheral

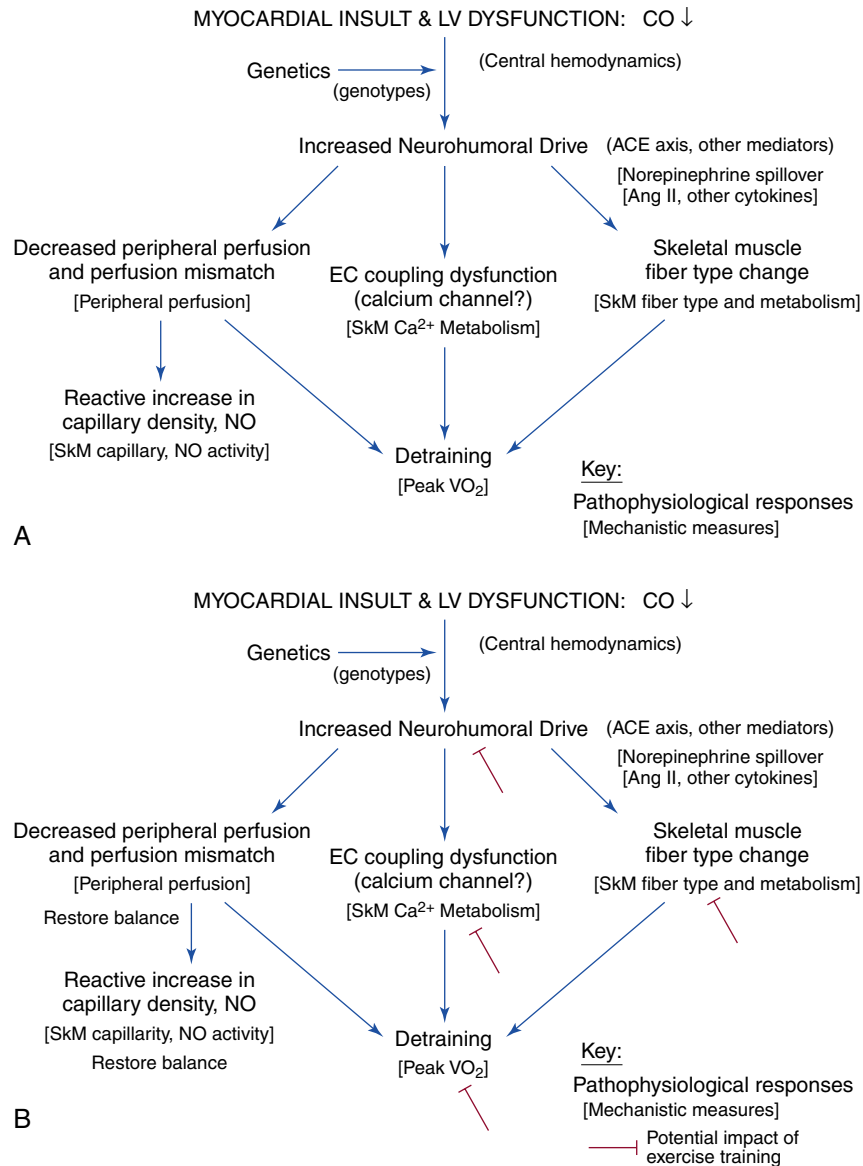

Measures of central hemodynamic function, such as filling pressures (e.g., LV end-diastolic pressure), do not substantially explain the exercise intolerance experienced by the majority of patients with heart failure.<sup>12</sup> Clinicians increasingly appreciate the role of peripheral factors in exercise intolerance in heart failure, including abnormalities of endothelial

function, ergoreflex activation, vasodilatory capacity, and intrinsic abnormalities in skeletal muscle, such as capillarity, fiber type, oxidative capacity, and channel function (see Duscha and associates<sup>8</sup> for review; **Figure 57-3, A**). Peripheral mechanisms account for exercise intolerance in heart failure in several ways: (1) The correlation between exercise capacity and measures of LV systolic function is poor,<sup>3,13</sup> and (2) central hemodynamic improvements can occur immediately with pharmacological therapy, but they do not translate into corresponding improvements in exercise capacity, which are delayed for weeks or months, if they occur at all.<sup>14,15</sup> This may be explained by the presence of a peripheral block in translating acute improvements in cardiac output into increased oxygen uptake and utilization in muscle. Perhaps a symptomatic improvement in heart failure results in increases in physical activity and exercise that lead to relief of the peripheral block, and improvements in translation of therapeutic increases in cardiac output translate into increases in exercise tolerance (see **Figure 57-3, B**).

### Blood Flow

In general, patients with heart failure have decreased blood flow to the periphery because cardiac output is decreased. However, up to 26% of patients with heart failure have normal peripheral blood flow.<sup>16</sup> Muscle blood flow normally increases during exercise; in patients with heart failure, this does not happen, largely because of an abnormality in peripheral vasodilation.<sup>17</sup> In the late 1960s, peripheral vasodilatory capacity was shown to be impaired in response to an ischemic challenge (postocclusion hyperemia).<sup>18</sup> Zelis and colleagues<sup>18-20</sup> demonstrated that forearm blood flow during rest and exercise was reduced in patients with heart failure, and this abnormality was present in response to a variety of stimuli, including isotonic and isometric exercise, adrenergic blockade, ischemia, and direct arterial vasodilation.

More recent studies have demonstrated that in such patients, leg vascular resistance fails to decrease normally during exercise.<sup>21,22</sup> This impairment in vasodilatory capacity has been attributed to excessive sympathetic stimulation, which causes vasoconstriction, activation of the plasma renin-angiotensin-aldosterone system, excessive levels of endothelin, or a combination of all these.<sup>23,24</sup> In addition, stiffness of the vascular wall secondary to increased vascular sodium content may impair appropriate vasodilatation. This finding is supported by

**FIGURE 57-3** Exercise intolerance and training in heart failure. **A**, Model of exercise intolerance in heart failure. Left ventricular (LV) systolic dysfunction, induced by myocardial insult (e.g., myocardial infarction or myocarditis) and decreased cardiac output, can impair exercise tolerance. Pathophysiological responses at each step are represented in *large type*, and the corresponding mechanisms are represented in *small type in brackets*. **B**, Model of how exercise training might alleviate exercise intolerance in heart failure. This model is similar to that shown in **A**: At certain points, exercise training has been shown to induce a physiological response that might block progression to symptomatic exercise intolerance; these points are shown with *flat-headed arrows*. ACE, angiotensin-converting enzyme; Ang III, angiotensin III; EC, excitation-contraction; NO, nitric oxide; SkM, skeletal muscle; VO<sub>2</sub>, oxygen consumption.

the observations that the capillary basement membranes may be thickened in heart failure<sup>25</sup> and that vascular responsiveness is partially improved by diuretic therapy.<sup>26</sup> Angiotensin-converting enzyme (ACE) inhibition has been demonstrated to normalize impaired vasodilation after chronic (but not short-term) administration.<sup>15,27</sup> Improvements in leg blood flow after ACE inhibition parallel increases in exercise capacity.<sup>27</sup> In addition, a “vascular deconditioning” hypothesis suggests that abnormal vasodilatory capacity is related to deconditioning and that localized training of a specific limb may improve the vasodilatory response in heart failure.<sup>28,29</sup>

### Intrinsic Skeletal Muscle Changes (see Chapter 19)

In heart failure, anaerobic metabolism, as a result of intrinsic abnormalities in skeletal muscle, occurs during exercise and is an important correlate of exercise intolerance. Previous studies with magnetic resonance imaging with phosphorus-31 have demonstrated that early anaerobic metabolism occurs

independently of reduced muscle blood flow and appears to be a systemic response, not limited to muscles that would normally be used during exercise.<sup>30,31</sup> This latter observation implies that the stimuli that cause this metabolic skeletal muscle abnormality are systemic. Other skeletal muscle changes include fiber atrophy, loss of oxidative type I fibers with an increase in glycolytic type IIb fibers,<sup>32-34</sup> and changes in mitochondrial density and enzymes. Fiber changes can reduce muscle performance and cause early fatigue.

Skeletal muscle characteristics, furthermore, have important ramifications on substrate and oxygen use during exercise. Myosin heavy chain type I isoforms have also been shown to be decreased and related to peak oxygen consumption (VO<sub>2</sub>) in heart failure.<sup>32</sup> Although glycolytic enzyme levels appear to be unchanged, oxidative enzyme levels are decreased in heart failure.<sup>30</sup> Specifically, mitochondrial enzymes (citrate synthase and succinic dehydrogenase) and enzymes involved in  $\beta$ -oxidation of fatty acids (3-hydroxyl coenzyme A dehydrogenase) are decreased. Sullivan and associates<sup>35</sup> found

inverse relationships between oxidative enzyme activity and blood lactate accumulation during sub maximal exercise. Drexler and colleagues<sup>34</sup> demonstrated a close relationship between cytochrome *c* oxidase, mitochondrial volume density or cristae surface density, and peak  $\text{Vo}_2$ . More recently, Hambrecht and colleagues<sup>36</sup> established that in patients with heart failure, the volume density of cytochrome *c* oxidase activity, which is reduced by 45%, could be increased with physical activity. Duscha and associates<sup>37</sup> also demonstrated a decrease in capillary density. Together, these findings suggest that intrinsic aberrations in skeletal muscle may contribute to abnormal oxygen extraction or substrate delivery and use and may further limit exercise tolerance in heart failure.

### Endothelial Dysfunction (see Chapter 17)

The vascular endothelium releases vasoactive substances that play an important regulatory role in peripheral vasomotor tone. Vasodilating and vasoconstricting factors—including nitric oxide, endothelins, and prostaglandins derived from the endothelium—are released in response to various chemical, pharmacological, and exercise stimuli. A pivotal role of the endothelium in coordinating tissue perfusion has been recognized in heart failure. Studies have demonstrated that endothelium-dependent vasodilation is impaired in heart failure, manifested by a reduction in the release of nitric oxide in response to acetylcholine.<sup>38-40</sup> The release of nitric oxide, an important mediator of flow-dependent vasodilation, is normally stimulated by exercise but appears to be attenuated in patients with heart failure. This may contribute to a reduction in peripheral vasodilation and tissue perfusion. Blood flow during reactive hyperemia or exercise is reduced in response to blockade of nitric oxide synthesis.<sup>41-43</sup> L-Arginine (a nitric oxide precursor) improves abnormal vasodilation in response to acetylcholine or an ischemic stimulus in heart failure. These observations are consistent with the concept that impaired endothelial function contributes to reduced vasodilatory capacity in heart failure.<sup>44</sup> The severity of impairment in endothelium-dependent vasodilation is correlated with the degree of exercise intolerance and severity of New York Heart Association (NYHA) class.<sup>43</sup> Exercise training with or without supplemental L-arginine improves endothelial nitric oxide formation and endothelium-dependent vasodilation of the skeletal muscle vasculature.<sup>44-46</sup> Of interest is that exercise of specific muscle groups, such as those of the lower extremity, systemically enhances endothelial function. As noted, the aberration of intrinsic skeletal muscle properties is systemic in origin. It is conceivable that this aberration is related to systemic abnormalities in nitric oxide metabolism in heart failure and may underlie the power of exercise to reverse these defects (see Figure 57-3, A and B).

### Ergoreflex Activation (see Chapter 16)

A specific proventilatory signal arising from exercising muscle, possibly including respiratory muscle, may be abnormally enhanced in heart failure.<sup>47,48</sup> Ergoreceptors are intramuscular afferent receptors that are sensitive to metabolic changes within skeletal muscle. Acidosis, when present in patients with heart failure, may sensitize these ergoreceptors to enhance their activity. Ergoreflex overactivity may be an early beneficial compensation that enhances sympathetic stimulation with increased ventilation and vasoconstriction to nonexercising muscle to maintain blood flow to essential circulatory beds. These compensatory mechanisms may lead to detrimental excess activity of sympathetic nerves, excessive vasoconstriction, and blunted vagal responses, which are characteristic of patients with heart failure.<sup>49</sup> Ponikowski and coworkers<sup>48,49</sup> showed that ergoreflex activation parallels exercise intolerance, whereas ventricular function is

poorly related to neural reflexes. In addition, in this study, ergoreflex sensitivity was predictive of autonomic and reflex disturbances such as baroreflex attenuation and lower levels of central catecholamines, thus confirming that sympathetic inputs are enhanced and vagal reflex is impaired. Periodic breathing, in which enhanced chemoreflex plays an important role, was particularly prevalent in the subjects with enhanced ergoreflex.

The overactive muscle ergoreflex is more closely related to exercise intolerance and the abnormally elevated ventilatory response to exercise than are other autonomic indexes or reflexes. These data are consistent with a key role of the muscle ergoreflex in symptom generation and disease progression. The relation between ergoreflex activation and ventilatory responses that are known to be abnormal in patients with heart failure during exercise is stronger than expected for any level of workload and is related to outcome in chronic heart failure. No single theory has totally explained the overactive ventilatory drive noted in patients with heart failure during exercise. Activation of these reflexes appears to be attenuated by exercise training.<sup>50</sup>

## FUNCTIONAL EXERCISE TESTING IN HEART FAILURE

Despite a marked increase in the population with heart failure since the 1990s, only more recently has exercise testing taken a more prominent role in the diagnosis and management of heart failure. Heart failure is characterized by the inability to perform desired activities because of dyspnea or fatigue, or both. Exercise testing is now a critical component of the evaluation of a patient with a presumed cardiac origin of presenting symptoms. Three exercise testing modalities of general use in the population with heart failure are discussed in this chapter: the 6-minute walk test; graded exercise testing with electrocardiographic monitoring; and cardiopulmonary exercise testing (CPET), which is graded exercise testing with gas exchange analysis. Each testing method has advantages in given clinical situations. Of these, CPET and the 6-minute walk are the most common modalities for evaluating the functional capacity of patients with heart failure. The 6-minute walk is used to evaluate low-level or submaximal work and is more compatible with activities of daily living; CPET is used to evaluate maximal exercise capacity, for prognostic stratification, and for staging for possible cardiac transplantation.

In addition, there are various graded exercise testing protocols in which the workload is progressively increased during the test, either on a bicycle or a treadmill. The selection of a particular protocol should be based on the experience of the testing physician, on the physical ability of the patient, and on the availability of the facility where the test is being performed. Exercise testing of patients with heart failure is supported by the American Heart Association<sup>50,51</sup> for clinical and research application.<sup>52</sup>

### 6-Minute Walk

The 6-minute walk test was first described by Guyatt and associates<sup>52</sup> for the evaluation of patients with pulmonary disease and was later adapted for patients with heart failure. Patients are asked to walk for 6 minutes at whatever pace is comfortable on a premeasured flat surface. Communication with the patient consists only of simple instructions and of the time remaining in the test. The number of meters covered during the 6 minutes is recorded. This test has been used in clinical trials to determine the benefits of pharmacotherapy in patients with heart failure because it is easy and inexpensive, and testing personnel require minimal training. However, the 6-minute walk test may not help distinguish between patients

with mild to moderate heart failure and those with more advanced disease.<sup>53</sup> A distance of less than 300 m is considered indicative of severe exercise intolerance. Lucas and colleagues<sup>53</sup> tested patients with a wide range of  $\text{Vo}_2$  values and observed that the 6-minute walk test best helped discriminate patients with peak  $\text{Vo}_2$  of more than 20 mL/kg/min or Weber class A from those with extreme functional limitations of peak  $\text{Vo}_2$  (<10 mL/kg/min) or Weber class D.

In clinical trials, the reliability of the 6-minute walk test as a reliable marker of clinical improvement, progression of disease, or mortality has been inconsistent. For example, in the U.S. Carvedilol Heart Failure Study,<sup>54</sup> the 6-minute walk test was unable to detect improvements in symptoms or the clinical endpoints of hospitalizations or mortality despite the fact that carvedilol resulted in significant decreases in the rate of disease progression. Only in the SOLVD trial, was there a significant relation between the 6-minute walk test and clinical endpoints, including mortality.<sup>55</sup>

## Cardiopulmonary Exercise Testing

CPET has a significant advantage over simple exercise testing with electrocardiographic monitoring, in that it provides a measure of coupling between central pulmonary gas exchange, cardiac output, and peripheral oxygen delivery to and use by skeletal muscle. Therefore, as discussed subsequently, it provides access to a number of respiratory, central cardiac, and peripheral metabolic measures that can provide insight into the causes of dyspnea and exercise intolerance, insight that is not provided by the simple electrocardiogram. Finally, in assessing peak  $\text{Vo}_2$  directly, it provides a more accurate measure of functional capacity than can be provided by the estimate derived from exercise testing with electrocardiographic monitoring, which depends on assumptions that can vary significantly among individuals and disease states. The diagnostic utility of the CPET depends on the fact that oxygen uptake is a direct measure of cardiac output and extraction of  $\text{O}_2$  by the periphery, according to the Fick equation (see Figure 57-2). For example, as shown in Figure 57-2, the  $\text{O}_2$  pulse is a direct measure of cardiac output, if a constant oxygen extraction in the periphery is assumed. A premature plateau in the  $\text{O}_2$  pulse during a graded test can be a reliable sign of cardiac ischemia. Also, CPET is helpful in differentiating the cause of dyspnea in patients. Heart failure often coexists with chronic obstructive pulmonary disease. The breathing reserve (the difference between the maximal ventilatory volume and the ventilatory volume at peak exercise) is readily obtained from CPET. In patients with heart failure but without chronic obstructive pulmonary disease, the breathing reserve remains normal at maximal work or above dyspnea threshold. Conversely, patients whose limitation is primarily pulmonary in origin have impaired exercise capacity and limited breathing reserve accompanying the dyspnea. Box 57-1 defines breathing reserve in two ways and gives normative values for each.

Furthermore, serial measurements of carbon dioxide production and oxygen consumption during a steady state or a graded

exercise test can provide numerous additional data, discussed subsequently, that have both diagnostic and prognostic information, such as the ratio of volume of expired gas to carbon dioxide production ( $\text{V}_E/\text{VCO}_2$ ), ventilatory threshold, and respiratory exchange ratio. When used in combination with electrocardiography, CPET testing can be a cost-efficient way of obtaining useful clinical information about the patient with heart failure, which abrogates the need for further and more costly testing, such as diagnostic radionuclide or echocardiographic stress testing, although imaging clearly has additional utility.

Unlike the 6-minute walk test, CPET requires specialized equipment for gas exchange, coupled to electrocardiographic monitoring, and can be performed with various instruments such as a treadmill or bicycle ergometer. Specialized training of personnel is also needed in order to administer the test, and regular quality control of the testing laboratory is necessary to ensure that equipment works accurately. The risks in testing are similar to those in standard treadmill exercise tests and are surprisingly modest, as shown in a study from Heart Failure and A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION), in which the risks in the population with heart failure compare favorably with those in testing in populations with coronary artery disease.<sup>56</sup> The Exercise Testing Statement of the American Heart Association provides guidance on personnel training and equipment, as well as space needs.<sup>57,58</sup> Although a low peak  $\text{Vo}_2$  is correlated with poor survival, improvements in peak  $\text{Vo}_2$  have not been consistently correlated with mortality-related benefits in clinical drug trials when those values are used as a surrogate.<sup>59</sup> In the Veteran's Administration Cooperative Vasodilator-Heart Failure Trial (V-HeFT) studies, the hydralazine-nitrate combination improved  $\text{Vo}_2$  better than did enalapril, albeit for a short time.<sup>60</sup> However, mortality-related benefits from enalapril were superior to those of the vasodilator combination. Similarly, flosequinan demonstrated marked improvements in exercise capacity, but it increased mortality. The use of CPET as a surrogate marker for clinical drug trials remains somewhat controversial.

## Prognostic Measures Derived from Cardiopulmonary Exercise Testing

CPET provides important prognostic information, particularly peak  $\text{Vo}_2$ , in identifying the most appropriate candidates for cardiac transplantation.<sup>59</sup> A peak  $\text{Vo}_2$  of 14 mL/kg/min is often identified as the critical value for transplantation eligibility. This criterion is not usually adjusted for age or gender, however. Peak  $\text{Vo}_2$  is inherently lower in women and decreases monotonically with age after approximately 30 years, even in persons with heart failure.<sup>61</sup> Some authorities advocate using less than 50% of predicted  $\text{Vo}_2$  as a better criterion than a universal value that is applied to all ages and both genders.<sup>62</sup> For example, in an 18-year-old man with dilated cardiomyopathy, a  $\text{Vo}_2$  value of 18 to 20 mL/kg/min is obviously above the minimum 14 mL/kg/min value; however, such functional capacity is markedly abnormal for his age and gender, for which normal subjects should have a  $\text{Vo}_2$  value greater than 35 mL/kg/min. Conversely, in a small 65-year-old woman, a peak  $\text{Vo}_2$  value of 14 mL/kg/min is close to 70% of her predicted value; however, the peak  $\text{Vo}_2$  normograms currently in use were developed in apparently normal populations, and in morbid populations, in contrast, the effects of disease on peak  $\text{Vo}_2$  are greatly variable. For example, peripheral arterial disease, arthritis, and type 2 diabetes mellitus negatively affect peak  $\text{Vo}_2$  values in otherwise normal subjects. Therefore, the percentage of predicted value in clinical reports must be interpreted in a patient-specific context in view of other comorbid conditions. In spite of these limitations, CPET is routinely used for functional outcome measures in the population with heart failure and for selection of patients for cardiac transplantation and for implantation of LV assist devices.

### BOX 57-1 Breathing Reserve

$\text{MVV} - \text{V}_E$  at maximal exercise or  $\text{MVV} - \text{V}_E$  at maximal exercise/  
MVV

Normal = at least 15 L/min or 20% to 40% MVV

Low breathing reserve = ventilatory limitation (e.g., as in pulmonary disease)

True MVV may be lower than predicted in patients with restrictive pulmonary disease

MVV, maximal ventilatory volume;  $\text{V}_E$ , volume of expired gas.

In addition, other parameters derived from CPET are of prognostic significance, including ventilatory equivalents of  $\text{VCO}_2$  ( $\text{VE}/\text{VCO}_2$ ),<sup>63,64</sup> postexercise recovery oxygen kinetics,<sup>65-68</sup> and onset of anaerobic (ventilatory) threshold. The promise of CPET testing for research and clinical care is still under active exploration, and further advances are anticipated.

## SPECIALIZED USES OF CARDIOPULMONARY EXERCISE TESTING

### Evaluation of Patients with Heart Failure for Mitral Valve Surgery

There is a significant association between heart failure and mitral regurgitation: Mitral annular dilation resulting from LV remodeling can lead to mitral regurgitation. Hemodynamic function is significantly worse, and adverse outcomes are associated with mitral regurgitation in the setting of heart failure.<sup>69</sup> As the number of patients awaiting transplantation increases and the number of donors remains unchanged, correction of mitral regurgitation in the population with heart failure can be a temporizing measure and a bridge to eventual transplantation. However, the criteria for identifying the best candidates for mitral valve repair or replacement have remained elusive.

Some authorities have advocated the evaluation of the degree of mitral regurgitation by using the proximal isovelocity surface area (PISA) method, through color flow Doppler imaging, during exercise; the results are correlated with elevation of the systolic pulmonary artery pressure.<sup>70</sup> The analysis by PISA was feasible and, interestingly, better during exercise, probably because the regurgitant volume was larger. Of the 27 patients studied, none had heart failure secondary to valvular heart disease or had NYHA class IV heart failure. During exercise, all patients demonstrated an increase in their systolic pulmonary artery pressures, measured from the tricuspid regurgitant jet velocities. Pulmonary hypertension was associated with higher mitral valve regurgitant volume and was significantly correlated with the reason why patients stopped the test: because of dyspnea rather than fatigue.

### Evaluation of Chronotropic Incompetence

Normal heart rate increases linearly with increasing workload (and oxygen demand; see Figure 57-2). According to widely accepted criteria, a normal individual, not taking  $\beta$ -adrenergic blockers, should be able to achieve at least 85% of the age-predicted heart rate.<sup>71</sup> This observation has been validated in multiple studies, most of which were conducted before the  $\beta$ -blocker era. At present, however, there is no valid guideline on the expected increase in heart rate from the baseline in patients, with or without heart failure, who do take  $\beta$ -blockers.<sup>72-74</sup> In the HF-ACTION study, more than 94% of the 2331 subjects with heart failure tested were receiving optimal medical therapy for heart failure, including  $\beta$ -adrenergic blockers; data from this study should address this issue.<sup>61</sup> Furthermore, many patients with heart failure may have inherent chronotropic incompetence as a result of cardiac conduction disease or pacemaker therapy. This has also been addressed in the HF-ACTION population.<sup>75</sup> Other studies have shown that reactivation of the parasympathetic nervous system may also play a role in the abnormal response to heart rate noted in patients with heart failure.<sup>76</sup> Such information is helpful in order to interpret CPET results correctly for patients with heart failure, who are increasingly and more intensively treated with agents and devices that interact with normal cardiorespiratory physiology (e.g.,  $\beta$ -adrenergic agents, biventricular pacemakers). Furthermore, CPET can be

used to identify causes of excessive dyspnea and exercise-induced fatigue in patients with heart failure, such as chronotropic incompetence from excessive  $\beta$ -adrenergic dosing or a poorly functioning cardiac pacemaker.

### Adjustment of Pacemakers

The question of whether implantation of a rate-responsive pacemaker would improve exercise tolerance was investigated by Braith and coworkers<sup>76</sup> in a pilot study that involved patients after heart transplantation. Using a graded treadmill exercise test with metabolic measurements in eight patients, they observed that exercise tolerance, peak  $\text{VO}_2$ , and minute ventilation were statistically better when the pacer was on. Further larger trials are needed to completely demonstrate the beneficial effect of rate-responsive pacemaker in patients with chronotropic incompetence. The long-term benefits of cardiac resynchronization therapy on exercise tolerance in heart failure have not yet been fully established, and further work is therefore needed in this area as well.

### Safety of Exercise Testing and Training in Patients with Heart Failure Who Have Implantable Defibrillators

Patients with an implantable cardioverter-defibrillator (ICD) very often avoid performing routine exercise for fear of either triggering an arrhythmic event or causing the device to fire inappropriately in the setting of exercise-induced tachycardia. In one study, 63% of young patients with ICD reported concerns about engaging in exercise.<sup>77</sup> This fear also characterizes many technicians and clinicians who test patients with heart failure in the exercise laboratory.

These concerns are, however, unfounded. First, a patient with an ICD and stable symptoms should be able to exercise and raise the heart rate to within 70% to 80% of the predicted maximum safely. This was shown in the HF-ACTION study, in which the results of more than 6000 CPET tests in 2331 subjects with heart failure were studied; the major cardiovascular event rate, which included ICD firing, was less than 0.5 per 1000 tests.<sup>56</sup> Furthermore, in the HF-ACTION exercise training condition, involving 1159 patients with heart failure, exercise training was observed to be safe, with no increase in the number of events during or within the 3 hours after exercise training, in comparison with the inactive control condition.<sup>78</sup> Finally, whenever there are concerns with regard to the presence of ICD in a patient with heart failure who is undergoing exercise training, the cardiologist who is familiar with the patient's condition should work with the exercise staff to guide the exercise program. With close cooperation, a compromise between ICD detection algorithms, type of therapy applied, and level of exercises can be achieved, and the patient will benefit from the physical and mental benefits of exercise.<sup>77,79</sup>

## THERAPEUTIC EXERCISE TRAINING FOR HEART FAILURE

### Physiological Benefits of Exercise Training in Heart Failure

It is clear from HF-ACTION<sup>80</sup> and other studies that exercise training can be undertaken in patients with heart failure and that the potential benefits of training exceed the risks. Significant physiological benefits accrue with prolonged exercise training in the population with heart failure, and they potentially counteract the pathophysiological processes of the symptomatic heart failure state (see Figure 57-3, A and B). Some of these are discussed in detail as follows.

The benefits of exercise training in patients with heart failure include an improvement in exercise tolerance, as assessed through exercise duration and peak  $\text{Vo}_2$ .<sup>81-95</sup> Table 57-1 lists randomized, parallel, or crossover studies with definitive improvements in peak  $\text{Vo}_2$ . The exercise training program may be in the setting of supervised or home training; it may involve a treadmill or a bicycle; the duration may vary from 8 weeks to 3 months; and the level of intensity may vary from low to moderate. Although most studies have included primarily aerobic activity, one study involved mainly circuit weight training for 8 weeks; results indicated a modest but significant increase in peak  $\text{Vo}_2$ .<sup>95</sup> Changes in peak  $\text{Vo}_2$  have ranged from 12% to 31%. Most of the improvement occurs by the third week but can still be noted at 6 months if patients comply with the training program.<sup>96,97</sup> Improvements occur not only in maximal exercise performance but also in indexes of submaximal exercise, as measured by the 6-minute walk test or the ventilatory (anaerobic) threshold.<sup>84</sup>

The benefits in  $\text{Vo}_2$  have been correlated with other indexes of improvements in exercise capacity, such as an increase in muscle mitochondria<sup>84</sup> and decreased ventilation.<sup>82</sup> However, these studies represent highly selected populations of extremely motivated volunteers, and they occurred before the use of devices (most notably biventricular pacing and LV devices) and  $\beta$ -adrenergic pharmacological therapy for heart failure became widespread; the interaction of these types of therapies with exercise training responses is relatively unknown. In the HF-ACTION study, among 1159 patients with classes II and III heart failure who were receiving optimal medical and device therapy (including 19% using biventricular devices and over 94% taking optimal doses of  $\beta$ -adrenergic agents), the improvement in peak  $\text{Vo}_2$  (which was 14.4 mL/kg/min at baseline) was only 4.2% at

3 months and 4.9% at 12 months after patients transitioned to home exercise for at least 6 months.<sup>78</sup> The corresponding improvements in the 6-minute walk test were 20 and 13 m, respectively.

**Neurohormonal Activation**

Higher levels of neurohormonal activation are associated with worse ventricular function, worse symptoms, and worse prognosis in heart failure. Excessive catecholamine levels, as manifested by norepinephrine spillover, were ameliorated after only 8 weeks of bicycle training in a population with heart failure.<sup>82</sup> In a small crossover trial by Coats and colleagues,<sup>81</sup> 8 weeks of home training enhanced vagal control with a shift away from sympathetic activity. Also, peak exercise levels of angiotensin II, aldosterone, and vasopressin decreased after 16 weeks of endurance training. However, observations about exercise-induced changes in resting epinephrine levels have been inconsistent. For example, Kiilavuori and coworkers<sup>98</sup> observed a 19% drop in resting epinephrine levels after a 3-month training program, whereas Keteyian and colleagues<sup>94</sup> found no changes in resting norepinephrine after 24 weeks of training. Hambrecht and associates<sup>99</sup> described not only a significant drop in epinephrine levels at rest, with a trend toward decreased norepinephrine levels at rest, but also during submaximal exercise. More recently, Tyni-Lenne and coworkers<sup>100</sup> observed that local muscle training could not only improve aerobic activity but also lower catecholamine levels. The variability in these findings may be related to the severity of disease, cause of disease, duration of the heart failure syndrome, intensity and duration of exercise training, the modulation of sympathetic activity by drugs, and the technical difficulties associated with measuring true catecholamine levels at rest.

**Endothelial Dysfunction (see Chapter 17)**

Researchers have focused attention on exercise training effects on the well-known endothelial dysfunction that accompanies heart failure. Because heart failure is not simply “pump failure” but a multisystem disorder that includes neurohormonal imbalance, researchers have extensively studied alterations in systemic vasomotor tone, particularly the role of endothelial release and regulation of nitric oxide metabolism, and these alterations have been identified as contributing to the disease state.<sup>101</sup> Exercise training has local and systemic beneficial effects on agonist-mediated endothelium-dependent vasodilation and on flow-dependent vasodilation.<sup>102</sup> Elevations of shear stress at the local level, coupled to the systemic effects of heart rate and blood pressure, increase peripheral blood flow. Furthermore, L-arginine supplementation, which increases nitric oxide availability, augments the effects of exercise training on endothelial function and vasomotor regulation.<sup>43</sup> These may be the mechanisms underlying significant improvement in endothelial function that is noted with exercise training in the population with heart failure.

**Effects on Intrinsic Skeletal Muscle Characteristics**

Alterations in skeletal muscle structure and function, representative of and consistent with a movement from a more oxidative to glycolytic fiber-type distribution, have been linked to exercise intolerance in patients with heart failure.<sup>8</sup> Loss of skeletal muscle oxidative capacity is one of the hallmarks of heart failure, and the effects of training on this are under active investigation. Hambrecht and associates,<sup>83</sup> Keteyian and colleagues,<sup>103</sup> and others have studied the effect of exercise training on muscle oxidative ability in patients with heart failure in the vastus lateralis muscle. In Hambrecht and associates’

TABLE 57-1 Change in Peak $\text{Vo}_2$ with Exercise Training in HF		
Authors (Year)	Number of Patients (Total, 439)	$\text{Vo}_2$ Increase in Comparison with Controls (Average, 20%)
Jette et al (1991) <sup>68</sup>	18	22% in group with ejection fraction < 30%
Belardinelli et al (1992) <sup>87</sup>	20	20%
Coats et al (1992) <sup>81</sup>	17	18%
Belardinelli et al (1995) <sup>82</sup>	55	12%
Hambrecht et al (1995) <sup>83</sup>	22	31%
Keteyian et al (1996) <sup>84</sup>	29	16.3%
Radaelli et al (1996) <sup>88</sup>	6	15%
Dubach et al (1997) <sup>85</sup>	25	26%
Tyni-Lenne et al (1997) <sup>89</sup>	16	14%
Callaerts-Vegh et al (1998) <sup>90</sup>	17	30.9%
Reinhart et al (1998) <sup>91</sup>	25	29%
Belardinelli et al (1999) <sup>86</sup>	99	18% at 2 months
Taylor (1999) <sup>92</sup>	8	17.6%
Sturm et al (1999) <sup>93</sup>	26	23.3%
Keteyian et al (1999) <sup>94</sup>	43	14.3%
Maiorana et al (2000) <sup>95</sup>	13	11.8%

$\text{Vo}_2$ , oxygen consumption.

randomized controlled study, after 6 months, subjects assigned to an ambulatory exercise training program demonstrated a significant increase in mitochondrial density, with enhanced oxidative enzyme activity and a shift from white, fast-twitch type II fibers to red, slow-twitch type I fibers. There were no changes in submaximal blood flow in the legs; therefore, it is unlikely that the changes in peripheral perfusion could account for the changes seen in the mitochondria.

The functional limitations of heart failure occur not only at high workloads but also at submaximal workloads, which are levels that correspond to many activities of daily living in this patient population. In addition to beneficial effects of exercise training on skeletal muscle oxidative capacity, effects on other skeletal muscle parameters support the concepts that skeletal muscle abnormalities are the primary cause of functional limitation in heart failure and that exercise training may be a viable modality for counteracting these effects and thus increase functional capacity (see [Figure 57-3, A and B](#)).<sup>89</sup> For example, exercise training reduces muscle lactate release and increases levels of oxidative enzymes from skeletal muscle.<sup>84</sup> In addition, increases in muscle mass by resistance training might very well lead to alleviation of some symptoms, especially in elderly patients, in whom type II fiber atrophy exacerbates the loss of type I fibers that is associated with heart failure. For example, skeletal muscle mass, as determined with dual-energy x-ray absorptiometry (DEXA), is an independent predictor of peak  $\text{VO}_2$  and of the slope of the ventilation to carbon dioxide production, regardless of NYHA functional class, age, gender, extent of neurohormonal activation, or resting hemodynamic status.<sup>104</sup> Whether an increase in the skeletal mass by resistance exercise will lead to improvement in functional capacity remains to be seen.

### Central Mechanisms: Cardiac Output

Some authorities have suggested that only patients with heart failure who have preserved cardiac output might benefit from exercise training.<sup>105</sup> Although this suggestion has not been investigated in any large trial, results of several smaller studies are suggestive of improvements in cardiac output with exercise conditioning. Coats and colleagues<sup>81</sup> performed a randomized, crossover, controlled trial of exercise training in 17 men with stable but moderate to severe heart failure and a mean ejection fraction of 19.6%. In the training condition, cardiac output increased significantly at both submaximal and maximal workloads, in parallel with improvements in  $\text{VO}_2$ . Other studies have demonstrated similar improvements in cardiac output with training even at low training intensities.<sup>106,107</sup> Larger scale trials are needed.

### Circulating Inflammatory Factors (see Chapter 11)

High concentrations of proinflammatory markers and mediators of cellular apoptosis have been linked to the syndrome of heart failure. Cytokines, such as tumor necrosis factor  $\alpha$ , may modulate cardiac and vascular viability and function by mechanisms that include abnormal regulation of nitric oxide synthase. Some studies concern the effects of training on inflammatory markers. Exercise training over 12 weeks at 60% to 80% of maximal heart rate reduces plasma levels of inflammatory cytokines, including tumor necrosis factor  $\alpha$ , in patients with heart failure. The improvements parallel a significant improvement in peak  $\text{VO}_2$ .<sup>108</sup>

### Exercise Improvement with Medical or Exercise Therapy: A True Surrogate of Mortality and Morbidity?

It would be logical to assume that because exercise capacity is directly correlated with prognosis, improvements in exercise function would translate into improvements in rates

of mortality and morbidity. However, as other studies have demonstrated, these logical assumptions linking intervention with surrogate marker of clinical benefit do not always hold (refer to the Cardiac Arrhythmia Suppression Trial [CAST]<sup>109</sup> of the effects of antiarrhythmic agents on cardiac events and death; the Heart and Estrogen/Progestin Replacement Study [HERS]<sup>110</sup> for the effects of estrogen replacement therapy on cardiovascular events; and the Women's Health Initiative<sup>111</sup> for the effects of dietary manipulation on cardiovascular outcomes). The same can be said for the effects of exercise therapy in heart failure.

Agents that do improve rates of mortality from and hospitalization for heart failure, such as ACE inhibitors, have failed to be linked consistently to exercise improvement. This is probably because functional capacity—and, by extension, skeletal muscle function—is related to exercise-related symptoms; the ability to perform activities of daily living and improvements in central cardiac function and output, especially in acute situations, as facilitated by these cardiovascular agents, do not translate into improvements in functional capacity, immediately or in the long term. This was true in large trials of  $\beta$ -adrenergic blockers, which yielded marked improvements in progression of disease and hospitalization but little or no improvement in functional capacity or exercise tolerance. Conversely, other pharmacological agents have been linked to improvements in symptoms and exercise tolerance but worse mortality rates. The only way to understand whether exercise training prevents cardiovascular morbidity and mortality is to conduct randomized studies.

### Effects of Exercise Training on Clinical Outcomes in Heart Failure

Before the initiation of the HF-ACTION study, few randomized controlled studies had been directed at determining whether exercise training in patients with systolic heart failure prevented hospitalization and death. Some of these studies are summarized in [Figure 57-4](#); a meta-analysis of 11 studies had been conducted to compare the effects of control conditions with those of exercise training on hard cardiovascular outcomes (morbid events or mortality) in a total of 729 subjects with heart failure.<sup>43,84,87,99,112-117</sup> The meta-analysis revealed a hazard ratio of 0.61 (95% confidence interval, 0.37 to 1.02;  $P = .06$ ) in favor of exercise training. In 2007, Dracup and colleagues<sup>118</sup> reported the results of a study of 173 patients with systolic heart failure who were randomly assigned to the control condition or to undergo home-based exercise. The primary endpoint was a composite of all-cause hospitalizations, emergency department admissions, urgent transplantation, and death at 12 months. A home-based walking program that incorporated aerobic and resistance exercise did not result in improved clinical outcomes at the 1-year follow-up in this cohort of patients. However, the exercise program resulted in reduced rates of repeated hospitalizations.

### HF-ACTION

In 2008, the primary results of the much-awaited HF-ACTION trial were released. This study was a large multicenter, randomized, controlled trial of 2331 medically stable outpatients with NYHA class II to class IV heart failure and reduced ejection fraction (<35%). In contrast to previous studies, all subjects were receiving optimal medical and device therapy (94%,  $\beta$ -adrenergic blockade; 94%, angiotensin pathway inhibition; 40%, ICD; and 19%, biventricular pacing). Participants in HF-ACTION were randomly assigned to conditions from April 2003 through February 2007 at 82 centers in the United States, Canada, and France; median length of follow-up was 30 months. The intervention consisted of usual care plus aerobic exercise training (36 supervised sessions

**FIGURE 57-4** A summary of studies of exercise training in heart failure as of 2004. Randomized controlled studies of exercise training in systolic heart failure up to the initiation of the Heart Failure and A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION) in 2004 are listed. Studies are indicated by first author and date, if appropriate, to the left and are included in this chapter's reference list (Belardinelli et al,<sup>86</sup> Giannuzzi et al,<sup>112,113</sup> Hambrecht et al,<sup>45,99</sup> Keteyian et al,<sup>84</sup> McKelvie et al,<sup>114</sup> Wielenga et al,<sup>115</sup> and Willenheimer et al<sup>116</sup>). Also listed is a meta-analysis performed in 2004 ("Fixed Combined [9]"). For each study or analysis, the point estimate and confidence intervals are indicated in the *heavy vertical lines* and *horizontal lines*, respectively. Hazard ratios are shown, with benefit of exercise ( $<1$ ) shown to the left and increased risk with exercise shown to the right ( $>1$ ). A hazard ratio of 1 indicates no effect one way or another on the outcome. (Adapted from Smart N, Marwick TH. Exercise training for patients with heart failure: a systematic review of factors that improve mortality and morbidity. *Am J Med* 2004;116:693-706.)

followed by home-based training) or usual care alone for 1 to 4 years. The composite primary endpoint was all-cause mortality and hospitalization, and the prespecified secondary endpoints were all-cause mortality, mortality from or hospitalization for cardiovascular disorders, and mortality from cardiovascular disorders or hospitalization for heart failure.

Regular exercise training in patients with systolic heart failure was safe. According to the main analysis, adjusted only for cause of heart failure, exercise training produced nonsignificant reductions in the primary endpoint (all-cause mortality and all-cause hospitalization) and in key secondary clinical endpoints (hazard ratios, 0.84 to 0.96, all in favor of exercise training). Furthermore, in protocol-specified supplementary analyses adjusted for prognostic factors, the treatment effect was statistically significant for the primary endpoint and for the secondary endpoint of mortality from cardiovascular disorders or hospitalization for heart failure (hazard ratios, 0.85 to 0.91, all in favor of exercise training). These findings were found to be consistent with those of the 33 previous trials and the meta-analyses that demonstrated improved outcomes with exercise training. Of interest was that the beneficial effects of exercise training appeared to be more pronounced in patients with NYHA class III heart failure and in women. The investigators concluded that, on the basis of the safety of exercise training and the modest reductions in clinical events, in addition to the modest increases in health-related quality of life (reported in the accompanying article by Flynn and associates<sup>119</sup>), the results supported a prescribed exercise training program for patients with reduced LV function and heart failure symptoms, in addition to evidence-based therapy.

## FUTURE DIRECTIONS

Numerous questions about the role of exercise training in heart failure remain unanswered. Some of these have been raised by the results of trials, including HF-ACTION. For example, the optimal amount, intensity, and combination of modalities of exercise training for patients with systolic heart failure are issues still unexplored. Also questionable is the relative utility of different regimens for comorbid conditions combined with heart failure, such as type 2 diabetes mellitus, for which a more frequent and less vigorous program than that previously tested in heart failure might be of most benefit.

The utility and role of exercise training in combination with other therapies, such as chronotropic resynchronization therapy, are just now being studied.<sup>120</sup> The relative effects of exercise in subpopulations in the HF-ACTION study that showed the most benefit (e.g., in patients with NYHA class III systolic heart failure and in women) should be explored further. Finally, the role of aerobic exercise training—whose benefit may be in reducing the adverse cardiac hypertrophic effects of long-term hypertension for treatment of diastolic heart failure—should be an active area of investigation.

result of locally invasive disease or distant metastasis. The cardiovascular system can also be affected by indirect complications, most notably hyperviscosity syndromes, resulting from myeloproliferative disorders or leukemias. Finally, several of the therapies used to treat cancer, including radiation, traditional chemotherapeutics, and so-called targeted therapeutics that are aimed at factors that are causal or that promote cancer growth and metastasis, can also be toxic to the heart and cardiovascular system (Table 58-1). This chapter focuses on traditional and targeted therapeutics that can cause heart failure. Additional complications of cancer therapies are reviewed elsewhere.<sup>4</sup>

## ANTHRACYCLINES

The anthracyclines currently approved in the United States—doxorubicin (Adriamycin), daunorubicin (Cerubidine), epirubicin (Ellence), and idarubicin (Idamycin)—are key components of many chemotherapeutic regimens, having demonstrated efficacy in the treatment of lymphomas and many solid tumors, including breast and small cell lung cancer. This class of chemotherapeutic agents also is clearly the most cardiotoxic to date: In the acute setting, they produce arrhythmias, left ventricular (LV) dysfunction, and pericarditis; in the chronic setting, they produce LV dysfunction and heart failure (see Table 58-1).

Anthracycline-induced cardiotoxicity is usually dose related and is thought to result from, among other things, free radical formation that damages the myocardium.<sup>5,6</sup> Anthracycline toxicity is most likely related to oxygen free radicals; in particular, the combination of doxorubicin, ferric iron, and free radical leads to mitochondrial damage and myocyte cell death. The oxygen free radical generated through the semiquinone moiety of the molecule causes lipid peroxidation and results in cell damage. This may explain how chelating agents, such as dexrazoxane, work as a cardioprotective agent in patients receiving doxorubicin.<sup>7</sup> Other authorities believe that large calcium influx into the cell may be partly responsible.<sup>8-10</sup> The downregulation of  $\beta$ -adrenergic receptors

described by some authors may represent a final common pathway, inasmuch as this has been described for other cardiomyopathies, including cardiomyopathy induced by 3,4-methylenedioxymethamphetamine (ecstasy) and by stress.<sup>11</sup> Other authors have pointed to effect of anthracyclines on release of endogenous proinflammatory agents such as tumor necrosis factor as partly responsible for the toxicity. This hypothesis is of some interest because tumor necrosis factor receptors are present on the myocardium. A similar mechanism involving interleukin-2 has also been described.<sup>12,13</sup> Data from studies of cultured cardiomyocytes suggest that cardiotoxicity could be induced by DNA damage and that dexrazoxane antagonizes doxorubicin-induced DNA damage through its interference with topoisomerase II $\beta$  (Top2 $\beta$ ), which is expressed in the heart. The specific involvement of Top2 $\beta$  in doxorubicin-induced DNA damage is consistent with a model in which proteasomal processing doxorubicin-induced Top2 $\beta$ -DNA covalent complexes exposes the Top2 $\beta$ -concealed DNA double-strand breaks and cause cardiomyocyte death.<sup>14</sup>

Why patients develop cardiotoxicity at different times is not known. Anthracycline-induced cardiac injury can be acute, manifesting as nonspecific ST-segment and T-wave abnormalities, ventricular arrhythmias, and transient LV dysfunction. Early cardiotoxicity manifests within the first year of therapy with LV failure that may be progressive. Late-onset anthracycline cardiotoxicity that causes dilated cardiomyopathy, which manifests years to decades after anthracycline treatment is completed, is increasingly recognized, often after a prolonged asymptomatic period.<sup>15</sup> Cardiac changes such as reductions in LV mass, mass index, and compliance have been reported in anthracycline-treated survivors of childhood cancer who were monitored for more than 7 years after chemotherapy was completed.<sup>15</sup>

Although anthracycline-induced cardiotoxicity can occur with low doses of an anthracycline, the risk of clinical cardiotoxicity increases with the cumulative dose. Researchers who have studied the cumulative incidence of doxorubicin-induced heart failure have found that it occurs in 3%

TABLE 58–1 Cancer Drugs That Can Cause Left Ventricular Dysfunction or Heart Failure

Drug Class	Incidence (%)	Comments
Anthracyclines <ul style="list-style-type: none"><li>• Doxorubicin</li><li>• Epirubicin</li><li>• Idarubicin</li></ul>	3-48 0.9-3.3 5-18	Highly dose-dependent Risk factors include age (old and young), prior mediastinal XRT, history of heart disease, female gender, and other agents (especially trastuzumab) Risk is decreased by liposomal encapsulation or dexrazoxane
Alkylating agents <ul style="list-style-type: none"><li>• Cyclophosphamide</li><li>• Ifosfamide</li></ul>	7-28 17	Primarily seen with high-dose “conditioning” regimens Risk factors are prior mediastinal XRT or anthracycline treatment Myocarditis, pericarditis, and myocardial necrosis can also be present
Taxanes <ul style="list-style-type: none"><li>• Docetaxel</li></ul>	2.3-8	
Targeted therapeutics <ul style="list-style-type: none"><li>• Trastuzumab</li><li>• Imatinib</li><li>• Sunitinib</li><li>• Bevacizumab</li></ul>	2-28 0.5-1.7 2.7-11 1.7-3	Relatively uncommon as single agent Increased risk with anthracyclines, paclitaxel, cyclophosphamide Frequency not clear but probably <5% Can also cause severe fluid retention with peripheral edema, pleural effusion, and pericardial effusion not secondary to left ventricular dysfunction Heart failure can occur in setting of severe hypertension, which occurs in 4%-35% of patients
Proteasome inhibitor <ul style="list-style-type: none"><li>• Bortezomib</li></ul>	2-5	

XRT, x-ray therapy.

to 5% of patients who received 400 mg/m<sup>2</sup>, in 7% to 26% of patients who took 550 mg/m<sup>2</sup>, and in 18% to 48% of patients who received 700 mg/m<sup>2</sup>.<sup>4,16-18</sup>

In contrast to doxorubicin, epirubicin or idarubicin appears to cause lower incidences of heart failure.<sup>19,20</sup> The development of cardiomyopathy associated with anthracyclines is influenced by such factors as cumulative dose, intravenous bolus administration, higher single doses, history of prior irradiation, the use of other concomitant agents known to have cardiotoxic effects (such as cyclophosphamide, trastuzumab, and paclitaxel), female gender, underlying cardiovascular disease, age (young and old age; **Figure 58-1**), and increased length of time since completion of the anthracycline regimen.<sup>4,21-23</sup>

Thus, the prevention of anthracycline-induced cardiotoxicity necessitates decreasing myocardial concentrations of anthracyclines and their metabolites, which may be accomplished by altering the anthracycline administration method (e.g., continuous infusion vs. bolus administration). Other preventive measures include the use of anthracycline analogues (e.g., idarubicin, epirubicin, mitoxantrone) or liposomal anthracyclines, administration of cardioprotective agents (e.g., dexrazoxane), and the use of angiotensin-converting enzyme (ACE) inhibitors and  $\beta$ -blockers (discussed later) to attenuate the effects of anthracyclines on the heart.<sup>4,24-26</sup>

Monitoring and Anthracycline Toxicity

LV function should be assessed in patients at baseline, before anthracycline therapy is initiated, and should be monitored periodically after that, especially when the cumulative dose exceeds 350 to 400 mg/m<sup>2</sup>.<sup>57,58</sup> for doxorubicin or the comparable doses for the other anthracyclines. By relying on history and physical examination alone, clinicians can miss significant deterioration in LV function in a substantial number of patients. Routine troponin measurements are not highly predictive except in patients receiving high-dose chemotherapy (for treatment of aggressive malignancies). Of those patients, those who will develop LV dysfunction can be identified by an elevated troponin I level with high sensitivity, albeit low predictive accuracy. A negative troponin I level was a strong

**FIGURE 58-1** Risk of doxorubicin-associated congestive heart failure by patient age: Cumulative doxorubicin dose at onset of doxorubicin-associated congestive heart failure in 630 patients, according to patient age (older or younger than 65 years [y]). (Redrawn from Swain SM, Whaley FS, Ewer MS: Congestive heart failure in patients treated with doxorubicin: a retrospective analysis of three trials. *Cancer* 2003;97:2869.)

predictor of which patients would not experience deterioration of LV function.<sup>27</sup>

ALKYLATING AGENTS

Cyclophosphamide

Cyclophosphamide is an alkylating agent used in the treatment of lymphomas, some types of leukemias, and some solid tumors. In contrast to anthracyclines, the cardiotoxicity of cyclophosphamide seems to be related to the total dose given at a single time, rather than the cumulative dose.

Heart failure associated with cyclophosphamide occurs at high doses ( $>150$  mg/kg and  $1.5$  g/m<sup>2</sup>/day) in 7% to 28% of patients.<sup>4,19,28-30</sup> The clinical manifestations of cardiotoxicity range from asymptomatic pericardial effusions to heart failure and myopericarditis,<sup>28,30</sup> which occur within 1 to 10 days after the administration of the first dose of cyclophosphamide.<sup>4,19</sup> Besides total dose, risk factors for cardiotoxicity include prior anthracycline or mitoxantrone therapy and mediastinal radiation.<sup>19,29</sup>

Although the precise mechanism of cyclophosphamide cardiotoxicity is unknown, it is theorized that cyclophosphamide causes direct endothelial injury, followed by extravasation of toxic metabolites resulting in damage to cardiomyocytes, interstitial hemorrhage, and edema.<sup>4,19,29-31</sup> Intracapillary microemboli, resulting in ischemic myocardial damage,<sup>4,30,31</sup> and myocardial ischemia caused by coronary vasospasm are other proposed mechanisms of cyclophosphamide-related cardiotoxicity.<sup>4,19</sup>

## Ifosfamide

Ifosfamide is an alkylating agent related to cyclophosphamide used to treat a variety of malignancies. Like cyclophosphamide, ifosfamide causes cardiotoxicity in a dosage-related manner (dosages  $\geq 12.5$  g/m<sup>2</sup>).<sup>4,19</sup> In a retrospective review of patients with advanced lymphoma or carcinoma treated with high-dose ifosfamide as part of combination chemotherapy with autologous bone marrow transplantation, cardiotoxicity developed in 17% of patients.<sup>4,19,32</sup> Acute onset of heart failure occurred within 6 to 23 days after the first dose of ifosfamide.<sup>4,19</sup>

Because ifosfamide and cyclophosphamide are structurally similar, it is probable that ifosfamide may induce heart failure through a similar mechanism. In addition, because ifosfamide causes nephrotoxicity, it is thought that this decrease in glomerular filtration rate may delay the elimination of cardiotoxic metabolites. Other factors such as fluid disturbances, acid-base imbalance, and electrolyte disturbances related to tubular defects may also contribute to cardiac problems.<sup>4,32</sup>

## ANTIMICROTUBULE AGENTS

### Docetaxel

The incidence of heart failure associated with docetaxel ranges from 2.3% to 8%.<sup>4,33,34</sup> In a trial in which docetaxel plus doxorubicin and cyclophosphamide (TAC) was compared with fluorouracil plus doxorubicin and cyclophosphamide (FAC), the overall incidence of heart failure at 55 months was 1.6% among the TAC recipients and 0.7% among the FAC recipients.<sup>33</sup> At 70 months' follow-up, heart failure was reported in 2.3% of the TAC recipients, in comparison with 0.9% of the FAC subjects.<sup>4</sup> However, in another breast cancer trial, the incidence of docetaxel-induced heart failure was higher (8%).<sup>4,34</sup>

### Proteasome Inhibitor

Bortezomib (Velcade) is the first therapeutic proteasome inhibitor to be tested in humans, and it has been approved by the U.S. Food and Drug Administration (FDA) for use in patients with multiple myeloma, a B-cell malignancy with overgrowth of monoclonal plasma cells in the bone marrow. The concept behind the use of proteasome inhibitors is that malignant cells have altered proteins that regulate the cell cycle, which leads to more rapid cell division and, in turn, increased accumulation of damaged proteins. Therefore, the continued health of the malignant cell, as opposed to normal

cells, may be more dependent on degradation of the damaged proteins.

The exact incidence of heart failure associated with bortezomib remains unclear; however, in 669 patients with multiple myeloma who were treated with bortezomib or high-dose dexamethasone, the incidence of cardiac disorders during treatment was 15% with bortezomib and 13% with dexamethasone.<sup>4,35</sup> Heart failure events occurred in 5% of bortezomib-treated patients and in 4% of dexamethasone-treated patients. Two percent of patients in each of the treatment groups developed heart failure. The mechanism of heart failure associated with bortezomib is unknown, but it has been proposed that bortezomib may cause cardiotoxicity through proteasome inhibition.<sup>4,36</sup>

## TARGETED THERAPEUTIC AGENTS

The treatment of malignancies has changed dramatically with the advent of so-called targeted therapies. In comparison to traditional chemotherapeutic agents that target basic cellular processes that are present in most cells, the newer agents target factors that are specifically dysregulated in cancerous cells. The anticipation was that this approach would reduce a number of the toxic effects that plague standard chemotherapeutics (alopecia, gastrointestinal toxicity, myelotoxicity) and at the same time treat the cancer more effectively. For the most part, these goals have been achieved; however, a number of concerns about cardiotoxicity have surfaced for some agents.

Before these therapies and their toxic effects are discussed, it is important to understand these agents and how they work. Most targeted cancer therapeutic agents inhibit the activity of tyrosine kinases (Table 58-2).<sup>37</sup> Tyrosine kinases attach phosphate groups to tyrosine residues of other proteins, thereby changing the activity, subcellular localization, or rate of degradation of the protein. In the normal cell, these wild-type (i.e., normal) tyrosine kinases play many roles in regulating basic cellular functions. However, in leukemias and cancers, the gene encoding the causal tyrosine kinase is either amplified (leading to overexpression) or mutated (leading to a constitutively activated state), which drives proliferation of the cancerous clonal cells or blocks their normal death. Inhibiting these kinases could then retard cell proliferation or induce cell death, or both. Cardiotoxicity arises when the normal kinase (present in cardiomyocytes), which is also inhibited by the agent, plays a central role in maintenance of cardiomyocyte homeostasis. In some cases, cardiotoxicity of these drugs may be predictable, but in most cases the cardiotoxicity is not predictable. This is because the targeted kinase was not known to provide a maintenance function in the cardiac myocyte or because of "off-target" effects (e.g., inhibition of tyrosine kinases other than those the drug was designed to target). The majority of the tyrosine kinase inhibitors competes with adenosine triphosphate for binding to a pocket in the kinase that is moderately conserved across many tyrosine kinases. More than 90 tyrosine kinases have been identified thus far. The two major classes of tyrosine kinases are receptor tyrosine kinases (RTKs), which have an extracellular ligand-binding domain and an intracellular kinase domain that is responsible for cell signaling, and non-receptor tyrosine kinases (NRTKs) that are located within the cell.<sup>38</sup> Tyrosine kinases are important in the malignant transformation of cells because of their integral role in the cell survival and differentiation. In addition, there is evidence for a role of tyrosine kinases in tumor angiogenesis.<sup>39</sup> Activation of tyrosine kinases may be involved in many cancers, such as leukemias or solid tumors, in which gene mutation may result in overexpression of the kinase and lead to a constitutively activated state, driving proliferation of cancer cells and preventing apoptosis.<sup>40</sup>

**TABLE 58–2 Tyrosine Kinase Targets in Malignant Hematologic Disorders and Solid Tumors**

Tyrosine Kinase*	Activating Mechanism†	Type of Cancer‡	Targeted Therapy
<b>Hematological Disorders</b>			
ABL	Transloc	CML ALL AML	Imatinib (Gleevec) Dasatinib (Sprycel) Nilotinib (Tasigna)

\*ABL, Abelson tyrosine kinase; aCML, atypical chronic myeloid leukemia; ARG, Abl-related gene (ABL2); ALK, anaplastic lymphoma kinase; c-FMS, \*\*\*; c-KIT, stem cell factor receptor; c-MET, hepatocyte growth factor receptor; EGFR, epidermal growth factor receptor; FGFR, fibroblast growth factor receptor; FLT3, Fms-like tyrosine kinase 3; HER2, human EGFR-2; JAK2, Janus kinase 2; NTRK, neurotrophin receptor kinase; PDGFR, platelet-derived growth factor receptor; RET, *ret* proto-oncogene; SYK, spleen tyrosine kinase; VEGFR, vascular endothelial growth factor receptor.

†Mut, activating point mutations in the kinase; Overexp, overexpression of the kinase; Transloc, chromosomal translocations producing fusion proteins with the tyrosine kinase; VEGF, vascular endothelial growth factor.

‡ALCL, anaplastic large cell lymphoma; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CML, chronic myeloid leukemia; CMML, chronic myelomonocytic leukemia; ET, essential thrombocythemia; GIST, gastrointestinal stromal tumor; HES, hypereosinophilic syndrome; IMF, idiopathic myelofibrosis; IMT, inflammatory myofibroblastic tumor; MDS, myelodysplastic syndrome; MEN, multiple endocrine neoplasia; MM, multiple myeloma; NSCLC, non-small cell lung cancer; PCV, polycythemia vera; PTC, papillary thyroid cancer; RCC, renal cell carcinoma; SCCN, squamous cell carcinoma of the head and neck; SCLC, small cell lung cancer; SM, systemic mastocytosis.

The first molecularly targeted therapies, trastuzumab (Herceptin) and imatinib (Gleevec), are typical of the two general classes of tyrosine kinase inhibitors: (1) humanized monoclonal antibodies targeting growth factor receptors on the surface of the cancer cell (trastuzumab) and (2) small molecule inhibitors either of receptors or of intracellular pathways that regulate growth of the cancer cells (imatinib). All generic names for monoclonal antibodies end in “-mab,” and all generic names of small molecule inhibitors end in “-nib.”

## Trastuzumab

Trastuzumab, a recombinant, humanized, monoclonal antibody, was the first FDA-approved targeted anticancer monoclonal antibody. Trastuzumab was approved for the treatment of metastatic epidermal growth factor receptor 2 (ErbB2)-positive breast cancer. Overexpression of the ErbB2 receptor was associated with more poorly differentiated tumors, higher rates of metastases, and shorter survival.<sup>38</sup> Trastuzumab binds to the extracellular domain of ErbB2, which inhibits growth and causes apoptosis of tumor cells expressing ErbB2. Although trastuzumab is very well tolerated as far as side effect profile, heart failure has been reported. The overall incidence of trastuzumab varies in the literature from 2%-28%. The incidence of cardiac dysfunction ranges from 2%-7% when trastuzumab is used as monotherapy, 2%-13% when trastuzumab is used in combination with paclitaxel, and up to 27% when trastuzumab is used concurrently with anthracyclines plus cyclophosphamide.<sup>20-27</sup> In a recent study looking at the long-term cardiac tolerability of trastuzumab at MDACC, the overall incidence of cardiotoxicity was 28%.<sup>28</sup> Cited risk factors for trastuzumab-induced CMP include age >50, borderline left ventricular ejection fraction (LVEF) prior to treatment, history of cardiovascular disease, the sequence in which chemotherapy is administered, and prior treatment with anthracyclines (cumulative doses >300 mg/m<sup>2</sup>).<sup>20-31</sup>

### Mechanism of Toxicity

Deletion of human epidermal growth factor receptor 2 (ErbB) is lethal in mice in midgestation because the left ventricle fails to form properly. Mice with cardiac-specific deletion of ErbB2, after cardiac development was complete, were viable. However, these mice developed dilated cardiomyopathy as they aged and had shorter survival when subjected to pressure overload induced by aortic banding. Neuregulin-1-induced activation of ErbB2 in cardiomyocytes activates the extracellular receptor kinase (ERK) and the phosphoinositide 3-kinase (PI3K)/protein kinase B (Akt) pathways that promote cardiomyocyte proliferation during development and cardiomyocyte survival during adulthood. Cardiomyocyte apoptosis in ErbB2-deficient hearts was not significantly increased; however, expression of the antiapoptotic protein Bcl-X was increased. Thus, inhibition of ErbB2 signaling appears to lead to dysfunction and death both in breast cancer cells that overexpress the ErbB2 receptor and in normal cardiomyocytes (i.e., “on-target” toxicity).<sup>38,45-47</sup>

## Bevacizumab

Bevacizumab (Avastin) is a monoclonal antibody that recognizes all vascular endothelial growth factor isoforms, thus blocking the kinase activation and tumor angiogenesis. Bevacizumab was the first angiogenesis inhibitor that was clinically available in the United States; it has been very effective in treating colorectal cancer and is now approved for use in combination with 5-fluorouracil-based therapy for metastatic colorectal carcinoma.<sup>48</sup> Hypertension is a common adverse effect in patients treated with bevacizumab, with an overall incidence reported to vary from 4% to 35%.<sup>4</sup> The fact that bevacizumab causes hypertension is important because uncontrolled blood pressure and inhibition of signaling by vascular endothelial growth factor (VEGF) and vascular endothelial growth factor receptor (VEGFR) have been implicated as the principal mechanisms underlying heart failure.<sup>38</sup> The incidence of heart failure among patients taking bevacizumab ranges from 1.7% to 3%.<sup>4</sup> According to the prescribing information, heart failure developed in 1.7% of patients treated with bevacizumab during clinical trials. In addition, two phase III clinical studies demonstrated that the rate of heart failure in the bevacizumab-treated conditions was 2.2% to 3%.<sup>49,50</sup>

## Imatinib

The first targeted small molecule inhibitor to be used successfully in malignancies was imatinib (Gleevec). This agent inhibits the activity of the fusion protein, Bcr-Abl, which arises from the chromosomal translocation that creates the Philadelphia chromosome and is the causal factor in approximately 90% of cases of chronic myeloid leukemia and some cases of B-cell acute lymphoblastic leukemia. This translocation creates a constitutively active protein kinase that drives proliferation and inhibits apoptosis in bone marrow stem cells, which leads to the leukemias. Imatinib has dramatically changed the management and prognosis of chronic myeloid leukemia; sustained remissions have been reported in more than 90% of patients after 5 years of initial treatment. However, imatinib has been reported to cause heart failure.<sup>51</sup> In contrast to trastuzumab, the cardiotoxicity of imatinib was surprising because c-Abl, the kinase expressed in all cells, including cardiomyocytes, was not known to play a role in maintenance of cardiomyocyte viability. In cardiomyocytes, inhibition of c-Abl led to activation of stress responses, culminating in marked mitochondrial dysfunction and cell death (Figure 58-2).

Although the incidence of LV dysfunction with imatinib is not known precisely, peripheral edema is observed relatively frequently, with reported incidence of up to 86%, and another 12% to 21% of patients complain of dyspnea, according to the package insert. A newly reengineered version of imatinib, WBZ-4, has been designed to inhibit c-KIT without inhibiting Abl, and has been shown to be just as effective as imatinib against gastrointestinal stromal tumors with significantly less risk of heart disturbances.<sup>52</sup>

Imatinib therapy as a causal factor of heart failure is relatively uncommon and occurs mainly in elderly patients with preexisting cardiac conditions. Accordingly, patients with a

**FIGURE 58-2** Targeted tyrosine kinase inhibition can lead to cellular apoptosis. Under stress, cells undergo an endoplasmic reticulum (ER) stress response (also called the “unfolded response”), which can lead to activation of cell death pathways through protein kinase R (PKR)-like ER kinase (PERK) and eventually to growth arrest DNA damage 34 (GADD34)-protein phosphatase 1 (PP1) complex, which in turn results in dephosphorylation of eukaryotic translation initiation factor (eIF2), thereby promoting apoptosis. ER stress also activates *c-jun* N-terminal kinase (JNK) signaling, mediated by integral membrane protein of the ER (IRE1) and by tumor necrosis factor receptor-associated factor 2 (TRAF2), which leads to translocation of Bax to the mitochondrial membrane. The result is cytochrome *c* release and collapse of the mitochondrial membrane potential. Salubrinal is a small-molecule inhibitor of the ER stress response that prevents dephosphorylation of eIF2 and prevents apoptosis through a pathway upstream from JNK activation. The nonreceptor tyrosine kinase c-Abl may act to suppress the ER stress response indirectly by preventing mitochondrial collapse or directly through a mechanism as yet unidentified. Anticancer drugs that target tyrosine kinases (e.g., imatinib mesylate) may promote apoptosis and heart damage by inhibiting c-Abl, thereby leading to a sustained ER stress response. ROS, reactive oxygen species. (Redrawn from Mann DL. Targeted cancer therapeutics: the heartbreak of success. *Nat Med* 2006;12:881-882.)

history of cardiac conditions should be monitored closely and treated aggressively with standard medical therapy (described later) if they develop symptoms suggestive of heart failure. In general, imatinib is considered safe and remains one of the most effective therapies for chronic myeloid leukemia.

### Sunitinib

Sunitinib (Sutent) is an oral, small-molecule, multitargeted receptor tyrosine kinase inhibitor that was approved by the FDA for the treatment of renal cell carcinoma and imatinib-resistant gastrointestinal stromal tumor. Sunitinib targets VEGFR-1, VEGFR-2, VEGFR-3, platelet-derived growth factor receptors  $\alpha$  and  $\beta$ , *c-KIT*, FMS-like tyrosine kinase-3 (FLT-3), colony-stimulating factor-1 receptor, and the product of the human *ret* proto-oncogene (RET, mutated in medullary thyroid carcinomas).<sup>53</sup> Although sunitinib is generally well tolerated, in one retrospective analysis of 75 patients treated with this agent, 8 (11%) had a cardiovascular event and 6 (8%) developed heart failure.<sup>54</sup> Of 36 patients treated at the approved sunitinib dose, 10 (28%) had absolute reductions in left ventricular ejection fraction (LVEF) of at least 10%, and 7 (19%) had LVEF reductions of 15% or more. Treatment with sunitinib resulted in increases in mean systolic and diastolic blood pressures; 35 (47%) of 75 individuals developed hypertension (blood pressure > 150/100 mm Hg). Both heart failure and LV dysfunction generally recover when sunitinib therapy is withheld and appropriate institution of medical management is initiated (see later discussion).

Sunitinib caused mitochondrial injury and cardiomyocyte apoptosis in mice and in cultured rat cardiomyocytes.<sup>54</sup> Hypertension induced by sunitinib may play an important

role in causing heart failure, inasmuch as sunitinib may inhibit a receptor tyrosine kinase that aids in regulating the response of cardiomyocytes in the setting of hypertensive stress.<sup>55</sup> In addition, sunitinib may cause cardiotoxicity through inhibition of ribosomal S6 kinase, leading to the activation of the intrinsic apoptotic pathway and adenosine triphosphate depletion.<sup>56</sup>

### DIAGNOSIS AND MONITORING OF PATIENTS RECEIVING CARDIOTOXIC CHEMOTHERAPEUTIC AGENTS (see Chapters 36 and 37)

In order to detect cardiac dysfunction in patients treated with chemotherapy, heart function must be monitored regularly during treatment. A baseline evaluation of LVEF must be obtained for comparison, and it is recommended that the same method be used for comparing serial measurements. Serial assessment of LVEF was first shown to be useful in clinical practice by Alexander and associates.<sup>57</sup> On the basis of their experiences, algorithms have been developed for serial monitoring of LVEF during anthracycline-based therapy.<sup>58,59</sup> Measurement of systolic function through evaluation of the LVEF with either multiple-gated angiography (MUGA) or echocardiography is one of the most commonly used methods of monitoring and diagnosing chemotherapy-induced cardiomyopathy. Radionuclide imaging of LV function appears to yield results comparable with those of 2-dimensional echocardiography with regard to monitoring changes in LV function.<sup>60,61</sup> However, it is not sensitive for early detection of preclinical (subclinical) cardiac disease, and it is influenced

by contractility and preload/afterload effects that lead to transient changes. Therefore, other measurements of systolic function (e.g., fraction shortening) and diastolic function (e.g., ratio of early to late diastolic filling) have been used to detect early cardiotoxicity in addition to LVEF.<sup>60</sup> Abnormalities on exercise echocardiograms may be a better predictor of impending heart failure.<sup>25</sup>

Biomarkers may also provide useful clues about patients at risk for developing heart failure, as well as the progression of heart failure. Measurements of brain natriuretic peptide (BNP) are helpful in differentiating symptoms of heart failure from those of noncardiac causes when patients present to the emergency room.<sup>62</sup> The test is, however, limited because it is relatively nonspecific and because of a large range of “normal” values.<sup>63</sup> An elevated BNP level in patients undergoing chemotherapy appears to be more closely associated with impairment of LV diastolic function than with impairment of LV systolic function.<sup>64</sup> As noted in the “Monitoring and Anthracycline Toxicity” section, cardiac troponin measurement is a very sensitive way of diagnosing myocardial injury and damage. Not surprisingly, their persistent elevation is predictive of poor outcome and development of heart failure in cancer patients receiving chemotherapy.<sup>27</sup>

Endomyocardial biopsy is the most sensitive method of detecting anthracycline cardiotoxicity; light microscopy reveals marked myofibril loss and vacuolar degeneration, and electron microscopy reveals extensive loss of myofilaments.<sup>65,66</sup> However, abnormalities detected on electron microscopy have not been shown to be correlated highly with risk of development of heart failure, and these abnormalities are often present in patients at cumulative doses well below those associated with an increased risk of heart failure. Because of the technical nature of the procedure and the inherent risks, this is not a practical way to detect or monitor patients with anthracycline cardiotoxicity; serial determination of LV function, although insensitive, is the currently accepted method. Moreover, not every form of drug-induced cardiomyopathy can be detected reliably with endomyocardial biopsy, inasmuch as cardiac damage may be scattered.<sup>67</sup>

## MANAGEMENT OF PATIENTS RECEIVING CARDIOTOXIC CHEMOTHERAPEUTIC AGENTS

At present, the guidelines of the Heart Failure Society of America and the American College of Cardiology/American Heart Association (ACC/AHA) do not contain specific recommendations for treatment of patients with what is presumed to be chemotherapy-induced heart failure. However, it is probably most reasonable at this time to treat the patient like any patient with newly diagnosed heart failure, as discussed in Chapters 45 and 46. In this regard, it is critical to rule out other potential causes of heart failure (see Table 35-2) before chemotherapy is assumed to have been the cause. Medical management of patients with stage A disease should focus on risk-factor reduction by controlling hypertension, diabetes, and hyperlipidemia, with the goal of preventing ventricular remodeling. Treatment of stages B, C, and D disease is aimed at improving survival, slowing disease progression, and alleviating symptoms. Patients with end-stage heart failure with refractory symptoms at rest despite maximal medical therapy and without evidence of cancer recurrence could be considered for synchronized pacing, placement of a ventricular assist device, or cardiac transplantation.<sup>65</sup> The effects of several agents discussed previously (including trastuzumab, imatinib, and sunitinib) appear to be reversible to some degree, and such reversal may be promoted by aggressive treatment with ACE inhibitors and  $\beta$ -blockers. Treatment with specific agents is discussed as follows.

### Dexrazoxane

Dexrazoxane (Zinecard) is a free-radical scavenger that is used to protect the heart from the cardiotoxic side effects of anthracyclines. Several randomized control trials have been conducted to examine the effects of dexrazoxane in combination with anthracyclines, and all of these studies revealed that dexrazoxane is a highly effective cardioprotective agent that allows higher cumulative doses of doxorubicin.<sup>16</sup> However, one trial demonstrated that dexrazoxane might interfere with the antitumor activity of doxorubicin,<sup>17</sup> but this has not been a consistent finding in other studies. In the meta-analysis conducted by Van Dalen and colleagues,<sup>68</sup> a statistically significant benefit was found in favor of dexrazoxane for the occurrence of heart failure (relative risk, 0.29; 95% confidence interval, 0.20 to 0.41). No evidence was found for differences in response rate or survival between the subjects taking dexrazoxane and the control group.

In children with acute lymphoblastic leukemia, Lipshultz and associates<sup>7</sup> found that dexrazoxane prevented cardiac injury (as reflected by elevations in troponin T levels) related to doxorubicin therapy, without compromising the antitumor efficacy of doxorubicin. In this study, children treated with doxorubicin alone were more likely to have elevated troponin T levels (50% vs. 21%;  $P < .001$ ) and extremely elevated troponin T levels (32% vs. 10%;  $P < .001$ ) than were those who received dexrazoxane and doxorubicin. The rate of event-free survival at 2.5 years was 83% in both groups ( $P = .87$  by the log-rank test).<sup>7</sup> Data for children confirm the protective role of dexrazoxane in patients receiving anthracyclines.

At present, however, the American Society of Clinical Oncology guidelines<sup>69</sup> recommend that dexrazoxane be considered for patients with metastatic breast cancer who have received more than 300 mg/m<sup>2</sup> of doxorubicin and who may benefit from continued doxorubicin-containing therapy. The use of dexrazoxane can also be considered in adult patients with other malignancies who have received more than 300 mg/m<sup>2</sup> of doxorubicin-based therapy; however, caution should be exercised in the use of dexrazoxane in settings in which doxorubicin-based therapy has been shown to improve survival.

### Neurohormonal Antagonists (see Chapters 45 and 46)

**$\beta$ -Blockers.** To date, there have been four case series in which researchers have evaluated the benefit of  $\beta$ -blockers in the treatment of anthracycline-induced cardiomyopathy.<sup>4,70-73</sup> In one study, beta blockers improved left ventricular ejection fraction in patients with anthracycline-induced cardiomyopathy. This improvement in myocardial function was comparable if not greater than the beneficial effects seen with beta blocker use in idiopathic dilated cardiomyopathy (Figure 58-3).<sup>72</sup> Of the  $\beta$ -blockers, carvedilol may have therapeutic advantages over the others in anthracycline-induced cardiomyopathy, inasmuch as it has been shown to possess antioxidant properties.<sup>4</sup> Moreover, in a single-blind, placebo-controlled trial in which the primary outcome was change in LVEF within 6 months of treatment, treatment with carvedilol prevented a decline in LVEF and prevented LV diastolic dysfunction.<sup>24</sup>

**Angiotensin-Converting Enzyme Inhibitors.** There is some evidence supporting the use of ACE inhibitors in patients with anthracycline-induced cardiomyopathy.<sup>25,75,76</sup> In a randomized, double-blind, controlled clinical trial in which enalapril was compared with placebo in 135 long-term survivors of pediatric cancer who had at least one cardiac abnormality identified at any time after anthracycline exposure, enalapril was shown to prevent a decline in LVEF in these long-term survivors. Although there was no difference in the primary outcome variable of maximal cardiac index, as determined by cycle ergometry, the rate of decline in LV end-systolic wall stress was greater in the subjects who took enalapril than in

**FIGURE 58-3**  $\beta$ -Blockade in left ventricular dysfunction induced by doxorubicin (Adriamycin). Affected patients were treated with  $\beta$ -blockers (metoprolol, carvedilol, and propranolol). The control group consisted of 16 consecutively chosen age- and sex-matched patients with idiopathic dilated cardiomyopathy (IDC) that was treated with  $\beta$ -blockers. The mean left ventricular ejection fraction (LVEF) improved from 28% to 41% ( $P = .041$ ) in patients with doxorubicin-induced left ventricular dysfunction, whereas the LVEF improved from 26% to 32% ( $P = .015$ ) in the patients with IDC. ACM, Adriamycin-induced cardiomyopathy; EF, ejection fraction. (From Noori A, Lindenfeld J, Wolfel E, et al. Beta-blockade in Adriamycin-induced cardiomyopathy. *J Card Fail* 2000;6:115-119.)

those who took the placebo ( $-8.59$  vs.  $1.85$  g/cm<sup>2</sup>;  $P = .033$ ); the reduction was 9% by year 5 of the study.<sup>25</sup> However, in an observational study of 18 children treated with enalapril for LV dysfunction or heart failure, the beneficial effects of enalapril diminished after 6 to 10 years as a result of progressive LV wall thinning.<sup>76</sup> Thus, the clinical effects of ACE inhibitors in chemotherapy-induced heart failure are variable. Patients already taking  $\beta$ -blockers and ACE inhibitors before receiving chemotherapy should continue taking these medications, because withdrawal from these drugs can lead to deterioration of LV systolic function.

## REVERSIBILITY OF CANCER THERAPY-INDUCED LEFT VENTRICULAR DYSFUNCTION

In contrast to that caused by anthracyclines, the LV dysfunction that occurs with several of the tyrosine kinase inhibitors, including trastuzumab, imatinib, and sunitinib, appears to have some degree of reversibility.<sup>77</sup> Discontinuation of trastuzumab is generally recommended when clinically significant heart failure occurs. However, patients who experience cardiotoxicity while receiving trastuzumab generally recover cardiac function when trastuzumab is discontinued over a mean time period of 1.5 months.<sup>77</sup> Patients who have experienced benefit with trastuzumab therapy and who have improved cardiac function while on a standard heart regimen may restart trastuzumab therapy while receiving protective heart failure medications and close cardiac monitoring.<sup>77</sup> In addition, Memorial-Sloan-Kettering Cancer Center has proposed guidelines for the management of patients treated with trastuzumab on the basis of physical status and LVEF.<sup>78</sup>

## CONCLUSION

Cancer therapy-induced heart failure is a common problem observed by cardiologists and oncologists. Recognition and early detection of heart failure is critical for optimal management of patients undergoing cancer therapy. Once heart

failure is identified, these patients should be treated aggressively with heart failure medications, which often lead to reversal of heart failure. Future studies will address the identification of genetic profiles of patients at risk for developing cancer therapy-induced heart failure, the optimal treatment strategies, and whether therapy for heart failure can be discontinued safely.

be preventable because they are precipitated by factors that are modifiable and could be better addressed during outpatient management. The major reasons for preventable hospitalizations are patients' lack of adherence to prescribed regimens and failure to seek early treatment for worsening symptoms.<sup>5,6</sup>

According to the traditional view of the relationship between the patient and health care provider, the physician or advanced practice nurse prescribes a regimen, and the patient follows it.<sup>7</sup> In this view, failure of the regimen to produce the desired outcome usually is blamed on the patient's failure to follow the regimen. Indeed, even the best therapeutic plan will fail if patients do not follow it. However, reasons for patient nonadherence are complex. By simply blaming the patient for not following the prescribed plan, clinicians ignore these complexities and overlook contributing factors that could be remedied with intervention.

Many factors that contribute to failure to implement the treatment plan have been identified. These factors are related to the patient, provider, and health care system. Patient-related factors can often be overcome or compensated for by changes in the health care provider's approach or by changing the health care delivery system.<sup>8</sup> Inadequacies in the delivery of advice and recommendations by clinicians contribute significantly to treatment noncompliance and poor outcomes.<sup>9-12</sup> Other common reasons for rehospitalization are poor discharge planning, inadequate follow-up after discharge, and health care providers' failure to attend to patient characteristics (e.g., depression, cognitive impairment, lack of a social support system, inability to pay for expensive medications) that render patients prone to repeated hospitalizations.<sup>13-15</sup> Thus, to understand why therapeutic regimens fail, it is more helpful to address issues involving the patient, provider, and health care system.<sup>16</sup> Optimal outpatient management of patients with heart failure depends on a thorough understanding of all three factors that contribute to nonadherence and how to address them (Table 59-1). Knowing what to recommend and prescribe for patients is important in outpatient management, but understanding how to convey this information to patients and how to structure the system to support treatment adherence is even more important. Thus, the focus of this chapter is on application of effective models of care for outpatient management.

## SIGNIFICANCE OF THE PROBLEM

### Treatment Adherence

In a report on adherence to long-term therapies, the World Health Organization estimated that rates of such adherence are about 50% in developed countries and even lower in developing countries.<sup>8</sup> The consequences of poor

adherence include adverse health outcomes, poor quality of life, and increased health care costs.<sup>8</sup> As Haynes emphasized in a Cochrane Database report on medication adherence, "Increasing the effectiveness of adherence interventions may have a far greater impact on the health of the population than any improvement in specific medical treatments."<sup>17</sup>

Treatment adherence among patients with heart failure is poor.<sup>18</sup> Medication nonadherence is a significant contributor to rehospitalization. In one study, of 231 patients with heart failure who were hospitalized with sodium retention, 20% had not adhered to the drug regimen.<sup>19</sup> In another study of 94 patients with heart failure, 13% admitted to not taking their medications as prescribed.<sup>20</sup> These statistics, obtained through patient self-reports, are probably underestimates of the true prevalence of nonadherence. Objective indicators of adherence reveal far greater levels of nonadherence. In a study of more than 7000 elderly patients prescribed digoxin, only 10% of the sample refilled their prescription often enough to have taken the appropriate amount of medication for 1 year; 19% of patients refilled the prescription only one time.<sup>21</sup> Electronic event monitoring of angiotensin-converting enzyme (ACE) inhibitor therapy revealed that 19% of patients took less than 70% of the prescribed doses and that adherence declined markedly among patients who were prescribed formulations that required dosing more than once per day.<sup>22</sup> Lack of medication adherence is clearly linked to increased risk for rehospitalization and mortality in patients with heart failure.<sup>23</sup>

Adherence to a low-sodium diet is important for patients with heart failure, according to heart failure guidelines. Adherence to dietary recommendations of sodium restriction is even lower than adherence to medication regimens. Fewer than half of patients consistently follow a low-sodium diet.<sup>19</sup> Even after a 6-month education intervention, only 35% of patients studied routinely avoided salty foods, which demonstrates the need to take into account factors involving patients, providers, and the health care system.<sup>24</sup> One reason for poor adherence to dietary sodium restrictions may be failure

of providers to stress the importance of a sodium-restricted diet. Although heart failure guidelines consistently emphasize the importance of sodium restriction, one study revealed that fewer than 22% of patients admitted for an exacerbation of heart failure were prescribed a sodium-restricted diet at discharge.<sup>19</sup> Another reason may be failure of clinicians to assess patients' skill in choosing a diet low in sodium. Only one study was located in which clinicians assessed patient skill in the ability to sort foods into those containing high and low sodium content.<sup>25</sup> The authors found that only 14% of patients were aware of the sodium restriction guideline and only 58% was able to read the label's sodium content. Clearly, the current approaches to educating patients about this important aspect of therapy are lacking in some manner.

## Symptom Recognition

According to the self-care model described in "The Self-Care Paradigm" section, patients must be able to recognize symptoms if they are to manage their heart failure successfully. Patients with heart failure who are able to recognize their symptoms are more successful in subsequent steps of the self-care process.<sup>26</sup> However, symptom recognition has been found to be poor in most patients with heart failure.<sup>13,27</sup> In careful studies of patients' recognition of symptoms, fewer

than 50% of patients were able to recognize the common symptoms of worsening heart failure, including weight gain, edema, difficulty sleeping because of shortness of breath, and fatigue, and 40% of patients were unable to recognize escalating shortness of breath.<sup>26</sup> Difficulty in recognizing symptoms may stem, in part, from failure of health care providers to teach this important aspect of care. Few patients are instructed, even during a hospitalization for exacerbation of heart failure, to weigh themselves to monitor fluid status; most patients do not appreciate the importance of daily weighing, and as a consequence, most do not weigh themselves daily.<sup>24,28,29</sup> Bennett and colleagues<sup>30</sup> noted that self-monitoring was reported only by patients who attended a heart failure clinic. Self-monitoring (e.g., daily weighings, edema assessment) was apparently not emphasized to patients receiving care in other settings.

## Seeking Assistance When Needed

Knowing when to seek assistance from a health care provider and doing so are important self-care behaviors for patients with heart failure. Failure to seek care in a timely manner—before symptoms have escalated to the point where hospitalization is necessary to control them—is common among patients with heart failure. However, care-seeking behavior

among patients with heart failure is an understudied area. Frontiero and associates<sup>20</sup> found that only about half of patients reported talking to their physician whenever they needed guidance. Many patients wait days with worsening symptoms, even shortness of breath, before seeking care.<sup>31</sup>

## Changing Unhealthy Lifestyles

Exercise, limiting alcohol consumption, and smoking cessation would benefit many patients with heart failure, but adherence with these recommendations is poor. In one study, 67% of patients reported not exercising regularly.<sup>20</sup> Ni and colleagues<sup>32</sup> reported that 30% of patients had stopped exercising after heart failure was diagnosed. One fourth of patients failed to appreciate the risk of drinking excess alcohol, 12% were current smokers, and 21% engaged in physical exercise less than once a month or never. It has been noted in other patient populations that physicians often fail to recommend changing unhealthy lifestyle behaviors.<sup>33</sup>

## FAILURE OF THE TRADITIONAL HEALTH CARE DELIVERY MODEL

It is really no surprise that adherence to treatment is poor; many patients with heart failure are unable to recognize their early symptoms, and unhealthy lifestyle behaviors are common, in view of the traditional health care delivery model. In most cases, patients with heart failure are treated by clinicians who use usual practices typical of traditional health care delivery models. Management in traditional models is characterized by episodic, brief encounters with health care providers and punctuated by hospitalizations for acute exacerbations of heart failure. Several aspects of this typical care model actually contribute to increased rates of rehospitalization.<sup>10</sup> Despite the opportunity to closely assess patients, modify therapy under observation, and provide intensive education during a hospitalization for an acute exacerbation, the preponderance of evidence suggests that management during hospitalization is inadequate.<sup>10</sup> Approximately 20% of unplanned hospital readmissions for heart failure have been attributed to substandard inpatient care.<sup>10</sup> The areas of substandard care thought to contribute most to readmissions are lack of patient and family education and failure to organize follow-up care. In-hospital patient education is limited; many patients receive inadequate education and counseling.<sup>9,34</sup> Follow-up after hospital discharge usually consists of a few short visits with physicians in which there is little time to address the multiple and complex medical, behavioral, psychosocial, environmental, and financial issues that complicate the care of patients with heart failure.

Failure to prescribe appropriate drug therapy also contributes substantially to the high rate of rehospitalizations for heart failure. Multiple guidelines<sup>35-38</sup> describe standards for heart failure medical therapy that are based on results of large controlled clinical trials; nonetheless, as many as 50% to 72% of patients still do not receive prescriptions for ACE inhibitors and other drugs demonstrated to be effective in heart failure, do not receive them in adequate doses, or receive prescriptions for drugs such as calcium channel blockers that may have deleterious effects in heart failure.<sup>12,39-41</sup> Thus, although there have been some improvements in prescription patterns for patients with heart failure, the use of appropriate medications for heart failure is not yet widespread.

Because these issues must be addressed in order to improve heart failure outcomes, and because of the increasing incidence, prevalence, and economic costs of heart failure, many authorities have recommended that the current treatment patterns of fragmented care, in which acute in-patient episodes are common, be changed to comprehensive, integrated expert

multidisciplinary care patterns.<sup>2,42</sup> By changing the outpatient health care delivery model for patients with chronic heart failure to incorporate evidence-based components shown to improve outcomes, many patient, provider, and system factors that contribute to nonadherence will be addressed.

## MANAGEMENT OF HEART FAILURE

Most patients with heart failure seek the attention of health care providers because they experience worrisome symptoms. The most common symptoms of heart failure are manifestations of volume overload, including shortness of breath, fatigue, peripheral edema, and difficulty sleeping, which greatly impair patients' quality of life.<sup>43</sup> These symptoms are particularly burdensome because patients with heart failure are usually elderly and often have multiple comorbid conditions, multiple drug prescriptions, psychosocial concerns, financial constraints, and physical limitations.<sup>13</sup> In addition, many of these patients are socially isolated, cognitively impaired, and depressed.<sup>13,44-48</sup>

The symptoms of heart failure, although burdensome, are often subtle initially and may be confused with signs of normal aging or drug side effects.<sup>49</sup> Because of the subtlety of early symptoms, patients need access to experts with whom they can discuss their questions and concerns. Sorting out the various symptoms and managing the complex medication regimen require a specialized knowledge base that general practitioners may not have mastered.<sup>50</sup>

The complexities of heart failure care are suited to disease management, which, by definition, involves practice redesign with increased availability of experts, use of evidence-based guidelines, improved education and counseling, and use of monitored outcomes to improve care processes. Disease management has been shown to (1) improve knowledge about heart failure; (2) facilitate health behavior change that improves self-care, including adherence to treatment and management of symptoms; and (3) improve clinical outcomes, such as lower rehospitalization rates, lower hospitalization costs, and lower rates of mortality.<sup>51-60</sup>

Since the 1980s, when the first program of management for heart failure was tested, more than 50 published studies have been conducted to test the effects of heart failure specialty care delivered in a disease management model. Although each program is different, all programs include care that reflects a significant departure from traditional episodic care delivery. These programs can be categorized broadly into two types: (1) heart failure clinics and (2) heart failure care delivered in or to the home. In addition, there are other heart failure-specific programs that do not meet criteria of disease management programs. Although these approaches are not disease management in the true sense, some authors have referred to them as disease management, and some have been effective in improving outcomes in patients with heart failure.<sup>61-63</sup>

Heart failure clinics are disease management programs in which service is provided primarily in an outpatient clinic setting; patients come to the clinic to receive care from practitioners with expertise in heart failure. Programs providing heart failure care in or to the home include a variety of disease management approaches, all of which entail heart failure-specific care that is delivered primarily in the patient's home; care may be delivered by telephone, in person, or by both means. Many of these programs take a case management approach. Included in this group of studies are examples of true multidisciplinary care in which experts from three or more disciplines work collaboratively to deliver heart failure specialty care.<sup>64</sup> Other programs involve only mailed educational materials,<sup>63</sup> only a home telemonitoring system,<sup>61</sup> or increased access only to primary care.<sup>62</sup>

Although a few studies have demonstrated a neutral or negative effect of management programs for heart failure, most such programs, regardless of type, have yielded positive outcomes.<sup>51-60</sup> Meta-analyses have confirmed that in most studies, patients who are cared for in these programs experience fewer rehospitalizations, incur lower health care costs, and, in many cases, have longer survival (Table 59-2).<sup>51,54,57</sup> Many patients demonstrate improved functional and symptom status and enjoy better quality of life than they did before the intervention and in comparison with patients treated with usual care.<sup>54,56,57</sup>

### Management of Heart Failure in Special Populations (see also Chapter 49)

Surprisingly few investigators have tested disease management approaches in vulnerable patient populations such as minority, immigrant, or poor populations or populations of color. In one systematic review of cardiovascular disease interventions, only seven studies in vulnerable populations with heart failure were identified. This lack of research is surprising, inasmuch as significantly more African Americans than white patients are hospitalized for heart failure.<sup>65</sup> Prevalence and incidence of heart failure appear to be lower among Hispanic populations than among African American and white populations, but hospitalization rates may be higher. Alexander and colleagues<sup>66</sup> found that the percentage of patients rehospitalized for heart failure or other causes, total hospital days, and total hospital charges were all significantly higher for Hispanic patients than for non-Hispanic white patients; Hispanic patients were more likely to be rehospitalized multiple times. Little to nothing is known about Native American and Asian Pacific Islander residents in the United States.

The studies included in a systematic review<sup>65</sup> were a subset of some of the major disease management studies, chosen if they included a significant proportion of African American patients. Artinian and associates<sup>67</sup> enrolled 18 patients, 65% of whom were African American. Benatar and associates<sup>68</sup> enrolled 216 patients, of whom 186 (86%) were African American. DeWalt and coworkers<sup>69</sup> enrolled 25 patients, of whom 15 (60%) were African American with poor literacy. Naylor and colleagues<sup>70</sup> enrolled 239 patients, of whom 86 (36%) were African American. Rich and associates<sup>71</sup> enrolled 282 patients, of whom 155 (55%) were African American. Sisk and coworkers<sup>72</sup> enrolled 406 patients, of whom 187 (46%) were African American and 134 (33%) were Hispanic. Finally, O'Connell and associates<sup>73</sup> enrolled 35 indigent patients, of whom 18 (51%) were Hispanic, into a pretest/posttest assessment of case management for heart failure.

After Davis and coworkers<sup>65</sup> completed their review, Riegel and colleagues<sup>74</sup> published the report of a randomized, controlled trial testing a telephone-based disease management approach, previously shown to be effective in the general population, in a sample of Hispanic patients. Patients self-identified as Hispanic who were hospitalized with chronic heart failure were enrolled and randomly assigned to receive either telephone calls from bilingual/bicultural nurse case managers for 6 months ( $n = 69$ ) or usual care ( $n = 65$ ). Surprisingly, the intervention had no effect on hospitalization rate, quality of life, or depression in this sample. In comparison with the results of Sisk and coworkers<sup>72</sup>—the only other randomized controlled trial with a significant proportion of Hispanic patients—Riegel and colleagues' method effectively lowered the rehospitalization rate (143 hospitalizations among patients receiving telephone calls vs. 180 hospitalizations among the patients receiving usual care at 12 months). However, only 33% of Sisk and coworkers' population were Hispanic, and results were not analyzed by race or ethnicity. Riegel and colleagues suggested that a different approach may be needed in culturally diverse, elderly, functionally

compromised, poorly educated, or unacculturated groups. This is clearly an area in which further research is needed.

## PUTTING MANAGEMENT OF HEART FAILURE INTO PRACTICE

Despite the superiority of outpatient management of heart failure, only a minority of patients with heart failure receive care through these care delivery models. Assuming that nonadherence is the result of factors related to the patient, provider, and health care system, a concerted effort to influence each of these components will have the best chance of improving outcomes in this challenging patient population. Programs of management for heart failure address each of these three areas. Patient factors are assessed and addressed, providers work from a knowledge base and framework that ensures appropriate care, and the system for care delivery has been modified to produce optimal outcomes. Thus, appropriate patients should be referred to these management programs when possible. However, these management programs are not available to the majority of patients and providers. In such cases, it is possible for providers to use the principles of management of heart failure in their practice (Box 59-1). An individual provider will have difficulty using disease management principles alone; therefore, a physician-advanced practice nurse team is suggested and described further later in the "Care Delivered by Advanced Practice Nurse-Physician Team" section. A vital first step in implementing management of heart failure is to understand and promote patient self-care.

### The Self-Care Paradigm

Clinicians long ago accepted the idea of self-care for patients with diabetes mellitus. They have been much slower to accept it for patients with other types of chronic illnesses, despite compelling evidence that promotion of patients' self-care abilities results in improved outcomes.<sup>75-77</sup> Self-care is the process in which patients, often with the help of their families or another caregiver, participate in their own care (Figure 59-1). Self-care is the foundation upon which successful management of heart failure is built. The terms *self-care*, *self-management*, *adherence*, and *knowledge* frequently are used interchangeably, but each has a distinct meaning.<sup>78</sup> Investigators have often measured regimen adherence or knowledge and call these "self-care".<sup>24</sup> In other studies, knowledge is assumed to be sufficient for self-care by authors who overlook the fact that knowledge is necessary but not sufficient for self-care.<sup>79</sup> Thus, it is important that clinicians understand the process of self-care so that they can assist patients to participate effectively in it.

The self-care process includes both maintenance and management components.<sup>80</sup> An assumption of self-care is that for patients with heart failure to be successful at self-care, they must engage in the behaviors that will help them to stay physiologically stable (e.g., eating a low-sodium diet) and they must adhere to the prescribed regimen, which is self-care *maintenance*. They also must make decisions about how to address signs and symptoms when they occur (e.g., take extra diuretic if weight increases 3 pounds [1.4 kg] in 1 week), which is self-care *management*. The process of self-care consists of the stages illustrated in Figure 59-1. A major factor that influences patients' skill at self-care management activities is self-efficacy, or confidence in one's ability to perform self-care.<sup>80</sup>

Stage 1 of the self-care process, maintenance, involves symptom monitoring and treatment adherence. Self-care maintenance involves following the advice of health care providers to follow the treatment plan, make healthy lifestyle choices, and monitor for symptom changes. Patients who

Phillips et al (2004) <sup>54</sup>	14 Trials (10 in the United States): 3 studies of a single home visit; 6 studies of a home visit with or without frequent telephone contacts; 4 studies of frequent clinic visit and telephone follow-up or a home visit, or both; 1 study of a day hospital with an available specialized heart failure unit	All randomized, controlled trials	3304 Patients; 62% men, 14% nonwhite; mean age of study participants: 70 years or older in 16 studies and younger than 70 years in 2 studies; LVEF < 40% in 8 studies and LVEF > 40% in 2 studies	Readmission (8 studies): <ul style="list-style-type: none"> <li>Fewer intervention recipients were readmitted: NNT = 12, RR = 0.75, 95% CI = 0.64-0.88</li> <li>CHF- or CVD-specific readmission: RR = 0.65; 95% CI = 0.54-0.79</li> <li>Combined endpoint of death or readmission: RR = 0.73; 95% CI = 0.62-0.87</li> </ul> Mortality (14 studies): <ul style="list-style-type: none"> <li>Trend toward lower rates of all-cause mortality (RR = 0.87; 95% CI = 0.73-1.03)</li> </ul> Length of stay, QOL, and medical costs: <ul style="list-style-type: none"> <li>Difference of length of stay between intervention and control groups was not significant</li> <li>Significant improvement in QOL in intervention recipients</li> <li>Cost effectiveness (cost difference: −\$359, 95% CI = −\$763-\$45, for non-U.S. trials and −\$536, 95% CI = −\$956-\$115, for U.S. trials)</li> </ul>	Comprehensive discharge planning with postdischarge support for older adults with heart failure significantly reduced readmission rates and may improve survival and QOL without increasing costs

ACE, angiotensin-converting enzyme; CHF, congestive heart failure; CI, confidence interval; COPD, chronic obstructive pulmonary disease; CVD, cardiovascular disease; DMP, disease management program; LVEF, left ventricular ejection fraction; NNT, number needed to treat; NYHA, New York Heart Association; PCP, primary care provider; QOL, quality of life; RR, relative risk.

### BOX 59–1 Putting Principles of Management of Heart Failure into Practice

1. Understand and promote patient self-care
2. Assess and address patient factors that affect adherence to regimens and ability to engage in self-care
3. Teach skills preferentially over knowledge
4. Include family members and informal caregivers in education
5. Identify and target patients who are at high risk for rehospitalization
6. Employ components of management programs for heart failure that improve outcomes
  - Individualized, comprehensive patient and family or caregiver education and counseling on an outpatient basis
  - Optimization of medical therapy
  - Vigilant follow-up
  - Increased access to health care professionals
  - Early attention to fluid overload
  - Coordination with other agencies as appropriate
  - Either physician-directed care with assistance from nurse coordinators or nurse-managed care by experienced advanced practice cardiovascular nurses with access to a cardiologist
7. Use behavioral strategies to increase adherence to regimen

routinely monitor themselves are more likely to seek treatment at the early stages of exacerbation. Heart failure is notable for the subtlety of early symptoms, and so symptom monitoring is an essential component of self-care maintenance.

Subsequent stages of the self-care process reflect management, which is an active, iterative, deliberate decision-making process undertaken in response to symptoms.<sup>80</sup> Symptom management is essential for patients with heart failure if they are to control what may be a precarious balance

between relative health and symptomatic heart failure. In self-care management, once the patient recognizes changes in signs and symptoms, the patient must make decisions about how to respond.

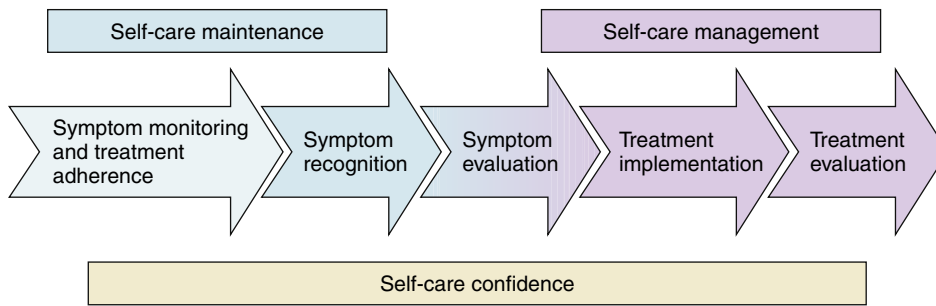

Stage 2, symptom recognition, involves recognition that a change in signs or symptoms has occurred and that the change is related to heart failure. If patients recognize a symptom as related to their heart disease, they are more likely to appropriately evaluate its urgency and respond more quickly.<sup>81</sup> Stage 3, symptom evaluation, is the process by which patients attempt to distinguish between important and unimportant symptom changes. If a symptom is judged to be important, it is more likely that the patient will decide that he or she needs to take action.<sup>80</sup> Patients may proceed through these stages and not take action because they lack knowledge about what to do, judge that the costs of the action outweigh the benefits, fail to understand the importance of the symptom change, or believe that no effective strategy is available. Health care providers can intervene at this point and increase patients' knowledge about important signs and symptoms and education them about the appropriate actions to take when changes occur.

Stage 4, treatment implementation, involves action in response to the prior stages. Some actions are intuitive and require little thought (e.g., rest). Some actions can be performed independent of others (e.g., diet adjustments), and some actions are interdependent or require some guidance from a health care provider (e.g., adjusting diuretic dose). Stage 5, treatment evaluation, concerns the effectiveness (e.g., in symptom relief) of selected treatments. If a treatment is effective, it may be attempted again. Research has shown that this ability is learned through experience.<sup>20</sup> However, other ways of increasing this expertise must be found if patients with newly diagnosed heart failure are to avoid rehospitalization during the first few months after their initial hospitalization. Outpatient management with a disease

## SELF-CARE OF HEART FAILURE MODEL

**FIGURE 59-1** Self-care encompasses two processes: maintenance and management. Self-care maintenance involves engagement in making healthy life style choices and being adherent to the prescribed regimen. Self-care management is the process of decision making when symptoms or signs change.

management approach to heart failure is one such way, but it is important to determine first what patient factors exist that could interfere with the patient's ability to optimally engage in self-care.

#### Assess Patient Factors That Interfere with Self-Care

Numerous issues can interfere with patients' self-care abilities.<sup>15</sup> Advancing age, low education level, and low health literacy can affect patients' ability to learn and comply with treatment recommendations.<sup>20</sup> Inability to communicate with the provider because of language-, age- and culture-related beliefs has also been demonstrated to be a major factor interfering with adherence to treatment regimens. Cognitive dysfunction is increasingly recognized as a common problem among patients with heart failure<sup>44,82</sup> that can contribute to poor self-care.<sup>83</sup> Simple measures such as a clock-drawing test are available for routine screening of cognitive abilities.<sup>44</sup>

Personal factors such as lack of motivation, low self-efficacy, emotional distress (especially depression), poor health habits such as smoking, and lack of perceived control also contribute to difficulties practicing self-care and changing health behaviors.<sup>28,84,85</sup> Situational factors such as social isolation, lack of support,<sup>28</sup> and the challenges of implementing a complex treatment regimen under limited economic resources<sup>13</sup> complicate matters further. Illness factors such as length of experience with the diagnosis, symptom severity, physical limitations, and presence of multiple comorbid conditions can contribute to poor compliance and poor self-care.<sup>28,86</sup> As the importance of these factors to self-care and outcomes becomes increasingly obvious, health care providers must be educated about assessing and managing them.

#### Include Family Members and Informal Caregivers in Education

Family members and friends are the unobserved and often neglected informal caregivers who provide substantial support for many patients with heart failure.<sup>87</sup> Failure to include informal caregivers in disease management approaches can contribute to poor outcomes. In particular, patients who have any of the factors above that can adversely affect self-care may need the support of informal caregivers.<sup>88-90</sup> Whenever possible, it is essential to identify these caregivers and include them in education and counseling sessions.<sup>91</sup>

#### Identify and Target Patients Who Are at Risk for Rehospitalization

Existing evidence suggests that approaches to the management of heart failure are most effective when used for patients who are at risk for rehospitalizations.<sup>92-94</sup> Because a patient's heart failure status can change over time, it is necessary to reassess risk status often. A number of risk factors for rehospitalization have been identified and confirmed in multiple studies. Older age, particularly older than 75 years, is a major risk factor.<sup>95</sup> A previous hospital admission for heart failure within the previous 30 days to 1 year<sup>92,96,97</sup> is another important risk factor, as are multiple hospitalizations for any reason within the previous 5 years.<sup>71,98</sup> The presence of comorbid illnesses,

particularly multiple active conditions, is another major risk factor.<sup>96,97</sup> Three specific comorbid conditions increase risk: (1) history of chronic obstructive pulmonary disease; (2) diabetes; and (3) renal insufficiency as reflected by creatinine level of 2.5 mg/dL or higher or by higher level of blood urea nitrogen.<sup>92,96,97</sup> Patients with depression or anxiety,<sup>99-101</sup> those with inadequate support systems or who live alone,<sup>102</sup> those with cognitive impairment,<sup>103</sup> and those with functional impairment<sup>98</sup> are also at increased risk for rehospitalization.

#### Components of the Management of Heart Failure That Improve Outcomes

Clinicians who do not have access to management programs for heart failure can, nonetheless, make great strides in improving heart failure patient outcomes by incorporating effective aspects of these programs in their practice. There have been no comparisons of the individual components used in management programs for heart failure, but examination of studies with neutral or negative findings and of recent studies where some components have been omitted provides sufficient information to make recommendations about the components that are likely to improve outcomes (see Box 59-1). Each of these components is described below.

**Individualized, Comprehensive Patient and Family or Caregiver Education and Counseling on an Outpatient Basis.** At the core of every successful management program for heart failure is individualized, comprehensive education and counseling, the goal of which is to improve adherence to the prescribed regimen.<sup>24,104-106</sup> The addition of comprehensive education and counseling alone to the regimen improves clinical outcomes as long as they include behavioral strategies to increase adherence.<sup>107</sup> Outpatient education and counseling must always supplement inpatient education. Inpatient education alone is inadequate, and patients are not able to retain most of what they are taught in the hospital.<sup>32</sup> Regardless of the quality of inpatient education, patients are ill, anxious, distracted, and thus in poor condition to learn and retain material. In addition, there is little time in the hospital to impart all of the needed information.

Patients and their families and informal caregivers must perform the majority of heart failure care at home. If a patient does not know what is required and why, does not have the motivation or skills to accomplish it, or does not appreciate the importance of the activities, the patient cannot participate effectively in care. Therefore, the goals of education and counseling are to help patients and their informal caregivers acquire the knowledge, skills, and motivation they need to adhere to the treatment plan and participate effectively in self-care. To help patients do this, health care providers not only need to impart necessary knowledge but also must impart it in a manner that promotes retention and application of what is learned.

**Content for Patient and Family Education and Counseling.** Patients with heart failure must perform specific behaviors to cope with the illness. They must limit dietary sodium to 2 to 3 g per day, take medications as prescribed routinely, and get periodic flu and pneumococcal immuniza-

tions (*comply with treatment*). They need to be taught to weigh themselves daily and how to monitor for common symptoms of decompensation such as shortness of breath, fatigue, peripheral swelling, waking at night with coughing or shortness of breath, dizziness, and swelling (*monitor signs and symptoms*).<sup>108</sup> They need to be taught when to report abnormalities to their health care provider (*seek assistance when necessary*). Finally, many patients with heart failure should be encouraged to exercise, stop smoking, limit or halt their alcohol intake, and control other comorbid conditions such as diabetes, hypertension, or hyperlipidemia (*change unhealthy lifestyles*).<sup>108</sup> Specific education and counseling to support patients successfully engage in these behaviors are described in Box 59-2.

**Teaching and Counseling Methods.** It is essential that effective behavior change strategies be given to patients and families along with provision of information. Behavior change researchers have long demonstrated that knowledge alone is insufficient for changing behavior,<sup>109</sup> and even now patients report frustration at being told what to do without being given the skills to make the expected behavior change.<sup>28</sup> In addition, a number of factors that contribute to nonadherence and rehospitalization also contribute to difficulties in putting information into action. Thus, clinicians need to understand factors that influence patients' ability to make recommended health behavior changes and must become familiar with effective behavior change strategies that they can teach.

In addition to the conditions described in the "Assess Patient Factors That Interfere with Self-Care" section, the following conditions are barriers to adherence. It is important to assess and address these barriers if they are present. Impediments inherent in recommended treatments themselves can limit adherence considerably. The number of medications, treatment complexities, drug side effects, cost of medications, cost of transportation to the pharmacy and to physicians' offices, and unsafe location of the neighborhood pharmacy all can contribute to medication nonadherence.<sup>13,28</sup> Other barriers to medication adherence included medication unpleasantness; difficulty remembering to take medication; having to take too many medications each day; the action of diuretics, which makes it difficult to leave home; and nighttime awakenings to urinate. It may be difficult to follow recommendations for dietary sodium restriction because of time, cost, taste, difficulty understanding diet requirements, inability to socialize when food is involved, limitations on eating out, and limitations on eating prepackaged and canned foods.<sup>28</sup>

**Education and Counseling Style.** Optimal patient education and counseling involve more than simply providing information. Counseling emphasizes individualized delivery of important information, taking into account the factors discussed previously that interfere with successful participation in care (e.g., language, cognitive function, mood), as well as a patient's readiness to change. Prochaska and colleagues<sup>110,111</sup> proposed a model of change that acknowledges that many people are not ready to engage in the behaviors that health care providers advocate. According to their model, patients in the *precontemplation* phase of change are not considering change; those in the *contemplation* phase are thinking about change but have yet to commit to change; and those in the *preparation* phase are planning to make changes in the future and may have already engaged in some early steps of change. Most patients are in one of these three early phases when a provider advocates a new behavior. Few patients are in the *action* phase (in which change has occurred) or *maintenance* phase (change has been maintained for 6 months or more), even when the need for behavioral change was recognized before it was addressed by a provider (e.g., smoking cessation).

Correction of patients' misperceptions regarding their condition and treatment is another important aspect of education and counseling. It is helpful to assess patients' current

## BOX 59-2 Education and Counseling for Patient and Family or Informal Caregiver

### General Topics

1. Explanation of heart failure
  - Include explanation of symptoms
2. Psychological responses
  - Possibility of increased depression and anxiety
  - Necessity of treatment if anxiety or depression persists
3. Immunizations needed
  - Flu and pneumococcal vaccines
4. Prognosis
5. Advanced directives

### Examples of Skills Needed to Manage Heart Failure Successfully

1. How to read nutrition labels
2. How to assess for ankle swelling, other edema, fatigue, and dyspnea
3. How to compensate for missing a medication
4. How to prepare for an office visit with the provider

### Symptom Monitoring and Recognition

1. Symptoms to be expected versus symptoms of worsening heart failure, and how to monitor
2. Self-monitoring with daily weighings
3. What to do in case of increased symptoms

### Dietary Recommendations

1. Diet with no more than 2 to 3 g of sodium
2. Fluid management
  - Fluid restriction unnecessary except for patients with hyponatremia, but moderation in fluid intake (<2 L/day) is warranted
3. Alcohol recommendations
  - Alcohol limited to 1 drink/day; abstinence if alcoholic cardiomyopathy is present
4. Behavioral skills
5. Adherence strategies
6. Overcoming barriers

### Medications

1. Nature of each drug, dosing, and side effects to watch for
2. What to do with prescriptions from other physicians or from prior hospitalizations
3. Natural remedies and vitamins
4. Coping with complicated regimens
5. Cost issues
6. Adherence strategies
7. Overcoming barriers

### Activity and Exercise

1. Management of various activity needs
  - Activities of daily living
  - Work and leisure activities
  - Exercise program
  - Sexual activity
2. Adherence strategies
3. Overcoming barriers

### Risk Factor Modification

1. Smoking cessation
2. Weight control for overweight patients
3. Management of hyperlipidemia, diabetes, and hypertension

knowledge and understanding by asking questions that elicit more than "yes" or "no" for an answer. Misperceptions are common among patients with heart failure. For example, a common misunderstanding among patients with heart failure is that an increase in fluid intake is necessary in patients with

heart failure because they are ill and because diuretics cause excessive urination.<sup>26,32,108</sup> Many patients misunderstand the reasons they are asked to weigh themselves daily, believing that they are being asked to watch for adipose weight gain.<sup>28</sup> Bennett and colleagues<sup>30</sup> documented an array of inappropriate or ineffective self-care techniques for symptom management, including use of cough drops, room temperature alteration, use of a cool cloth on the face for shortness of breath, and use of distraction and herbal teas for difficulty sleeping.

Internal motivation is an important factor contributing to successful self-care, and motivational techniques are extremely effective for individuals in one of the early stages of change. Motivation interviewing, a technique that emphasizes helping the patient resolve ambivalence about change, is effective even for those with difficult behaviors such as problem drinking and weight loss<sup>112,113</sup> and even with the behaviors that persons with heart failure are asked to implement.<sup>114</sup> Cognitive-behavioral techniques, which emphasize modifying barriers to change, are also quite useful with patients in the early stages of incorporating recommended behaviors into their lives.<sup>115</sup> Specific techniques have been suggested for helping patients progress through each of the stages of change.<sup>116</sup> For example, patients who are not considering change need information. To individuals in the contemplation stages of change, however, information is often superfluous and irritating; these patients benefit from an emphasis on the outcomes to be derived from change (e.g., “You can probably avoid rehospitalization if you take your medications routinely”). Patients in the preparation stage may benefit from efforts to increase their confidence in their abilities to make the recommended changes or by assistance in overcoming barriers that they face (e.g., difficulty in meal preparation).<sup>117</sup>

Simply avoiding ineffective educational approaches is helpful for patients. Fear and coercion, for example, are common techniques in clinical practice, but they are ineffective motivators because people who are pushed in one direction will resist change, even if the advocated approach is logical.<sup>116</sup> Messages that are couched in terms that evoke fear are commonly discounted and ignored by patients in order to reduce anxiety. Paternalism—characterized by making decisions for patients—is also common in clinical practice but rarely effective in the long term because patients lack ownership of the decision.

The most effective education and counseling approaches are individualized to include what the patient needs and wants to learn, build on prior knowledge and experience, involve the patient in discussion and skill practice, include a discussion of the benefits of acting on recommendations, and provide feedback and reinforcement. Following educational principles such as these enhances the effectiveness of patient education.<sup>118</sup> A major difference between patient teaching and formal didactic education is that patient teaching focuses on what patients need to *do* rather than what they need to *know*<sup>28</sup>; that is, teaching the pathophysiological processes of heart failure is not necessary unless requested by the patient. Instead, patients usually want to know what their drugs do, which symptoms are important to monitor, how to monitor symptoms and what to do about them when they occur, and to distinguish side effects of drugs from symptoms of heart failure.<sup>28,49</sup>

**Timing, Setting, and Form of Education and Counseling.** To be most effective, education and counseling must be provided when and where patients are most ready to learn. Inhospital education is traditional and required by accrediting agencies, but hospitalization is probably the worst possible time to educate patients because hospitalized patients are, as a group, more ill now than in years past. Furthermore, patients are being discharged earlier, and their days in the hospital are busy with tests and procedures. Therefore, just

brief, essential, but thorough education should be provided during hospitalization (e.g., medication teaching); comprehensive education should be deferred until after discharge. Teaching that is deferred should be begun within the first week after hospital discharge, preferably within the first few days, and continued during subsequent visits.<sup>16,64</sup>

Face-to-face education and counseling sessions that include written materials are vital. Written materials with sound educational principles (“educational modules”) that are prepared specifically for patients with heart failure can be obtained from the website of the Heart Failure Society of America ([www.hfsa.org](http://www.hfsa.org)). Prior investigators have also shown that patients who are motivated to learn and change can derive significant benefit from interventions delivered by mail, telephone, or technology. For example, Serxner and associates<sup>63</sup> demonstrated that personalized information on self-care and behavior change delivered by mail to patients with heart failure decreased hospital admissions and cost 51%. Fulmer and colleagues<sup>119</sup> demonstrated that elderly patients with heart failure who were randomly assigned to receive either daily telephone medication reminders or daily videotelephone call reminders adhered better to medication regimens than did control patients who received no reminders; for those control patients, adherence dropped from 81% to 57% after 10 weeks in the study. Thus, a combination of strategies is recommended.

**Health Behavior Change Strategies.** In a classic article, McKenney and associates<sup>120</sup> categorized strategies for improving adherence to treatment regimens into enabling, consequence, and stimulant. Enabling strategies—patient education, simplifying the medication regimen, increasing access to care, prescribing less costly therapies—equip patients with what they need to adhere to the regimen. Consequence strategies, such as maintaining records and rewarding adherence, reinforce desired behavior. Stimulant strategies, such as reminders or linking desired behaviors to daily rituals, are intended to prompt the desired behavior. Studies of enabling strategies such as patient education suggest that increasing knowledge does not necessarily increase adherence.<sup>121</sup> Stimulant strategies are more effective in achieving compliance than either enabling or consequence strategies.<sup>119</sup> This suggests that education and counseling interventions may need less emphasis on the transferring of information and more attention to behavioral techniques that help patients integrate new and important behaviors into their lives. Suggested strategies in each category are outlined in **Box 59-3**.

**Optimization of Medical Therapy.** Another important component of the management of heart failure is optimization of drug therapy, by means of recommendations from published guidelines that are based on large-scale randomized controlled clinical trials. The American Heart Association program “Get With the Guidelines,” which is available online (<http://www.americanheart.org/presenter.jhtml?identifier=1165>), is a helpful way to begin incorporating these guidelines into practice. Not only should the appropriate drugs be prescribed but also they should be prescribed in the appropriate doses whenever possible.<sup>12</sup> ACE inhibitors (see Chapter 45) and  $\beta$ -adrenergic blocking agents (see Chapter 46) that must be titrated up to the optimal dosage are the drugs most often not prescribed in optimal dosages; therefore, clinicians should take extra care during follow-up visits to assess proper dose titration. In each management program for heart failure in which drug therapy (types and doses) was evaluated, prescriptions of drug therapy have been better than either usual care or prescriptions before initiation of the program.<sup>122,123</sup> The optimal drug regimens are described in Chapters 42 to 44 and 46 of this book. The clinician’s obligation does not end with prescription of the drug; the clinician must ensure that the patient adheres to the regimen.

### BOX 59-3 Strategies for Changing Health Behavior

#### Enabling Strategies

- Adapting low-sodium diet to patient's usual eating style
- Teaching patients how to eat out at usual restaurants while following low-sodium diet
- Teaching patients how to read food labels for sodium content
- Teaching patients to identify high- and low-sodium foods
- Acknowledging cultural and religious food influences
- Providing materials written at the appropriate reading level
- Providing materials printed in large font for patients with visual disabilities (e.g., elderly patients)
- Sending annual reminds for flu vaccinations
- Calling with appointment reminders
- Providing a list of worrisome symptoms
- Referring to a dietitian for weight reduction counseling
- Referring to a smoking cessation program as needed
- Teaching alternative ways to monitor fluid retention (shoe or belt tightness, ankle circumference)
- Referring to Alcoholics Anonymous or other substance abuse support group as needed

#### Consequence Strategies

- Keeping a log of daily weights
- Keeping a log of symptoms and their quality (most severe to least severe)
- Keeping a log of distance walked and heart rate attained

#### Stimulant Strategies

- Providing patients with pill box and teaching its use
- Providing patients with medication log to check off daily
- Linking the taking of medications to everyday activities (e.g., brushing teeth)
- Providing patients with a pedometer to monitor activity
- Providing a scale to patients who do not have one
- Placing the scale somewhere unavoidable each morning
- Providing a daily sodium tracker to facilitate monitoring of sodium intake
- Teaching patients how to cook basic recipes with low sodium
- Allowing patients to self-regulate diuretic dosing on the basis of weight gain
- Offering flu shots in the office
- Providing a list of specific symptoms that should stimulate a call to the office

**Vigilant Follow-up.** Outcomes are improved when the frequency of and vigilance during follow-up appointments are increased, particularly after discharge from a hospitalization for heart failure. Investigators have demonstrated that the first 2 weeks after hospital discharge is a time of increased vulnerability for patients, and the clinician's vigilance must be increased during this time period.<sup>13,105</sup> In addition to more frequent office visits, a single home visit by a nurse during the first few weeks after discharge can substantially decrease rehospitalization rates and improve long-term survival.<sup>105</sup> Nurses are able to assess both the patient's physical status and understanding of instructions, and they can provide education and counseling. Because nurses are accessible by telephone, patients can contact a health care professional when they are reluctant to "bother" their physicians.

**Increased Access to Health Care Professionals.** Easy access to health care providers is a component of the management of heart failure that also is associated with improved clinical outcomes.<sup>124</sup> The usual method of contacting a physician involves a long telephone call that includes an unintelligible series of instructions about pushing multiple numbers in order to leave a message, which may or may not be returned;

many patients choose instead to wait until symptoms become severe. In addition, many patients do not feel comfortable calling their physicians to ask questions. When patients have easier and quicker access to a health care provider to ask questions, clarify instructions, and solve problems concerning their condition that arise unexpectedly, clinical outcomes are improved.

Improving access in this area begins with developing an open communication policy with patients so that they feel comfortable asking questions about their condition. Ways to increase accessibility include providing the services of an advanced practice nurse with whom patients have developed a relationship by telephone or on a walk-in basis. A fundamental component of this approach is to make sure that patients understand that early attention to problems improves outcomes.

**Early Attention to Fluid Overload.** Fluid overload is the most common cause of emergency hospitalization among patients with heart failure (see Chapter 43).<sup>6,19,125</sup> Thus, attention to early signs and symptoms of fluid overload is a common component of successful management of heart failure. As described previously, patients need to be taught to monitor for signs of fluid overload, weigh themselves daily, and keep a record of weights. Patients must be taught that signs of fluid overload are ankle and leg swelling; rings, belts, or waistbands becoming too tight; and increased dyspnea, including difficulty sleeping or orthopnea. Of importance is that patients need to be assisted to develop skill both in assessing themselves for fluid overload and in the ability to judge when to call their health care providers because of these signs or symptoms or if their weight increases by 2 to 3 pounds (0.9 to 1.4 kg) and remains elevated or continues to rise.<sup>108,122</sup> When appropriate, patients or their informal caregivers can be taught to use a flexible diuretic regimen in response to increased weight.<sup>108,122</sup> Although there are variations on the flexible diuretic regimen, one approach is for patients to double the diuretic dose for 2 days if their weight increases by 2 to 3 pounds in 1 to 2 days. If their weight continues to rise or does not fall, a call to the clinician is warranted.

**Coordination with Other Physicians and Agencies as Appropriate.** Because many patients with heart failure are elderly with multiple comorbid conditions and socioeconomic problems, other agencies may be involved in their care. In addition, for most patients with heart failure, more than one physician or other health care provider is involved in their care. Coordinating the care and services received, avoiding duplication and mixed messages, and ensuring that services are not missed are essential when patients have multiple providers or need the services of multiple providers.

**Care Delivered by Advanced Practice Nurse-Physician Team.** A final important component of optimal outpatient management of heart failure is the use of a team of at least two clinicians. In each disease management program tested, nurses successfully coordinated or facilitated care with assistance from a physician with expertise in the care of patients with heart failure. No single person can accomplish all that is needed to properly care for patients with heart failure.<sup>104</sup> Advanced practice nurses (i.e., nurses with a master's degree who are trained as either clinical nurse specialists or nurse practitioners) have the training to collaboratively care for complex patients.

## SUMMARY

The increased incidence and prevalence of heart failure, combined with the cost of caring for these patients, provide the opportunity to address many of the difficult issues that will confront society as the population ages. Currently, the most strenuous efforts are concentrated in investigations of

pharmacological and device therapies. In order to improve morbidity rates, mortality rates, and quality of life for a greater number of patients with heart failure, clinicians should use a more systematic, balanced approach to practice in which non-pharmacological or noninvasive, surgical, and pharmacological therapies and their interactions are considered equally.

emotional, social, and tangible costs to patients with heart failure and those involved in their care, cognitive impairment traditionally received relatively little attention in the literature.<sup>9,10</sup> Symptoms of dyspnea, fatigue, and edema have attracted greater interest and study; in fact, patients with cognitive impairment are frequently ruled out in terms of eligibility for participation in studies related to heart failure. The prevalence of cognitive impairment in patients over 65 years old with heart failure is nearly double (1.96 times) that in the general population.<sup>10</sup>

Health-related quality of life (HRQL)—a multidimensional construct in which the patient assesses his or her health status in comparison to what he or she hopes it to be—is significantly compromised in patients with heart failure.<sup>11,12</sup> Although the relationship is complex, as noted by Pressler,<sup>7</sup> cognitive impairment is associated with lower HRQL scores in patients with heart failure. There is evidence to suggest the possibility of a curvilinear relationship between cognitive impairment and HRQL; those individuals with the greatest degree of cognitive impairment have the highest HRQL scores, and individuals with less severe cognitive impairment have lower scores.<sup>13</sup> This seemingly paradoxical finding may be attributed to the compromised ability of more cognitively impaired individuals to evaluate their cognitive abilities realistically.<sup>14</sup> However, like individuals with severe cognitive deficits, those with asymptomatic heart failure who do not have cognitive deficits are more likely to have higher HRQL scores; this finding casts doubt on the reliability and validity of a subset of HRQL self-reports (individuals with severe heart failure who also evidence more severe cognitive impairment, and asymptomatic patients without cognitive impairment). Nevertheless, this finding does not negate the importance of assessing HRQL in patients with heart failure.

Heart failure affects approximately 5 million Americans, with an estimated 550,000 new cases per year. Hospital readmission rates are averaging 40% to 50% after discharge, at an average cost of \$12,400 per admission.<sup>1-3</sup> It is estimated that approximately 55% of readmissions are preventable,<sup>4</sup> a finding that is largely attributed to difficulties adhering to complex medication regimens, difficulties adhering to dietary restrictions, and delays in seeking medical attention.<sup>5</sup> Symptoms associated with heart failure include breathlessness or dyspnea, extreme fatigue, edema, and cognitive impairment, the last of which is the focus of this chapter.

Cognitive impairment in patients with heart failure includes (1) decreased capacity to sustain attention and concentration; (2) diminished memory capacity; (3) diminished capacity to engage with tasks that require executive functions of the brain, including problem solving and abstract reasoning; and (4) decreased motor speed, reflected in slower reaction time.<sup>6-8</sup> Overall, there is consensus among authorities with regard to the domains of cognitive impairment associated with heart failure.

Despite the clinical relevance and

## PREVALENCE

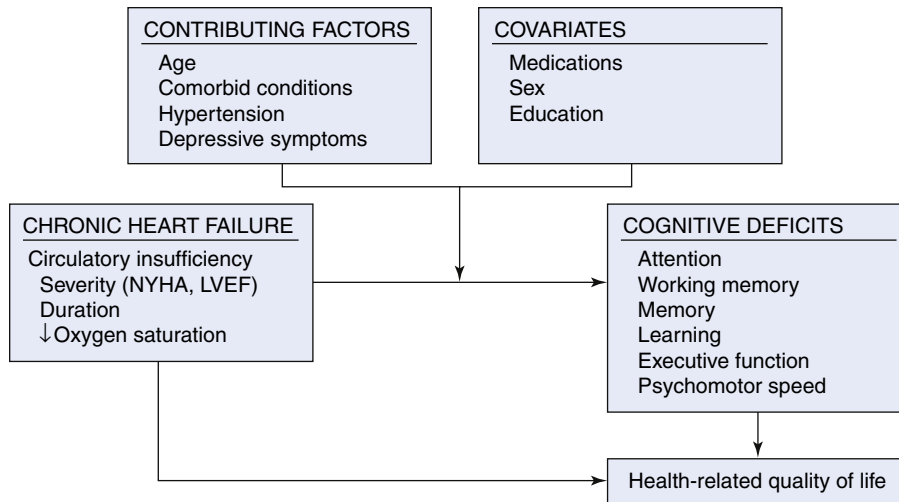

The literature on the prevalence of cognitive impairment in heart failure is sparse. It is characterized by inconsistency of instrumentation, as well as lack of depth of assessment tools used.<sup>15,16</sup> In view of the diversity of approaches to the study of cognitive impairment, including the use of experimental designs that are insufficiently powered, it is not surprising that reported prevalence rates range from approximately 25% to 80%.<sup>8</sup> A more conservative estimate is 25% to 30%.<sup>7,17,18</sup>

Feola and colleagues<sup>19</sup> reported that the degree of cognitive impairment in most patients with heart failure is mild. However, one fourth of patients with heart failure exhibit moderate to severe cognitive impairment. Severity of cognitive impairment is correlated with New York Heart Association (NYHA) classification; the more severe the impairment is, the more likely that the NYHA classification is higher (class IV).<sup>20</sup>

In the early stages of heart failure, cognitive impairment manifests as more nuanced, intermittent, and difficult to recognize than in later stages of heart failure. The severity of impairment is correlated with age and inversely correlated with left ventricular ejection fraction. Although findings are inconsistent, the degree of cognitive impairment is not associated with systolic or diastolic blood pressure, which may be a result of treatment of blood pressure.<sup>8</sup> Because of the episodic, inconsistent, and unstable manifestation of cognitive impairment, particularly in early stages, periodic cognitive screening may be most effective for appropriate detection and intervention.

## A CONCEPTUAL FRAMEWORK

There have been few systematic attempts to target specific populations of individuals with heart failure in terms of cause and severity of cognitive impairment. Most studies are not guided by a conceptual framework; for this reason, the understanding of prevention and attenuation of cognitive decline is seriously limited. On the basis of a literature review of the pathophysiology of cognitive impairment in patients with heart failure, as well as HRQL findings in

**FIGURE 60-1** Conceptual model of cognitive deficits in heart failure. LVEF, left ventricular ejection fraction; NYHA, New York Heart Association (classification). (From Bennett, S. J., Sauve, M. J., Shaw, R. M. (2005). A conceptual model of cognitive deficits in chronic heart failure. *J. Nurs. Scholars*. 37, 222-228.)

patients with heart failure, Bennett and colleagues<sup>21</sup> provided a working framework for conducting future research efforts. The model proposed allows for the inclusion and evaluation of cause and the assessment of key variables such as depression and HRQL. The model also presents opportunities to expand the knowledge base in order to make better and more evidence-based decisions.

Bennett and colleagues<sup>6</sup> suggested that circulatory insufficiency accounts for the majority of the difficulties associated with cognitive impairment in patients with heart failure; this view is supported in the literature. The model identifies additional contributors to impaired cognitive functioning: age, comorbid conditions, and their combined effects (e.g., hypertension and depressive symptoms), as well as covariates such as medications and education. **Figure 60-1** elucidates the proposed relationships among these contributors and how they may inform each other with regard to treatment.

## MECHANISMS RESPONSIBLE FOR COGNITIVE IMPAIRMENT: STRUCTURAL AND FUNCTIONAL CHANGES WITHIN THE BRAIN

Understanding cause with regard to heart failure and cognitive decline is critical for identifying patients most likely to experience cognitive impairment. Cause also has significant implications for interventions designed to ameliorate or halt cognitive decline. However, many of the studies have relied on heterogeneous sampling approaches with diverse underlying pathophysiological mechanisms (e.g., heart transplantation candidates, community-based populations), which results in difficulty in addressing issues related to cause.<sup>8</sup>

There is strong evidence that circulatory insufficiency leads to inadequate cerebral perfusion and that cerebral hypoxia is the probable primary cause of cognitive decline.<sup>7</sup> Cardiogenic embolism has also been proposed as the underlying pathophysiological mechanism.<sup>8</sup> Hypoxemia, possibly resulting from sleep apnea,<sup>22</sup> as well as abnormalities in blood viscosity in dehydrated patients,<sup>23</sup> have been proposed as other potential mechanisms.

Animal model studies are relevant to the discussion of cause in patients with heart failure. These studies suggest that oxygen deprivation is implicated in autoneurotoxicity or neuronal cell death. Areas of the brain that are particularly susceptible to oxygen deprivation are the hippocampus, amygdala, frontal lobes, and cerebellum.<sup>24,25</sup>

Although the current understanding of structural and functional changes in humans is limited, ongoing research efforts may be promising.<sup>7</sup> Evaluation techniques in humans include use of expensive measurement tools such as magnetic resonance imaging (MRI), positron emission tomography (PET), computed tomography (CT), single photon emission computed tomography (SPECT), transcranial Doppler imaging, transcranial ultrasonography, near-infrared spectroscopy, and jugular venous blood and cerebral scanning. These studies, unfortunately, are limited by sample size, because of associated costs and respondent burden. In addition, comparison groups are frequently not included, and changes over time are not measured. A notable exception is the study conducted by Woo and colleagues.<sup>26</sup> Nine patients with heart failure were compared with 27 age-matched healthy participants. MRI results revealed that patients with NYHA classes III and IV heart failure had significant loss of gray matter in the insular cortex, frontal cortex, parahippocampal gyrus, cingulate, cerebellar cortex, and deep cerebral nuclei, in comparison with age-matched healthy individuals. These brain regions are crucial for cognitive functioning and cardiovascular regulation. Woo and colleagues concluded that ischemia and hypotensive episodes are likely to cause perfusion deficits that contribute to the observed loss of gray matter.

In a well-designed study, Vogels and associates<sup>8</sup> found a significant relationship between cognitive impairment and medial temporal lobe atrophy. Memory and executive functions were the two most commonly affected domains. The findings are evidence of a hemodynamically mediated pathophysiological mechanism, in view of the vulnerability of the medial temporal lobe to inadequate oxygenation that results from hypoperfusion.<sup>25,27</sup>

In a small comparison group study, Alves and coworkers,<sup>28</sup> using SPECT, found that individuals with heart failure have significant reductions in cerebral blood flow. Differences between the patients and the comparison group of elderly individuals were demonstrated in structural areas such as segments of the precuneus and cuneus, the right lateral temporoparietal cortex, and the posterior cingulate gyrus. Reduction in cerebral blood flow was correlated with cognitive impairment, as assessed by the Cambridge Mental Disorders of the Elderly Examination. These results must be viewed with caution because of the small sample size. Similarly, Schmidt and colleagues,<sup>29</sup> on the basis of MRI results, found higher rates of cerebral infarcts and cortical atrophy, as well as lower scores on neuropsychological testing, in patients with idiopathic dilated cardiomyopathy in comparison with age-matched healthy controls.

A consistent pattern supports the association of the localization of gray matter loss with cognitive impairment. Structural and functional brain changes are associated with reductions in cerebral blood flow and with silent brain infarctions. These changes are associated with difficulties in perceiving heart failure-related symptoms (insular cortex and cingulate cortex, areas that receive and process viscerosensory input), in addition to difficulties with memory, attention, and concentration.

Further research is needed to isolate the mechanisms directly responsible for the observed changes in functioning. It remains unclear what the short- and long-term implications of these findings are in terms of cognitive functioning. As Pressler<sup>7</sup> noted, because of the expense associated with imaging measurements, in addition to the burden it places on the patient and family, it is likely that future studies will continue to be small in scope and that the generalizability of findings will therefore be limited.

## CONTRIBUTING FACTORS AND COVARIATES

In attempting to systematically understand the causes of cognitive impairment in patients with heart failure, it is important to consider contributing factors and covariates of heart failure. As discussed previously, circulatory insufficiency has been identified as key, as have silent brain infarctions; both are likely to affect attention, working memory, other memory, learning, executive functioning, and psychomotor speed.<sup>6,21,30</sup>

Cognitive impairment in patients with heart failure is significantly associated with age, activities of daily living, and overall reduced independence, as well as NYHA classification.<sup>31</sup> Reductions in left ventricular ejection fraction (LVEF) are also associated with cognitive impairment.<sup>29</sup> A relationship between cognitive impairment and the presence of the apolipoprotein E-ε4 (ApoE-ε4) allele, an established risk factor, has been observed in individuals with heart failure.<sup>8</sup> Studies have shown that gene-environment interactions between ApoE genotype and cardiovascular risk factors may accelerate cognitive decline in the elderly.<sup>32</sup>

With regard to age, research findings are limited by studies that do not represent the full range of possibilities. In general, older individuals (older than 70 years) tend to have a higher incidence of cognitive deficits than do younger individuals.<sup>30</sup> Cognitive deficits are associated with age, which probably interacts with the severity of heart failure, inasmuch as occurrence of cognitive impairment is associated with severity of NYHA classification. Elderly individuals are more likely than younger persons to have fluid shifts and dehydration, which are also associated with cognitive impairment.<sup>18</sup> However, studies with age-matched control participants have not revealed a significant relationship between age and cognitive impairment in patients with heart failure.<sup>6</sup> Bennett and colleagues<sup>21</sup> concluded that further investigation is needed to “identify profiles of patients most likely to experience cognitive deficits” (p. 225).

Coexisting major medical conditions contribute to cognitive impairment in patients with heart failure and can confound findings linking heart failure with cognitive impairment. For example, compelling data have emerged from studies of patients with chronic obstructive pulmonary disease (COPD). When severe, COPD has been found to cause cerebral hypoxia. In studies in which patients have diagnoses of both heart failure and COPD (approximately 12%), results indicate that they are more likely to be cognitively impaired, frequently requiring home care.<sup>6,22</sup>

Individuals with neurological conditions such as stroke and those with a history of alcohol and substance abuse are also likely to evince cognitive impairment. In the case of

stroke, individuals who are elderly, women, and those with more compromised LVEF are at increased risk for cognitive impairment. Risk for stroke increases linearly: an 18% increase for each 5% decline in LVEF.<sup>33</sup>

Studies have consistently demonstrated an association between cognitive impairment and hypertension.<sup>7,30</sup> However, the researchers have not controlled for the presence of cardiovascular disorders such as heart failure. Of importance is that treatment of hypertension is effective in reducing new-onset heart failure by 50%.<sup>7,34</sup> Jennings<sup>33</sup> proposed a vascular mechanism, suggesting that hypertension causes changes in autoregulation of cerebral blood flow, but at higher pressures than in normotensive individuals. The decrease in cerebral blood flow probably accounts for significantly lower scores in working memory, according to Jennings.

Cognitive deficits have also been reported in patients with diabetes, breast cancer, lupus, and fibromyalgia; these findings provide a broader perspective with regard to linkage between cognitive impairment and coexisting medical conditions. Because of the likely conflation, researchers in future studies of patients with heart failure must control for or rule out comorbid medical conditions in order to better understand the unique contributions of heart failure to cognitive impairment.

## Sleep-Disordered Breathing and Heart Failure (see Chapter 32)

Daytime sleepiness interferes with decision making, particularly as it relates to self-care. Sleep interruptions and sleep deprivation are relatively common in patients with heart failure and are associated with increasing age, comorbid illnesses, excess body weight, lack of exercise, excessive alcohol consumption, and chronic insomnia.<sup>36</sup> Killgore and associates<sup>37</sup> demonstrated that attention and concentration, working memory, and executive functioning are compromised when individuals are deprived of sleep. This finding has important implications for decision making and self-care in patients with heart failure. The results suggest the importance of screening for sleep-disordered breathing in patients with heart failure, particularly in patients who evince cognitive impairment. The effect of treatment for sleep-disordered breathing and depression and its influence on self-care must be further understood because it has significant implications for self-care. The next section focuses specifically on the comorbid condition of depression and its relationship to cognitive impairment in patients with heart failure.

## Depression and Heart Failure

One of the most common of all mental conditions is depression, which includes both subjective symptoms, such as feeling hopeless and worthless, and objective symptoms, such as decreased appetite and difficulty with attention. Clinical depression impairs daily functioning. Patients who report a decrease of interest and depressed mood for at least 2 weeks meet the criteria for the diagnosis of clinical depression.<sup>13</sup>

Sullivan and colleagues<sup>38</sup> estimated that depression and psychological impairment may be responsible for nearly 25% of the \$20 billion associated with treating heart failure.

Determining the incidence of depression in patients with heart failure is difficult because of variations in methods. Rates are not consistent between patients in nursing homes and those living independently. In addition, investigators have used various methods of diagnosis and instruments to measure the severity of depression.<sup>13</sup>

Studies have shown that the severity of depression is significantly related to increases in mortality among patients with heart failure. In comparison with patients with heart failure who were not depressed, those classified as severely depressed had four times the mortality rates during a 2-year

poststudy follow-up period. Although most studies have demonstrated a significant association between depression and heart failure, the incidence of depression in patients with heart failure varies considerably; reported rates range from 14% to 36%.<sup>39,40</sup> Studies show that even after depression has been successfully treated and symptoms ameliorated, it is not unusual for depression to recur. The study by Segal and associates,<sup>41</sup> although not specific to patients with heart failure, revealed that more than 80% of the patients treated for depression were at risk for multiple episodes of depression.

The nature of the relationship between depression and heart failure has been obscured by selection bias in research studies. It appears that patients with heart failure who participate in these studies are healthier, with fewer physical complaints, than patients with heart failure who decline to participate. In addition, some symptoms such as fatigue and insomnia may be associated with heart failure and therefore are not reported as depressive symptoms. Thus, the number of patients with heart failure who are depressed may be underestimated in these studies.

The mechanism by which depression contributes to poorer outcomes for patients with heart failure is unclear. The debate about whether depression is a risk factor for heart failure, whether heart failure may spur depression, or whether the two interact in some way continues in the research literature. There is agreement that because of the behavioral and physiological components of depression, patients with heart failure who are depressed are at greater risk of mortality and morbidity. Depression is associated with poorer compliance with medical regimens, which has significant consequences for patients with heart failure. Patients who have both heart failure and depression have been shown to have high sympathetic tone, hypercortisolism, increased platelet aggregability, and elevated levels of inflammatory markers.<sup>13</sup>

Because assessment of depression is crucial in treatment, accurate evaluation is key. Foreman and colleagues<sup>42</sup> provided a useful comparison of the clinical features of delirium, dementia, and depression. They identified important differences in clinical features such as onset, course, sleep-wake cycle, and memory. For example, in depressed patients, affect is depressed and mood is dysphoric with themes of hopelessness, helplessness, or self-deprecation, whereas in patients with dementia, affect tends to be inappropriate and labile, with impoverished thoughts, word-finding difficulties, and possible aphasia and agnosia. It is also important to assess and differentiate somatic depressive symptoms of heart failure and symptoms associated with depression. Assessment tools such as the Beck Depression Scale allow for systematic assessment and analysis of results that include both somatic depressive symptoms of fatigue and insomnia, symptoms associated with heart failure, and symptoms associated with depression.

Depression is associated with increased rates of mortality among patients with heart failure and appears to be linearly related to severity of depression. Comorbid psychiatric conditions, such as anxiety disorders, are strongly associated with depression. The literature focuses on medical treatment of depression in patients with heart failure, which is described as safe and effective for depression in patients with cardiovascular disease.<sup>43</sup> Alternative or complementary adjunct therapies such as cognitive behavioral therapy must be considered as well.<sup>13</sup>

## COGNITIVE FUNCTIONS RELATED TO SELF-CARE IN PATIENTS WITH HEART FAILURE

According to Dickson and associates,<sup>2</sup> “Cognitive function refers to the information-processing abilities of attention, learning and memory, executive functioning (e.g., cognitive flexibility and abstract reasoning), visual-spatial and visual-construction

skills, psychomotor abilities, perceptual skills and language—functions critical to self-care” (p. 426). For the individual with heart failure, self-care includes monitoring symptoms, taking prescribed medications, following dietary restrictions, exercising, keeping appointments, and maintaining instrumental activities of daily living. In the following section, self-care tasks are described, and the cognitive functions associated with their performance are discussed. Tests related to each cognitive function are identified, and assistive technology that may compensate for mild impairment is described.

## Medication Regimen

According to Insel and colleagues,<sup>44</sup> adherence to medication regimens may be more of a function of capacity than of attitude. Planning to take medications requires the abilities to create a plan (which involves executive functioning and abstract reasoning), to implement the plan (which involves attention and short-term memory), to remember to take the medication at the correct times (which involves long-term memory and both visual-spatial and visual-construction skills in perception of a clock face), to take medications in the prescribed manner (which involves executive functioning and long-term memory), and remembering whether the medication was taken as desired (which involves working memory).

Impairment in memory and concentration is frequently reported by patients with heart failure.<sup>21</sup> According to Miller and associates,<sup>45</sup> *working memory* is the type of memory that is necessary to plan and carry out behavior. The common experience of walking into a room only to forget the reason for going into that room is frustrating if not embarrassing. For a patient with heart failure, an interruption while taking medication may cause the patient to forget whether the medication was actually taken. This, in turn, could lead to either missing a dose or taking the medication twice. If a patient is interrupted while taking medication, working memory allows him or her to return to the task after dealing with the interruption.

Working memory is not considered completely different from short-term memory; it is considered to be a combination of short-term memory and other functions such as attention and information processing.<sup>46</sup> Because working memory is closely related to intelligence, measures of working memory may be biased in terms of education and social class. Working memory can be assessed by the Digit Span portion of the Wechsler Adult Intelligence Scale, in which the patient is asked to repeat numerical sequences forward and then backward.<sup>26</sup> Assistive technology options to assist patients with heart failure to take their medications as prescribed have expanded. For example, a *medication reminder watch* can be programmed with up to 12 medication reminders, including text messages with the name and strength of the medication or other prompts. Alarm options include sound alarm, text alarm, vibration, and a combination of these. Most models of cell phones also have reminder tools that could be used to remind a patient of medication regimen.

For patients who have trouble identifying their medication, *automatic pill dispensers* are useful because they have alarms and dispense a set of pills into a medication well. The most advanced option is a *monitored pill dispenser* that not only can dispense a month's worth of medications at various intervals (up to six times per day) but also can be programmed to call a caregiver if medications are not taken on time. Individual medication administrations can be programmed with text or voice reminders.

## Low-Sodium Diets

Patients with heart failure are routinely advised to make changes in their diets, especially with regard to the sodium content of their food. Impairments in executive functioning

could be a reason why most patients with heart failure do not closely follow dietary guidelines.<sup>2</sup>

Planning, abstract thinking, and judgment are all components of executive functions of the brain.<sup>26,47</sup> According to Cullen and colleagues, cognitive impairment relating to vascular conditions is also characterized by impairment in verbal fluency.<sup>48</sup> Impairments in verbal fluency, including basic reading skills, can hamper the patient's selection process as well as his or her ability to follow instructions in meal preparation.

Common measures of these executive functioning include trail-making tests, similar to a connect-the-dots task, in which patients are asked to connect numbers in sequence (either 1→2→3 ... or a more complex form such as 1→A→2→B→3→C ...). Tests of verbal fluency include naming objects, such as animals, or asking a person to say as many words beginning with a certain letter as he or she can in 1 minute.

Text readers that read aloud an entire page of text, as well as reading pens that read text word by word, are available to patients with heart failure to assist with reading fluency. Because of their portability, reading pens are ideal for taking to the grocery store and identifying the sodium content in food by scanning the label. Many of the adaptations used for individuals with poor vision can empower patients with heart failure in adhering to a low-sodium diet; these adaptations include picture-based grocery lists and color-coded cookbooks, which reduce the need for reading and verbal fluency.

## Symptom Monitoring

According to Dickson and associates,<sup>2</sup> monitoring symptoms involves complex cognitive skills. For example, patients with heart failure must remember to check daily for specific symptoms such as ankle swelling. Learning involves both attention and long-term memory; patients must learn that ankle swelling may indicate that they are experiencing fluid retention. In addition, they need to associate fluid retention with some immediate action, such as notifying the appropriate health care provider or taking an additional diuretic. If memory, judgment, and planning are impaired, fluid retention may go untreated.<sup>2</sup> Although many cognitive screening tools have a delayed-recall component, only the informant-based cognitive screens address impairment of long-term memory or learning abilities. Learning new routines can be difficult for many older adults; personal data assistants (PDAs) can provide verbal cues and reminders. For individuals with cognitive impairments, assistive technology providers have developed specific programs that can be adapted for use related to heart failure; they can keep a record for the health care provider regarding how well the individual is adhering to his or her treatment plan. One such programming option would be for the individual to record water percentage into their PDA. If the percentage reaches a target level, the PDA would cue the patient with heart failure to take appropriate action such as calling the health care provider or adjusting medication as prescribed.

Electronic scales can assist patients who have heart failure with water retention (in 0.1% increments) and those with weight gain. Simple body analyzer scales display the readings in large digital numbers. More advanced options allow for tracking up to 10 readings, programming alerts to targets, and even printouts of readings that could be reviewed by a caregiver or health care provider.

## Weight Management and Regular Exercise

Attention can be considered a foundational cognitive skill inasmuch as it is necessary for performing other cognitive functions such as calculations and planning. Attention skills have been found to be compromised in a significant subset of

patients with heart failure.<sup>49</sup> One of the challenges in detecting impairment of attention in patients with heart failure is that the ability may fluctuate depending on task or time of day.<sup>42,47</sup> Patients with attention deficits may be easily distracted.<sup>47</sup> Fluctuations in attention and overall declines in memory and executive functions may be attenuated through exercise.<sup>50</sup> The ability to complete serial 7s (counting backward from 100 by 7s), is a test commonly used to assess impairments in attention.

Developing new activities for weight loss and increasing overall fitness are general goals for patients with heart failure. Motorized bikes allow for the individual to move his or her legs in a passive exercise in which the motor can gradually lessen the assistance with the movement. Ideal for patients with heart failure who have been previously inactive, the miniature versions of these machines are small enough to fit under a desk.

Heart rate monitors are also beneficial. Originally designed for athletes who sought an alternative to chest or belt monitors, these comfortable semi-glove-shaped monitors entail the use of the base of the finger for sensing, which makes it easy for patients with heart failure to use while exercising. Because no transmitter is used with these heart rate monitors, there are no interference problems.

The interpretation of paradoxical findings regarding weight and patients with heart failure is challenging for the provider; thus, when appropriate, patients with heart failure can join the growing weight loss community on the Internet. Websites offering recipes, advice, and counseling are readily and inexpensively available. For tracking caloric consumption, assistive technology devices such as "Countdown to Slim" provide a digital monitor for tracking diet, including goals for calories, sodium, and other targets.

Significant cognitive impairments may limit the ability of patients with heart failure to maintain their independence; however, if a mild impairment is detected, assistive technology options may allow for independence to continue without compromising the patient's health. Professionals such as occupational therapists and rehabilitation counselors may be able to identify creative solutions by which patients with heart failure can accommodate mild cognitive impairments.

## ASSESSMENT OF COGNITIVE IMPAIRMENT

Cognitive impairment in patients with heart failure has implications for treatment. Some decline in cognitive functions may be age related. An estimated 17% of the elderly population (aged 65 and older) are struggling with mild to moderate cognitive impairment.<sup>51</sup> The detection and evaluation of cognitive functioning are significant for both HRQL and the medical management of individuals with heart failure.

## Cognitive Impairment Screening Tools

The development of instruments to screen for cognitive impairment are designed to detect deviation from normal cognitive functioning rather than to identify impairments in specific cognitive functions.<sup>6,48</sup> To date, no cognitive screening tools have been developed specifically for use with patients with heart failure.

This section of the chapter covers brief screening tests, cognitive impairment batteries, and informant report scales. Table 60-1 provides an overview of the screening measures and the cognitive domains assessed.

Individuals with mild cognitive impairments rarely report symptoms and may engage in denial, even when the impairments are apparent to family members and health care providers.<sup>52</sup> Documentation of cognitive impairment has been neglected, and reliance on medical records for information

**TABLE 60–1 Cognitive Impairment Screening Instruments and Cognitive Function Domains**

Features	AMT	MoCA	MMSE	CDT	Mini-Cog	GPCOG

AMT, Abbreviated Mental Test; CDT, Clock Drawing Test; GPCOG, General Practitioner Assessment of Cognition; MMSE, Mini Mental State Examination; MoCA, Montreal Cognitive Assessment.

about cognitive impairment has been shown to be inadequate.<sup>53</sup> Whereas severe impairment may be detected during routine care appointments, research has shown that medical personnel are poor at predicting moderate to mild impairment. Because of the relationship between cognition and mortality, it is important that an accurate screening assessment be made by appropriate medical personnel.<sup>21</sup>

When clinicians select a screening test, they should consider the types of cognitive impairments that are detected by the measure, as well as the sensitivity of the screening tool in detecting less severe impairment. Cultural and educational considerations should also be taken into account.

#### Mini Mental State Examination

The most commonly used screening tool in both practice and research is the Mini Mental State Examination (MMSE).<sup>18,47,48</sup> This tool has been used since the 1980s and translated into several languages.<sup>54</sup> The MMSE was originally developed to screen for cognitive disorders rather than cognitive impairment. Criticisms of this instrument include (1) both “ceiling” and “floor” effects<sup>47</sup>; (2) lack of rationale for cutoff scores<sup>54</sup>; (3) poor sensitivity to executive function<sup>44</sup>; and (4) education and socioeconomic biases.<sup>55,56</sup> The MMSE is easy to administer and interpret and test administration is estimated to take between 5 and 10 minutes.<sup>54</sup>

#### Abbreviated Mental Test

According to Woodford and George, the Abbreviated Mental Test (AMT) was derived from the MMSE; the 10 most discriminating items were kept in the instrument.<sup>47</sup> The AMT screens for impairment in long- and short-term memory, attention, and orientation. It is not considered sensitive enough to detect milder forms of cognitive impairment, but it is sensitive in detecting delirium and dementia in elderly patients.<sup>47</sup>

#### Montreal Cognitive Assessment

The more recently developed Montreal Cognitive Assessment (MoCA) is touted as a brief screening tool (10 minutes to administer) for detecting mild cognitive impairments in eight cognitive domains: “attention and concentration, executive functions, memory, language, visuoconstructional skills, conceptual thinking, calculations, and orientation.”<sup>57</sup> The

instrument, a one-page, 30-point test, has been translated into 17 languages, and studies have established its validity in several countries, including China, Korea, and the Czech Republic.

#### Clock Drawing Test and the Mini-Cog

The Clock Drawing Test (CDT) is a nonverbal screening tool in which the patient is asked to draw a clock. Placement of the numbers around the circle requires visual-spatial, numerical sequencing, and planning abilities.<sup>47</sup> The patient is then asked to draw the hands on the clock to indicate “ten minutes past 11 o’clock.” The test also assesses long-term attention, memory, auditory processing, motor programming, and frustration tolerance.<sup>18,58</sup> There are multiple approaches to scoring the CDT.<sup>58</sup> Advantages of this test include an absence of language and cultural biases. Riegel and colleagues<sup>18</sup> concluded that the CDT was better than the MMSE at detecting cognitive impairment in patients with heart failure. This may be because of the instability and subtle nature of cognitive impairment in patients with heart failure, in contrast to patients with dementia.

The Mini-Cog, in which a three-word recall test is added to the CDT, has the advantage of also assessing memory. It was developed to improve the relatively culture-free CDT by assessing the patient’s recall (memory) and thereby covering the domains of the MMSE.<sup>55</sup> If the patient is unable to recall all three words in the Mini-Cog, he or she is considered to have a cognitive impairment.

#### Cognitive Abilities Screening Instrument

The Cognitive Abilities Screening Instrument (CASI) is a mini-battery that has been validated in cross-ethnic studies.<sup>55</sup> It contains questions from both the MMSE and the Modified Mini Mental Status Examination (3MS).<sup>47</sup> The marginal increase in sensitivity is not considered to be sufficient because additional time (20 minutes) is needed to administer the test.

#### Cambridge Cognitive Examination

The Cambridge Mental Disorders of the Elderly Examination (CAMDEX) is a battery that includes history taking from both the patient and an informant, a structured examination, and

a mental state assessment (known as *CAMCOG*). The *CAMCOG* tests orientation, language, attention, memory, praxis, calculation, abstract thinking, and perception.<sup>49</sup> Diagnostic criteria from the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV)<sup>59</sup> and the *International Statistical Classification of Diseases and Related Health Problems* (ICD-9)<sup>60</sup> are included in the *CAMDEX* scoring manual; this allows the clinician not only to detect areas of cognitive impairment but also to diagnose specific conditions associated with the impairments detected.

### General Practitioner Assessment of Cognition

Developed in Australia, the General Practitioner Assessment of Cognition (GPCOG) measure combines questions for both patient and informant to detect cognitive impairments among elderly patients.<sup>58,61</sup> The 15 questions cover a variety of tasks used in other screening tools, such as clock drawing and memory recall. In addition, the questions for informants cover items such as misplacing objects and ability to manage money and medication. The test takes approximately 4 to 5 minutes to administer. In comparisons of the GPCOG with the MMSE, the two were considered equally sensitive for screening for dementia, but the GPCOG took less than half the amount of time.<sup>58,61</sup> In a validation study of almost 400 subjects, Brodaty and colleagues<sup>61</sup> deemed the GPCOG to have “sound psychometric properties” (p. 531), and in comparison with both the AMT and the MMSE, it is more sensitive in detecting mild impairments.

## Recommendations for Assessment of Cognitive Impairment in Patients with Heart Failure

The development of cognitive impairment in patients with heart failure may not be readily apparent. Assessment and screening tools, such as those described in the previous section, can detect the presence of, that impairment. In reviewing the screening tools available, clinicians must keep in mind the cognitive impairment features that are relevant to the medical management of these patients. Although comorbid dementias may exist, they are beyond the scope of this chapter.

Administration and interpretation of psychoneurological assessment batteries are time and labor intensive, and specialized training is required. Therefore, global measures are frequently used, but they do not generate the information needed for the purpose of identifying the extent and types of cognitive impairments, including the detection of more subtle yet significant deficits in patients with heart failure. The data generated by these global measures cannot be linked to cause for a broadly representative group of patients with heart failure. It also remains unclear whether the association of heart failure and cognitive impairment is related to poor cardiac output or is a function of multiple coexisting conditions.<sup>16,62,63</sup>

What is clear is the need to screen for the presence of cognitive impairment so that it can be proactively addressed in the medical management of the patient with heart failure. Although the MMSE has been the tool most frequently used in research, the MoCA appears to be an effective quick screen that does not have the biases and score limitations of the MMSE.

## INTERVENTION PROGRAMS FOR PATIENTS WITH HEART FAILURE AND COGNITIVE IMPAIRMENT

The needs of a significant but silent minority—patients with heart failure who are cognitively impaired—are insufficiently addressed in the literature on heart failure intervention; such neglect is perplexing, in view of prevalence data. In many

management programs specifically for heart failure, cognitive functioning is presumed to be intact in its participants. Patients with mild to moderate cognitive impairment do not appear to obtain the benefits of prolonged event-free survival or overall survival in such programs, in comparison with cognitively intact patients. This finding suggests that existing approaches to heart failure–specific management must be reevaluated and modified.<sup>33</sup> McLennan and associates<sup>28</sup> concluded that a likely explanation for the relationship between cognitive impairment and clinical outcome in patients with heart failure is the “cyclical” interaction of “physiological, cognitive and behavioural factors” (p. 499). However, an alternative explanation must be considered: that cognitive impairment is a marker of disease progression or concurrent cerebrovascular disease.

Depending on the degree of cognitive impairment, patients may profit from the development of an action plan, conceived in partnership with medical personnel, that is individually tailored to their functional level. The plan should reflect the patient’s existing strengths and resources, as well as those of his or her support network. As mentioned in the previous section, whenever possible, compensatory mechanisms and supplementary programs such as Internet-based instruction and interactional dialogue (e.g., support groups) can be introduced to address specific obstacles and reinforce needed skills.

Family members and additional support networks can also be harnessed judiciously as resources. Participation of family members seems to be key in effective management programs for heart failure; however, little is known about how to best engage family members in ways that do not diminish the autonomy and self-efficacy of patients with heart failure, with and without cognitive impairment. Family engagement on an as-needed basis, as well as the support of a social network, is a key factor in differentiating individuals with heart failure who are considered “expert” in heart failure self-care from those who are not.<sup>63</sup> Further research is needed to explore this potentially rich area of investigation.

The range of options available to patients and their support networks increases significantly with Internet-enhanced instruction.<sup>64,65</sup> It is a promising tool that may serve as an important supplement to self-care management programs for individuals with cognitive impairment. Although the elderly are least likely to access the Internet, the numbers of those who do are increasing significantly.<sup>4</sup> Strömberg and colleagues<sup>66</sup> observed that elderly patients with lower educational levels, with the aid of Internet-based instruction, are able to assimilate required information under nonpressured conditions. Rosamond and Paul<sup>4</sup> noted that “Books, newsletters, videos, CDs [compact disks], Web pages, and computer-based programs augment the learning process and offer further opportunities for education at patients’ convenience” (p. e70). Internet-enhanced instruction (e.g., the Patient Management Tool, at <http://www.americanheart.org/presenter.jhtml?identifier=651>) facilitates the repetition and reinforcement of heart failure–related skills. Follow-up telephone calls, newsletters, educational bulletins, and support groups may also serve as additional resources.<sup>4</sup> Role-playing exercises may assist patients with heart failure as well.

Exercise is an additional resource that has not been adequately tapped and investigated (see also Chapter 57). Tanne and colleagues<sup>67</sup> implemented an exercise program with 18 patients with stable heart failure (NYHA class III) and compared the results with those of a group of 5 patients who received no exercise program. Patients met twice a week for 18 weeks in a standard cardiac rehabilitation program that included a 15-minute warm-up, a 35-minute program on the treadmill, and a regimen of stair climbing and bicycling. Results indicated improvement in some cognitive domains

but not in others; measures of general attention and psychomotor speed (Trail Making Test and Stroop Test parts A and C) showed improvement. Although the reported gains were statistically significant, it is not clear whether they were clinically significant. Improvements in general attention and psychomotor speed were not associated with improved vasodilator reserve. The mechanisms by which these improvements occurred are not known, and the improvements may be attributable solely to increased alertness. Because of the number of tests given and the small number of subjects who participated in the intervention, the results are vulnerable to type I and type II errors. Furthermore, the 18-week treatment program may be too short in duration to make significant impact.

Yoga is another potential resource for patients with heart failure. Pullen and colleagues<sup>68</sup> found that an 8-week regimen of yoga for patients with heart failure improved exercise tolerance, improved estimated peak ventilatory oxygen uptake ( $\text{VO}_2$ ), and reduced levels of inflammatory markers. The mechanisms by which improvement occurred are unclear. Although these results are promising, caution is needed, in view of the small number of participants in the study.

Verhaegen and colleagues<sup>69</sup> conducted a meta-analysis of memory training effectiveness in healthy patients aged 60 years and older.<sup>57</sup> Results indicated that memory does remain amenable to improvement in old age. Individuals are most likely to benefit from mnemonic training (memory aids, such as short rhymes). Memory sessions are least effective when they are longer in duration (sessions ranged from 20 minutes to 2.5 hours); this finding was attributed to fatigue. Questions remain as to whether these results can be generalized to a population with heart failure and cognitive impairment. In addition, it would be helpful to understand why some patients with heart failure and cognitive impairment may be able to benefit but others gain little or no benefit from such programs.

## FUTURE DIRECTIONS

It is difficult to determine the extent to which clinicians can intervene effectively for patients with heart failure who are cognitively impaired. It remains unclear whether cognitive impairment can be alleviated or reversed in patients with heart failure; the data are simply not currently available. The relative silence and possible denial surrounding cognitive impairment in patients with heart failure must be systematically combated, and more recent efforts are promising.

In order to understand the pathophysiology and natural course of cognitive deficits over time in patients with heart failure, a conceptual framework is needed to systematically guide professionals in the field to make informed assessments. The consistent use of relevant and sensitive neuropsychological tools is currently problematic. Informed assessments, based on reliable and valid data, can guide professionals in determining whether and under what conditions cognitive deficits are amenable to targeted interventions. The implications are significant, particularly with regard to prevention or delay of impairment in patients with heart failure. In addition to understanding the progression of mental changes, further research is needed to understand the implications of these changes for prognosis and intervention.

**Conclusions, 883**

Despite optimal medical therapy targeted against neurohormonal aberrations responsible for cardiac remodeling, heart failure can transition into a chronic and progressive stage that leads to severe functional limitation. The left ventricle once again dilates, which leads to worsening backward flow as a result of mitral regurgitation, and causes a further increase in ventricular wall stress; these events set up a vicious cycle of additional depression of cardiac function and worsening right-sided heart failure. These central cardiac alterations, in turn, cause numerous end-organ defects that are manifested in pulmonary hypertension, renal dysfunction, hepatobiliary defects, and, eventually, neurocognitive decline. This is the genesis of the advanced syndrome of late-stage heart failure.

## DEFINING LATE-STAGE HEART FAILURE

Late-stage, or advanced, heart failure is associated with a miserable quality of life and ongoing high risk for clinical events. Affected individuals exhibit unrelenting, severe symptoms of fatigue and dyspnea on minimal activity, coupled with end-organ hypoperfusion. Many such patients experience repeated episodes of heart failure decompensation, followed by a brief period of symptom improvement, and eventually they die of heart failure–related causes. The American College of Cardiology/American Heart Association heart failure practice guidelines<sup>1</sup> detailed a staging system (A through D) to describe the progression of heart failure. Stage D of that classification describes the condition of significant symptoms at rest despite best medical therapy. Most affected patients have endured repeated hospitalizations, and their condition is refractory to current therapeutic interventions involving elaborate treatment strategies such as mechanical circulatory support, fluid removal by sophisticated means, continuous positive inotropic infusions, cardiac transplantation or other nontraditional surgical procedures, or supportive care.

The European Society of Cardiology provided a more comprehensive clinical definition of late-stage heart failure.<sup>2</sup> Patients with advanced heart failure are again described as having severe symptoms (New York Heart Association [NYHA] classes III to IV) along with clinical signs of fluid retention, with or without evidence of peripheral hypoperfusion, plus a history of more than one heart failure–related hospitalization in the previous 6 months. To fit this definition, however, patients must have echocardiographic evidence of cardiac dysfunction, demonstrated by left ventricular ejection fraction lower than 30% or pseudonormal or restrictive mitral inflow pattern on Doppler echocardiography. Elevated left-sided ventricular filling pressures, alone or in concert with excessive right-sided pressures, and increased levels of B-type natriuretic peptide also characterize these patients. Exercise testing is performed at the authors' institution, and severely impaired functional capacity is defined as a

6-minute walk test distance of less than 300 m or a peak oxygen uptake of less than 12 to 14 mL/kg/min. All these features must exist despite optimal therapy in order to meet the criteria for advanced heart failure.

## THE ROLE OF CHRONIC PARENTERAL THERAPY

Patients with late-stage heart failure who have evidence of end-organ perfusion are characterized by a chronic reduction in cardiac contractility with concomitant lusitropic dysfunction. Cardiac dysfunction and systemic perfusion pressure can be evaluated clinically simply by observing blood pressure. Specifically, in patients with acute decompensated heart failure, a low systolic blood pressure at admission coupled with abnormal levels of renal biomarkers has been shown to be a powerful predictor of a reduced cardiac output and adverse outcomes.<sup>3</sup> Clinicians can reliably predict diminished cardiac output by calculating the proportional pulse pressure—(systolic blood pressure – diastolic blood pressure)/systolic blood pressure—which, if detected to be less than 25%, is correlated strongly with cardiac index lower than 2.2 L/minute/m<sup>2</sup>.<sup>4</sup> Other clinical signs that signify poor perfusion include coolness of extremities, the presence of pulsus alternans, easy fatigability, altered mentation, and worsening renal dysfunction with attempted ongoing incremental diuresis.

In such advanced cases of late-stage heart failure, the goal of therapy is to restore end-organ perfusion and relieve symptoms without incurring adverse cardiac effects. Because this unique condition is typically refractory to oral pharmacological support, a series of incremental therapeutic interventions are usually employed. Immediately available are parenteral supportive agents such as inotropic, vasodilator, and diuretic drug infusions. The goal of therapy may differ according to the patient's circumstance at that time. For example, if there is a reversible cause for hypoperfusion, parenteral supportive therapy may be used as a bridge to recovery. However, in patients with late-stage heart failure, these agents are more often used as a bridge to advanced

options such as heart transplantation, placement of a ventricular assist device, or other nontraditional surgical procedures. Inotropic drugs have also been prescribed as part of the supportive care plan for patients for whom other advanced options are not suitable.

The decision to initiate chronic parenteral inotropic support is not an easy one. The need to establish hemodynamic stability in the patient must be weighed against the fact that use of oral or short-term intravenous inotropic drug therapy in well structured clinical trials has not demonstrated improved outcomes in heart failure.<sup>5</sup> Thus, the trial evidence in support of chronic parenteral inotropic therapy simply does not exist, and the clinician is left to draw meaningful conclusions from the numerous of usually small, mostly anecdotal and observational experiences reported in the literature.<sup>6</sup> This chapter details the arguments for and against this clinical strategy, and the potential applications and pitfalls of parenteral inotropic and vasodilator therapy in late-stage heart failure are discussed.

## CELLULAR REASONS FOR AND AGAINST CHRONIC PARENTERAL INOTROPIC THERAPY

### Arguments in Support

Lowes and associates<sup>7</sup> noted gene expression of myosin heavy-chain isoforms, with selective downregulation of the proportion of  $\alpha$ -myosin heavy-chain isoforms by 67% to 84%, in failing hearts. In a heterotopic rat transplantation model, Geenen and colleagues<sup>8</sup> demonstrated the exact reverse: an elevation of  $\alpha$ -myosin heavy-chain levels by 70%, which suggests that the myocyte type may switch to a high-velocity, fast-twitch subtype as a result of catecholamine stimulation. In earlier studies, Bristow and coworkers<sup>9</sup> revealed depressed contractile response to  $\beta$ -agonists in the failing heart, accompanied by a decrease in expression and function of cardiac  $\beta$ -receptors. Adamopoulos and associates<sup>10</sup> demonstrated that short-term pulsed inotropic support with dobutamine induces  $\beta$ -adrenergic receptor upregulation and that this action leads to enhanced chronotropic responsiveness to exercise in patients with chronic heart failure. In an evaluation of the ultrastructural effects of inotropic infusions, Unverferth and colleagues<sup>11</sup> were able to show that mitochondria structure and biochemical energetic properties improved more with dobutamine than with bed rest and saline infusion in chronic severe heart failure. Results of another investigation<sup>12</sup> have suggested that peripheral endothelial function might be improved by the administration of pulsed inotropic therapy for 72 hours and that these subclinical effects can be observed for up to 2 weeks after discontinuation of therapy; these findings might explain the sustained effects of inotropic therapy. These data form the scientific support for the investigation of inotropic infusion strategies as a component of comprehensive care of the patient with late-stage heart failure.

### Arguments Against

Chronic exposure to inotropic therapy has led to the generation of cardiac arrhythmias, desensitization of the  $\beta$ -adrenergic receptor complex in the heart, and worsening of cardiac function over time by creating a state of cellular energy starvation. The generation of cyclic adenosine monophosphate (cAMP), which is essential for the hemodynamic effectiveness of inotropic therapy, is hypothesized to enhance arrhythmogenicity and result in direct cardiotoxic effects.<sup>13</sup> The appearance of delayed afterdepolarizations is related to the increased

release of calcium from intracellular stores. Increased intracellular cAMP also might enhance automaticity and triggered responses.<sup>14</sup> Moreover, downregulation of  $\beta$ -adrenergic receptors and desensitization of the  $\beta$ -adrenergic pathway, coupled with the energy-exacting effects of inotropic intervention, are believed to perpetuate an inexorable cycle of decline in an energy-starved situation.<sup>15</sup>

Alterations in mechanoenergetics in severe ventricular dysfunction result from increased oxygen cost of excitation-contraction coupling, rather than from reduction in the efficiency of chemomechanical energy transduction.<sup>16</sup> Other data from studies of inodilator therapy suggest a somewhat heterogeneous response with reference to myocardial oxygen consumption, which may decrease, increase, or remain unchanged.<sup>17</sup> This response is a manifestation of the relative magnitude of energy expenditure. Thus, long-term exposure to inotropic drugs may exhaust energy reserve and worsen the state of energy starvation, as assessed by a disproportionate increase in myofibrillar size in comparison with energy-regenerating mitochondria.<sup>18</sup>

## CLINICAL EVIDENCE FOR AND AGAINST CHRONIC PARENTERAL INOTROPIC THERAPY

In appropriately selected patients, parenteral inotropic support in the outpatient or home setting might alleviate this daunting combination of profoundly diminished functional capacity, cyclical visits to the hospital, and enormous accompanying cost burden. The proposed strategies have ranged from pulsed inotropic or vasodilator therapy, administered in an intermittent manner at infusion centers, to chronic continuous infusions in the home setting.

### Arguments in Support

A number of observational studies have addressed the issue of morbidity reduction with parenteral inotropic support (Table 61-1). In the earliest (but uncontrolled) investigation, Leier and coworkers<sup>19</sup> treated 25 patients with severe heart failure with 10 to 15  $\mu\text{g}/\text{kg}$  per minute of intravenous dobutamine for 72 hours. Cardiac function improved significantly and remained better even after dobutamine had been cleared from the circulation, and 68% of these patients maintained their improvement in functional NYHA class for at least 1 week after cessation of therapy. Liang and associates<sup>20</sup> further explored these findings in a randomized, blinded, placebo-controlled trial of 72-hour infusions of dobutamine in 15 patients with stable dilated cardiomyopathy. The initial dobutamine dosage of 5  $\mu\text{g}/\text{kg}$  per minute was increased at 20-minute intervals to achieve a doubling in cardiac output. At the 4-week follow-up visit, functional NYHA class, treadmill exercise time, and left ventricular performance were improved significantly in the patients treated with dobutamine, but those parameters remained unchanged in the patients treated with placebo.

Leier and coworkers<sup>21</sup> went on to investigate the role of shorter and more frequent intravenous infusions of dobutamine in improving clinical status and objective measurements of cardiovascular performance in patients with heart failure. In their study of 26 patients with moderately severe heart failure, 11 patients were randomly assigned to control conditions, and 15 other patients received weekly dobutamine infusions for 4 to 5 hours per week for 24 weeks. Functional class improved in 12 of the 15 dobutamine-treated patients but in only 2 of the 11 control patients. Not only were enhancements noted in the clinical status of the dobutamine recipients but also exercise performance improved.

**TABLE 61–1 Parenteral Inotropic Therapy Trials in Late-Stage Heart Failure\*: Evidence of Benefit**

Investigators	N	Study Design	Therapy	Follow-up Duration	Key Findings
Leier et al <sup>19</sup>	25	Observational	Dobutamine, 10-15 µg/kg/min for 72 hr (in hospital)	Undefined	Improved symptoms in all patients 17/25 patients with persistent symptomatic improvement at 1 week
Liang et al <sup>20</sup>	15	Randomized, placebo controlled	Dobutamine ( <i>n</i> = 8) vs. D <sub>5</sub> W ( <i>n</i> = 7) infusions for 72 hr (in hospital)	4 weeks	Functional class improved in 6/8 patients receiving dobutamine and 2/7 control patients Dobutamine group: maximal exercise time and LVEF increased significantly above baseline Dobutamine group: improvement in resting hemodynamics, exercise tolerance, and symptoms for several weeks
Leier et al <sup>21</sup>	26	Randomized, controlled, single-blinded	Dobutamine administered for 4 hr weekly for 24 weeks (outpatient clinic)	24 weeks	Functional class improved in 12/15 patients receiving dobutamine and 2/11 controls Twice as much improvement in exercise tolerance in dobutamine recipients Investigators suggested evidence of “conditioning” with dobutamine
Marius-Nunez et al <sup>22</sup>	36	Observational	Milrinone ( <i>n</i> = 32) and dobutamine ( <i>n</i> = 4) weekly infusions (outpatient)	42 weeks	Reduction in hospital admissions, ED visits, and days spent in the hospital for heart failure-related care
Mehra et al <sup>23</sup>	30	Randomized, active controls	Milrinone ( <i>n</i> = 16) versus dobutamine ( <i>n</i> = 14) 1-2 infusions per week (outpatient clinic)	26 weeks	Decrease in medical resource use and improved functional capacity Significant major cardiac event rates noted (23% death or emergency transplantation) No difference between milrinone and dobutamine
Cesario et al <sup>24</sup>	10	Observational	Intermittent home infusions of milrinone (3 days/week, 6 hr each)	12 weeks	No deaths Functional improvement and trend toward hemodynamic improvement Decrease in hospitalizations from baseline
Oliva et al <sup>26</sup>	38	Randomized, open-label controls	Intermittent home dobutamine	26 weeks	No functional improvement with dobutamine Decrease in hospitalizations and no increase in deaths with dobutamine
Harjai et al <sup>27</sup>	24	Observational, retrospective	Continuous home therapy: dobutamine ( <i>n</i> = 17) and milrinone ( <i>n</i> = 4) and combination of dobutamine and milrinone ( <i>n</i> = 3)	12 weeks	Decreases in hospitalization rates, length of stay, and cost of care High rate of mortality at 3 months (38%)
Mavrogeni et al <sup>30</sup>	50	Randomized, open-label controls	Intermittent 24-hour infusion of levosimendan monthly	24 weeks	Symptom improvement in 65% of patients taking levosimendan vs. 20% of controls ( <i>P</i> < .01) Significant increase in LVEF in levosimendan pts and a reduction in MR Higher rate of mortality in control group than in patients taking levosimendan (32% vs. 8%)
Parissis et al <sup>31</sup>	63	Randomized, placebo controlled	24-hr infusion of levosimendan or placebo in hospitalized patients	Baseline to discharge	Levosimendan-treated patients had improvement in NYHA class, 6-minute walk distance, and BNP levels and shorter in-hospital stays Quality-of-life scores improved with levosimendan therapy, remained unchanged with placebo

\*Late-stage heart failure in all these trials was typically defined as systolic failure (LVEF < 0.30) and chronic long-standing symptoms (NYHA classes III to IV) despite ongoing background therapy defined at the time of study inception.

BNP, B-type natriuretic peptide; D<sub>5</sub>W, 5% dextrose in water; ED, emergency department; LVEF, left ventricular ejection fraction; MR, mitral regurgitation; NYHA, New York Heart Association.

Marius-Nunez and colleagues<sup>22</sup> assessed the use of medical resources by calculating the number of emergency department visits and hospitalizations of patients who received weekly infusions of either milrinone (32 patients) or dobutamine (4 patients) and compared the occurrence of these events in the period before pulsed outpatient inotropic infusions with their occurrence during treatment. With pulsed inotropic treatment, the number of hospital admissions, emergency department visits, and days spent in the hospital for heart failure care were reduced. Although a formal cost analysis was not performed, the decrease in hospital admissions was suggestive of the potential cost effectiveness of such a program.

Mehra and coworkers<sup>23</sup> sought to use pulsed inotropic therapy in patients in whom evidence-based pharmacological therapy and all efforts to improve the clinical state by means of a multidisciplinary effort had failed. This prospective randomized investigation of intermittent inotropic therapy with dobutamine or milrinone in 30 patients (12% of the population enrolled in the multidisciplinary team therapy approach) demonstrated decreases in the use of medical resources and improvements in functional capacity. The rate of adverse events (death or emergency transplantation) at 6 months was significant (23%). Cesario and associates<sup>24</sup> sought to determine the effects of low-dosage, intermittent home infusions

of milrinone in 10 patients with late-stage heart failure. After the patients exhibited hemodynamic improvement with milrinone while hospitalized, central lines were placed, and patients were given the drug at home with small portable infusion pumps, starting at 3 days a week for 6 hours at a time over a 3-month period. Patients tolerated the drug well, with no deaths and a 22% decrease in the number of hospitalizations during the study. Occurrences of arrhythmias were minimal, and the severity of angina decreased in two patients. Mean total, physical, and emotional scores on the Minnesota Living with Heart Failure Questionnaire<sup>25</sup> reflected a general trend of symptomatic improvement throughout the infusion period.

In the Dobutamine Infusion in Severe Heart Failure (DICE) trial,<sup>26</sup> 38 patients with advanced heart failure were randomly assigned to receive intermittent dobutamine infusion (48 to 72 hours per week; maximum dosage, 5 µg/kg/min) or to receive traditional therapy. During a 6-month follow-up period, the number of hospital admissions was decreased, but functional class was not significantly improved, among the dobutamine-treated patients. Rates of survival did not differ between the two groups.

Harjai and coworkers<sup>27</sup> studied 24 patients with late-stage heart failure and observed a marked reduction in the number of hospital admissions and lengths of stay after initiation of chronic parenteral inotropic support. The cost of overall care was decreased by 16%. However, 38% of the patients died within 3 months of initiating therapy, which again suggests that the decrease in medical resource use parameters is accompanied by short-term lethality. Several other such observational studies have been reviewed elsewhere.<sup>28</sup>

The calcium sensitizer levosimendan, which has a long half-life, has been touted as an ideal candidate for use of chronic support of the failing heart. Nieminen and associates<sup>29</sup> investigated levosimendan, at a dosage of 1 mg once or twice daily, in a placebo-controlled, double-blind, randomized trial of 307 patients with advanced heart failure. A unique “patient journey” primary endpoint was a composite of repeated symptom evaluations, worsening heart failure, and mortality during 60 days. The “patient journey” scores did not differ between levosimendan and placebo. However, in comparison with placebo, a net improvement in quality-of-life scores and persistent reduction in N-terminal pro-B-type natriuretic peptide (NT-proBNP) by 30% to 40% were observed with levosimendan. Mavrogeni and colleagues<sup>30</sup> administered levosimendan on a monthly intermittent 24-hour protocol for 6 months and compared outcomes by randomly assigning 50 patients to receive either active therapy or standard care in an open-label design. At 6 months, the patients receiving intermittent levosimendan treatment exhibited improvement in symptoms and echocardiographic systolic function without excess arrhythmia or mortality. Parissis and coworkers<sup>31</sup> studied the effects of levosimendan on quality of life, emotional stress, and symptoms in patients with advanced heart failure. In a 2:1 randomized study of 63 patients who received a 24-hour drug infusion or placebo, those investigators observed that levosimendan seems to have a beneficial effect on quality of life, physical activity, and emotional stress in these patients, and hospitalization length was concurrently reduced.

Ikonomidis and associates<sup>32</sup> suggested that at least some of the observed benefit of levosimendan may accrue from improvement in coronary flow and microcirculation, in parallel with an improvement in cardiac performance and neurohormonal activation. In another 2:1 randomized study, Parissis and coworkers<sup>33</sup> assigned 39 patients with advanced heart failure to receive either a 24-hour infusion of levosimendan, 0.1 µg/kg/min ( $n = 26$ ) or placebo ( $n = 13$ ). In this study, levosimendan was not found to increase

markers of oxidative and nitrosative stress in comparison with the placebo treatment. These small-scale findings provide an interesting rationale for the further study of levosimendan.

## Arguments Against

Dies<sup>34</sup> conducted a multicenter, randomized, double-blind, placebo-controlled trial with 60 ambulatory patients with severe heart failure who were receiving optimal standard therapy. The patients were given either dobutamine or placebo for 48 hours on a weekly basis; the mean dosage of dobutamine achieved was 8.1 µg/kg per minute. This study was terminated prematurely when an apparent increased risk for death was found among patients with evidence of baseline ventricular tachycardia who were administered high dosages of dobutamine. In this study, relatively high dosages of dobutamine were used with little regard to electrolyte maintenance.

Elis and colleagues<sup>35</sup> evaluated 19 patients with moderately severe systolic heart failure in a double-blind, placebo-controlled study. They found no significant effect of intermittent dobutamine therapy on hospitalizations or on survival at 6 months. These disparate findings might reflect a less effective pulse schedule (every 2 to 3 weeks) or selection of patients with ischemic heart failure alone. Although no statistically significant differences in survival were noted, there was a clear trend toward shortened survival among the dobutamine-treated patients (median length of survival, 4.6 months versus 7.97 months with placebo) in this investigation.

Even trials in which patients were exposed to short-term in-hospital inotropic therapy have yielded negative outcomes (Table 61-2), which have discouraged further longer term use. For example, in the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) study,<sup>36</sup> patients were randomly assigned to receive a 48-hour infusion of either milrinone or placebo; the primary endpoint was cumulative days of hospitalization for cardiovascular cause within 60 days following randomization. This study demonstrated no significant difference between the two groups of patients with regard to either the primary or secondary endpoints. However, among the patients receiving milrinone, the incidences of atrial fibrillation or flutter and hypotension were significantly higher. In this study, the agent was used in patients without advanced heart failure in the absence of end-organ hypoperfusion.

Although small-scale trials with levosimendan have yielded favorable outcomes in advanced heart failure, this enthusiasm has been tempered by the findings of the Survival of Patients with Acute Heart Failure in Need of Intravenous Inotropic Support (SURVIVE) trial, in which levosimendan was compared with dobutamine in patients with acute decompensated heart failure.<sup>37</sup> This randomized, double-blind trial enrolled 1327 patients hospitalized with acute decompensated heart failure who required inotropic support. Despite an initial reduction in plasma levels of B-type natriuretic peptide in patients who received levosimendan, in comparison with patients who received dobutamine, levosimendan did not significantly reduce rates of all-cause mortality at 180 days or affect any secondary clinical outcomes.

Disturbing findings also have emerged from the Flolan International Randomized Survival Trial (FIRST). O'Connor and associates<sup>38</sup> examined the outcomes of 471 patients with severe heart failure, of whom 80 were treated with dobutamine and 391 were not. These investigators found that dobutamine use at the time of randomization was associated with more frequent worsening heart failure, greater need for mechanical assist device, more resuscitations after cardiac arrest, more

**TABLE 61-2 Parenteral Inotropic Therapy Trials in Late-Stage Heart Failure\*: Evidence of Adverse Outcomes**

Investigators	N	Study Design	Therapy	Follow-up Duration	Key Findings
Dies <sup>34</sup>	60	Multicenter, randomized, double-blind, placebo controlled	Dobutamine or placebo infusions for 48 hr weekly (outpatient)	Terminated early	Increased rate of mortality with dobutamine
Elis et al <sup>35</sup>	19	Randomized, double-blind, placebo controlled	Dobutamine ( <i>n</i> = 10) or placebo ( <i>n</i> = 9) for 24 hr every 2 to 3 weeks	6 months	No difference in number of admissions for heart failure Shortened survival with dobutamine (median 4.6 months vs. 7.97 months with placebo)
Cuffe et al <sup>36</sup>	951	Multicenter, randomized, double-blind, placebo controlled	Intravenous milrinone vs. placebo for 48 hr in hospitalized patients with acute decompensated heart failure	2 months	No difference between groups in mortality or the composite endpoint of incidence of death and readmission Higher incidences of hypotension necessitating treatment and new-onset atrial arrhythmias in the milrinone recipients
Mebazaa et al <sup>37</sup>	1327	Multicenter, prospective, randomized, double-blind, controlled trial	Intravenous levosimendan vs. dobutamine for 24 hr in hospitalized patients with acute decompensated heart failure	6 months	Greater reduction in BNP levels at 24 hours that remained lower at 5 days No difference in mortality or morbidity (including functional assessment)
O'Connor et al <sup>38</sup>	471	Multicenter, randomized, controlled	Continuous intravenous epoprostenol plus conventional therapy: dobutamine ( <i>n</i> = 80; median dosage, 9 µg/kg/min) vs. no dobutamine ( <i>n</i> = 371) at the time of randomization	6 months	Higher incidences of worsening heart failure, need for intravenous vasoactive medications, need for mechanical assist device, resuscitation after cardiac arrest, myocardial infarction, and death among dobutamine-treated patients Higher incidence of mortality persisted after adjustment for baseline differences

\*Late-stage heart failure in all these trials is typically defined as systolic failure (left ventricular ejection fraction < 0.30) and chronic long-standing symptoms (New York Heart Association classes III to IV) despite ongoing background therapy defined at the time of study inception.  
BNP, B-type natriuretic peptide.

myocardial infarction, and higher rates of total mortality. These differences persisted even after adjustment for baseline differences.

To continue research on chronic inotropic therapy, investigators have suggested that a reduced dosage of inotropic agent, coupled with  $\beta$ -blocker therapy, would yield a beneficial response. The Studies of Oral Enoximone Therapy in Advanced Heart Failure (ESSENTIAL)<sup>39</sup> consisted of two identical, randomized, double-blind, placebo-controlled trials performed in North and South America (ESSENTIAL-I) and Europe (ESSENTIAL-II). Patients with NYHA classes III to IV heart failure symptoms, left ventricular ejection fraction of 30% or lower, and one hospitalization or two ambulatory visits for worsening heart failure in the previous year were eligible for participation in the trials. The trials had three coprimary endpoints: (1) the composite of time to all-cause mortality and cardiovascular hospitalization, analyzed in both ESSENTIAL trials; (2) the 6-month change from baseline distance in the 6-minute walk test; and (3) change in patient Global Assessment levels. In ESSENTIAL-I and ESSENTIAL-II, 1854 subjects at 211 sites in 16 countries were studied. In both trials, rates of all-cause mortality and the first coprimary (composite) endpoint did not differ between the two treatment groups. The two other coprimary endpoints were analyzed separately in the two ESSENTIAL trials, as prospectively designed in the protocol. The distance in the 6-minute walk test increased with enoximone, in comparison with placebo, in ESSENTIAL-I ( $P = .025$ ); however, this increase did not reach the prespecified criterion for statistical significance ( $P < .020$ ). This distance did not increase in ESSENTIAL-II. No difference in Patient Global Assessment levels was observed in either trial. Thus, although safety was demonstrated, no signals of efficacy were forthcoming.

In summary, the use of chronic inotropic therapy, either continuous or pulsed, appears to decrease short-term morbidities but is associated with increased mortality.

## CHRONIC PARENTERAL VASODILATOR THERAPY

Because of the disappointing evidence for inotropic therapy, some authorities have advocated the use of vasodilator therapy (Table 61-3). A chronic low-output state with systemic hypotension typically precludes such consideration; for this therapeutic consideration, however, patients with advanced heart failure who have secondary pulmonary hypertension or those with preserved blood pressure but excessive symptoms and frequent deterioration could be candidates. Furthermore, some authorities have argued that the deleterious proarrhythmic effects or tax on myocardial oxygen consumption that is the hallmark of inotropic therapy can probably be avoided by this drug class. This hypothetical consideration has been tested in several studies.

Sueta and associates<sup>40</sup> studied the safety and efficacy of continuous intravenous epoprostenol (prostacyclin), a potent pulmonary and systemic vasodilator. Their subjects were 33 patients with severe heart failure despite prior treatment with diuretics (100%), digitalis (91%), angiotensin-converting enzyme inhibitors (85%), and dobutamine (30%); the subjects underwent a baseline 6-minute walk test before the dosage of epoprostenol was titrated during invasive hemodynamic monitoring. Subjects responding during the dosage titration were randomly assigned, on an open basis, to receive either conventional therapy plus continuous epoprostenol infusion via an indwelling central venous catheter or conventional therapy alone for 12 weeks. The initial dosage-ranging study with epoprostenol produced a significant decline in systemic

**TABLE 61–3 Chronic Parenteral Vasodilator Therapy Trials in Late-Stage Heart Failure\***

Investigators	N	Study Design	Therapy	Follow-up Duration	Key Findings
Sueta et al <sup>40</sup>	33	Randomized, open-label (in hemodynamic responders)	Continuous epoprostenol infusion plus conventional therapy or conventional therapy alone	12 weeks	Epoprostenol therapy resulted in a decrease in pulmonary capillary wedge pressure and an increase in cardiac index. Epoprostenol therapy was associated with an improvement in 6-minute walk distance.
Califf et al <sup>41</sup>	471	Multicenter, randomized, open-label	Continuous epoprostenol infusion or standard care	Terminated early	Epoprostenol therapy resulted in a decrease in pulmonary capillary wedge pressure and an increase in cardiac index. Epoprostenol did not improve 6-minute walk distance, quality of life, or morbidity, and it increased risk of death.
Serra et al <sup>42</sup>	22	Observational, case-control	PGE <sub>1</sub> infusion (mean dosage, 10 ng/kg/min) for 24 hr over 3 consecutive days every 3 months ( <i>n</i> = 22) vs. case controls (no PGE <sub>1</sub> ) ( <i>n</i> = 23)	3 years	PGE <sub>1</sub> infusions improved NYHA class, LVEF, and pulmonary artery pressures. No difference in mortality rates.
Yancy et al <sup>43</sup>	210	Multicenter, randomized	Weekly infusions of nesiritide plus usual care vs. usual care alone in outpatients	12 weeks	Nesiritide decreased aldosterone and endothelin-1 concentrations. No difference among groups by outcome or adverse events. Improved quality of life in both groups. Nesiritide infusions resulted in a significant decrease in cardiovascular events in patients at higher risk (those with renal insufficiency).
Yancy et al <sup>44</sup>	911	Multicenter, randomized, placebo controlled	Nesiritide or placebo infusion for 4–6 hr, once or twice weekly in outpatients	12 weeks	No significant differences between groups in the number of hospitalizations for cardiovascular or renal causes, the number of days alive and out of the hospital, change in quality-of-life score, or rates of death from cardiovascular causes. Nesiritide infusions were associated with more hypotension.

\*Late-stage heart failure in all these trials is typically defined as systolic failure (LVEF < 0.30) and chronic long-standing symptoms (NYHA classes III to IV) despite ongoing background therapy defined at the time of study inception.

LVEF, left ventricular ejection fraction; NYHA, New York Heart Association; PGE<sub>1</sub>, prostaglandin E<sub>1</sub>.

and pulmonary vascular resistance and a substantial increase in cardiac index, despite a fall in pulmonary capillary wedge pressure. The change in distance during the 6-minute walk test from baseline to the last available test was significantly greater for patients who received epoprostenol than for patients assigned to standard therapy.

These initial benefits were not confirmed in FIRST, which was a larger and more robust study. Califf and coworkers<sup>41</sup> randomly assigned 471 patients to receive either epoprostenol infusion or standard care. The primary endpoint was survival; secondary endpoints were clinical events, congestive heart failure symptoms, distance walked in 6 minutes, and scores on quality-of-life measures. The median dosage of epoprostenol was 4.0 ng/kg/min; the results were a significant increase in cardiac index (from 1.81 to 2.61 L/min/m<sup>2</sup>), a decrease in pulmonary capillary wedge pressure (from 24.5 to 20.0 mm Hg), and a decrease in systemic vascular resistance (from 20.76 to 12.33 dynes/sec/cm<sup>-5</sup>). No improvement in distance walked or quality of life was noted, but the therapy was associated with an increased risk of death.

Serra and associates<sup>42</sup> performed an uncontrolled study of prostaglandin E<sub>1</sub> (PGE<sub>1</sub>) infusion in severe heart failure. These investigators studied 22 patients with advanced heart failure and pulmonary hypertension by treating them with PGE<sub>1</sub> and compared their 3-year outcomes to those of a control group in a case-control format. PGE<sub>1</sub> was infused at a mean dosage of 10 ng/kg/min for a total of 24 hours over 3 consecutive days every 3 months. The preliminary data suggested that intermittent PGE<sub>1</sub> infusion in patients with advanced congestive heart failure and high pulmonary pressure is able to improve mean NYHA class and ventricular contractility, pulmonary

pressure, and clinical profiles. These data, however, are too preliminary to draw meaningful conclusions.

In June 2004, a group of investigators who helped establish the natriuretic peptide treatment paradigm met to discuss the potential role of nesiritide as an outpatient treatment option for patients with symptomatic advanced heart failure. The Follow-Up Serial Infusions of Nesiritide pilot study (FUSION I) was then designed to assess the safety and tolerability of outpatient serial infusions of nesiritide in 210 patients with decompensated heart failure who were randomly assigned to receive either usual care only or usual care plus weekly infusions of nesiritide at dosages of 0.005 or 0.01 µg/kg/min for 12 weeks. A total of 1645 nesiritide infusions were administered; 11 (<1%) were discontinued because of an adverse event. Administration of nesiritide resulted in acute decreases in aldosterone and endothelin-1 concentrations. Although there were no statistically significant differences among groups by outcome, patients with prospectively defined higher risk (those with renal insufficiency) demonstrated significant decreases in cardiovascular events.<sup>43</sup>

Yancy and colleagues<sup>44</sup> then performed a definitive trial to further test nesiritide. The FUSION II trial included 911 patients with symptoms of advanced heart failure, two recent hospitalizations for heart failure, an ejection fraction of less than 40%, and creatinine clearance of less than 60 mL/min. The subjects were randomly assigned to receive nesiritide (2-µg/kg bolus plus an infusion of 0.01 µg/kg/min for 4 to 6 hours) or matching placebo, once or twice weekly for 12 weeks. There were no differences between groups in any of the secondary endpoints, including the number of hospitalizations for cardiovascular or renal reasons, the number of days alive and out of the hospital, change in Kansas City

Cardiomyopathy Questionnaire score, or death from cardiovascular causes. Adverse events were similar between groups; nesiritide was associated with more hypotension but less predefined worsening renal function.

The Transplant-Eligible Management of Congestive Heart Failure (TMAC) trial, a multicenter, placebo-controlled, randomized clinical outcomes trial with nesiritide, was initiated in 2006 but stopped by the sponsor after enrollment of the first 15 patients due to lack of funding.<sup>45</sup> In summary, the vasodilator hypothesis for chronic parenteral therapy remains unproven and unsupported.

## PHARMACOLOGICAL BRIDGING TO CARDIAC TRANSPLANTATION

One area in which the use of chronic parenteral inotropic therapy is commonly accepted is the setting of cardiac transplantation (see Chapter 54). The scarcity of donor organs has led to prolonged waiting times for transplantation. Nearly 20% of patients awaiting transplantation die without receiving an organ, and prolonged pharmacological support is needed to prevent the inexorable cycle of multiple organ failure.<sup>46,47</sup> In most transplantation centers, prolonged inotropic support is usually guided by hemodynamic goals in the hope of preventing progression to end-organ failure and pulmonary hypertension. The decision to use either dobutamine or milrinone is often ascertained according to the practitioner's comfort and exploitation of the drugs' disparate properties. Milrinone bypasses the  $\beta$ -adrenergic receptor complex, possesses potent vasodilator and lusitropic properties, and is assumed to be less exacting on heart rate and oxygen consumption than is dobutamine.<sup>48</sup> Dobutamine also has been associated with tolerance and an unique syndrome of hyper-eosinophilia associated with decline in cardiac function.<sup>49</sup> In an investigation to define the underlying mechanisms of this association, Uber and associates<sup>50</sup> were able to demonstrate elevated levels of tumor necrosis factor  $\alpha$  with the genesis of dobutamine-related eosinophilia.

In an earlier prospective trial, Mehra and coworkers<sup>51</sup> observed the outcomes of 99 patients with heart failure who were awaiting transplantation and initially were stabilized with either milrinone or dobutamine but later required adjunctive treatment with the other agent or proceeded to mechanical interventions. Similar rates of bridging to transplantation were noted, but the patients initially treated with milrinone required significantly lesser need for intra-aortic counterpulsation than did those initially treated with dobutamine. Higginbotham and coworkers<sup>52</sup> made similar observations in more than 100 patients who required inotropic therapy as a prelude to transplantation. In this study, milrinone caused a greater reduction in filling pressures than did dobutamine, and more milrinone-treated patients were bridged successfully to transplantation without needing mechanical support. Therefore, these two studies lend credence to the concept of hemodynamic-guided stabilization and point to a possible advantage of milrinone in achieving long-term success of bridging to transplantation.

Zemljic and colleagues<sup>53</sup> prospectively evaluated effects of levosimendan on renal function in patients with advanced chronic heart failure who were awaiting cardiac transplantation. Twenty patients were randomly assigned to receive levosimendan (10-minute bolus of 12  $\mu$ g/kg, followed by 0.1  $\mu$ g/kg/min for 24 hours), and 20 received no levosimendan (controls). At 3 months, Zemljic and colleagues found a decrease in serum creatinine level and an increase in creatinine clearance in the patients taking levosimendan but not in controls. An improvement in creatinine of 0.5 mg/dL or higher occurred in 50% of patients taking levosimendan, in comparison with 10% of controls ( $P = .005$ ).

In summary, the use of chronic parenteral inotropic therapy is well supported with clinical indications that such therapy effectively allows bridging to transplantation while maintaining end-organ perfusion. However, the optimal duration has yet to be determined.

## STRATEGIES TO WEAN FROM CHRONIC PARENTERAL INOTROPIC THERAPY

Investigators have attempted transition from parenteral inotropic therapy to oral inotropic therapy. Feldman and associates<sup>54</sup> performed a placebo-controlled study with 201 patients who had severe late-stage heart failure and required parenteral inotropic therapy. The patients were randomly assigned to receive enoximone or placebo. Patients receiving intermittent parenteral inotropic therapy were administered enoximone, 25 or 50 mg, three times a day. Those receiving continuous parenteral inotropic therapy were administered enoximone, 50 or 75 mg, three times a day for 1 week, which was reduced to 25 or 50 mg three times a day. The ability of subjects to remain alive and free of inotropic therapy was assessed for 6 months. The investigators then attempted to wean patients off parenteral inotropic therapy. At 60 days, 30% of the placebo recipients and 46.5% of the enoximone recipients were weaned (unadjusted  $P = .016$ ). These results suggested that a modest number of patients dependent on inotropic therapy can be successfully converted to an oral strategy without incurring safety concerns.

## PALLIATIVE CARE AND CHRONIC PARENTERAL THERAPY

It would be a disservice to patients with late-stage heart failure if the dying process were simply prolonged. The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT),<sup>55</sup> in patients seriously ill for whom death was predicted in the near term, demonstrated several shortcomings of care. Necessary decisions and discussions about end-of-life aspects were either left unaddressed or tackled late in the course. For example, half of all "do not resuscitate" orders were recorded within 2 days of death. More alarming was the account from families that more than half of all patients who were able to express their emotions reported that they spent the last days of their lives in significant pain. Thus, the portrayal of a dying patient with late-stage heart failure is a troubling one, and the issue of appropriate palliation cannot be ignored.

In such a situation, it is possible to argue for the judicious application of parenteral inotropic support as a palliative measure that serves to reduce morbidity in patients with late-stage heart failure, because this strategy may, in fact, be a worthwhile adjunct, even if survival is shortened. Whether patients prefer to trade duration of life for enhanced quality is an open question but important for the creation of clinical strategies. Stanek and coworkers<sup>56</sup> prospectively performed a full-profile conjoint analysis of individual preferences for outcomes of heart failure treatment. They determined that symptom improvement was of greater importance than survival alone. This conclusion was challenged by Stevenson and associates,<sup>57</sup> who suggested that the severity of a patient's symptoms and condition at the time of questioning may play a role in the outcome of their preferences to trade length of life for quality. The usefulness of time trade-off, symptom scores, and 6-minute walk distance was measured by Stevenson and colleagues in a substudy of 287 patients in the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial at hospitalization and again during 6 months after therapy

to relieve congestion.<sup>57</sup> Willingness to trade time for quality of life was bimodal. At baseline, the median survival time that patients were willing to trade for better quality was 3 months, with a modest relation to symptom severity. Preference for survival time was stable for most patients, but it increased after discharge for 98 (68%) of 145 patients initially willing to trade survival time and was more common with symptom improvement. Thus, preferences remain in favor of survival for many patients despite symptoms of advanced heart failure, but they increase further after hospitalization. Stevenson et al. suggested that the bimodal distribution and the stability of patient preference limit usefulness as a trial endpoint but support its relevance in the design of care for an individual patient.

If parenteral chronic inotropic therapy is offered to a patient who has no other options, the offer must be accompanied by a discussion and documentation of the patient's preference, and a structured approach to such open communication is vital.

## BEYOND PARENTERAL THERAPY: THE ROLE OF PALLIATIVE CARE

In contrast to the end of life in cases of malignancy, which often ends with obvious decline in the last few months to weeks of life, patients with late-stage heart failure exhibit intermittent exacerbations, and the exact timing of death is unpredictable. This obviously creates difficulty in developing clear expectations because patients are often confused by the intermittent partial recovery from decompensation episodes. In late-stage heart failure, attention must focus on clear symptomatic ameliorative targets (dyspnea, fatigue, depression, and pain), but at the same time, curative treatments are not typically abandoned. Therefore, an effective strategy for implementing palliative care must be integrated into a more traditional care paradigm in late-stage heart failure and must include a holistic underpinning (Figure 61-1).

Effective communication is the linchpin of a successful model of palliative care. Goodlin<sup>58</sup> reviewed techniques that must be learned in order to communicate prognosis to patients with advanced heart failure and to their families. In this regard, several core principles must be followed: the use of simple statistics and honest language, empathy, acknowledgment that the patient's future is uncertain, correction of any misunderstanding, and grounding of data in more than one way (thereby describing the chance of death, as well as the opportunity of life).

Often, clinicians are at a loss to establish a time for conversations about palliative care. In this regard, the Global Standards Framework<sup>59</sup> for patients with heart failure has been developed to suggest criteria for such guidance. In general, these guidelines advocate moving toward a conversation

about supportive care for patients with heart failure who demonstrate advanced and refractory symptoms in concert with repeated hospitalization and when no therapeutic targets are capable of reversing this morbid trajectory.<sup>59</sup>

Key ameliorative targets in palliation include breathlessness, pain, fatigue, and psychological consequences (anxiety and depression). These can be effectively addressed by attention to reversible causes and by symptom-directed treatment. Figure 61-2 depicts five elements of palliative care to address these targets.

One area of concern relates to “do not resuscitate” orders and decisions regarding implanted devices such as an implantable cardioverter-defibrillator (ICD). Ideally, an ICD should be converted to a pacing mode only. Goldstein and colleagues<sup>60</sup> identified potential barriers to developing a consistent standard in this regard. In their incisive analysis, they found that physicians often fail to discuss deactivation if they mistakenly believe they can predict the likelihood of ICD firing. Furthermore, clinicians often overestimate a patient's knowledge of understanding the indication for their devices, whereas investigations have revealed that most patients are unaware of the purpose of their ICD and often inaccurate in their assessments.<sup>61</sup> Goldstein and colleagues also found that clinicians often incorrectly believed that patients knew how to inactivate their devices. Thus, the notion of ICD inactivation from shock status requires very careful and sensitive deliberation. Repetitive shocks in a dying patient can be distressing, and although holding a strong magnet to the device is a deactivation option, it should not be considered an adequate substitute for advance reprogramming. In the event of death, the ICD should be switched to a pacing mode before removal by a mortician, to avoid shocking personnel.<sup>62</sup>

## CONCLUSIONS

The available evidence suggests that chronic parenteral inotropic support exerts a long-term deleterious effect on survival, but in the short term, its use is accompanied by hemodynamic stability that for some patients may translate into meaningful symptomatic benefit and success in cutting down on excessive use of medical resources. The decision to use chronic parenteral inotropic support should not be made lightly and must be considered only after all evidence-based therapeutic options have been exhausted. The use of parenteral inotropic support is accepted widely as a pharmacological bridge to transplantation but remains controversial in most other scenarios. In supportive palliative care, patient preferences remain in favor of survival despite symptoms of advanced heart failure. Thus, palliation strategies must be tailored to individual directives and should focus on symptom control in the domains of breathlessness, pain, fatigue, and psychological impairment.

**FIGURE 61-1** Underpinnings of a palliative care model in late-stage heart failure. ICD, implantable cardioverter-defibrillator.

### BREATHLESSNESS

Management of panic and breath control  
Use of a handheld fan  
Oxygen, if hypoxic  
Opioids (oxycodone 1–2 mg preferred  
or morphine 2.5–5 mg up to 4 times daily)

### FATIGUE

Identify reversible causes  
(hypokalemia, anemia, overdiuresis)  
Obtain a full sleep history  
Exclude depression as a cause  
Extremity-strengthening exercises

### NEUROPSYCHOLOGICAL IMPAIRMENT

Identify presence of anxiety, depression,  
and dementia  
SSRIs, benzodiazepines, and haloperidol  
are safe  
Counseling about death and dying  
and avoidance of social isolation

### SPECIAL CONSIDERATIONS

Avoid anticholinergics for nausea  
Appetite stimulants (megestrol  
acetate; dronabinol)  
Skin care (emollients)  
Itching (SSRI or 5-HT(3) inhibitors)

### PAIN SYNDROMES

Identify cause (angina, claudication, gout, arthritis, hepatic congestion,  
neuropathy, leg cramps)  
Avoid NSAIDs and tricyclic antidepressants  
Acetaminophen for mild pain; Add weak opioids for moderate pain (codeine  
30 mg, 2 tablets four times daily); Use morphine or equivalent for severe pain  
Opioid use must be accompanied with antiemetic and laxative preparations  
Gabapentin or equivalent for neuropathic pain

**FIGURE 61–2** Five elements of palliative care. 5-HT(3), 5-hydroxytryptamine (serotonin) receptor subtype 3; NSAIDs, nonsteroidal anti-inflammatory drugs; SSRIs, selective serotonin reuptake inhibitors.

     clinical features of, 467–468, 468b  
     endomyocardial biopsy for, 469–470, 469t, 470f, 471t  
     HF, presentations in, 467, 467b  
     noninvasive cardiac testing for, 468–469, 469f, 469b  
   cause of, 465–467  
   postviral cardiomyopathy, pathogenesis of, 465–467, 466f  
   treatment for, 470–472  
     antiarrhythmic therapy, 472  
     antiinflammatory agents, 470–472  
     physical activity, 470  
     specific therapy, 472  
 Viral cardiomyopathy, 378  
 Viscoelastic stiffness, 221–222, 222f  
 Vitamins, 392  
 Volume overload, management of, 650, 651t  
   diuresis  
     extent of, 652, 652f  
     risks with, 652–653, 653f  
   diuretics  
     combination of, 651–652  
     resistance and management of, 653, 654f  
     types of, 650–651  
   refractory conditions, 653–657  
     adenosine antagonists, 656, 656f  
     dopaminergic agents, 655  
     inotropic agents, 655, 655f

Volume overload, management of (*Continued*)  
   natriuretic peptides, 656  
   ultrafiltration and dialysis, 655–656  
   vasopressin antagonists, 656–657  
 Volume status, assessment of, 517–518

## W

Warfarin, for prevention of thromboembolism, 756f, 760–762, 762t  
 Wasting, 336–337  
 Water and salt, renal regulation of, 291–292, 292f–293f  
 Weaning  
   from chronic parenteral inotropic therapy, 882  
   from intravenous vasodilators, 642  
   and use, of intravenous inotropic agents, 642–643  
 Weight loss  
   in CHF, therapeutic approaches to, 337–341  
   OSA and, 488  
 Weight management and regular exercise, for cognitive impairment, with HF, 871  
 Women, HF in, 716, 722–725  
   clinical features of, 722–723  
   therapy for, 723–725  
     ACE inhibitors, 723, 723f, 724t  
     aldosterone antagonists, 723  
     ARBs, 723, 724f  
      $\beta$ -blockers, 723, 724t  
     cardiac resynchronization, 724–725  
     digoxin, 724  
     heart transplantation, 725, 725f, 725t  
     ICDs, 725  
     isosorbide dinitrate plus hydralazine, 723–724  
     VAD, 725

## X

XLCM. *See* X-linked dilated cardiomyopathy  
 X-linked cardiomyopathies, 421–424  
   cardiomyopathy and skeletal myopathy genes overlap, 423–424  
   XLCM, 421–423  
 X-linked dilated cardiomyopathy (XLCM), 421–423  
   autosomal dominant DCM, 422–423  
   Barth syndrome, 421–423  
   lamin A/C, 423

## Z

Zinecard. *See* Dexrazoxane
