activity<sup>104</sup> (i.e., impairment of flow-dependent, endothelium-mediated vasodilation).<sup>39</sup> Experimental work showed that chronically reduced blood flow is associated with reduced endothelial release of NO while increased flow is translated into increased release of NO<sup>105,106</sup> due to upregulation of eNOS and EC-SOD gene expression related to enhanced shear stress.<sup>107</sup> Consistent with these experimental observations, physical training improves endothelial function by increasing the bioavailability of NO (Figure 17-7). The positive effect of physical training appears to be restricted to the extremity exposed to physical training. The beneficial effect of training is quickly lost within weeks after the end of training.<sup>3</sup> These observations suggest that endothelial function is regulated locally and modulated by the extent of daily physical activity. These beneficial effects of physical training have now been demonstrated by different groups in healthy controls,<sup>108</sup> patients with chronic heart failure,<sup>109,110</sup> coronary artery disease,<sup>111</sup> hypercholesterolemia,<sup>112</sup> and arterial hypertension<sup>113</sup> in peripheral resistance<sup>109,110</sup> along with conduit arteries<sup>3</sup> and in the coronary circulation.<sup>111</sup> The positive effects of physical training on endothelial function are multifactorial, including increased expression of eNOS, EC-SOD, and potentially mobilization of endothelial progenitor cells.<sup>111a</sup> The effect of physical training on EC-SOD appears to be dependent on the upregulation of eNOS, since EC-SOD activity is reduced in eNOS knockout mice, but can be increased by physical training associated with increased eNOS gene expression.<sup>114</sup> ACE-activity is increased in patients with chronic heart failure and/or arteriosclerosis,<sup>58,115</sup> leading to increased formation of angiotensin II and increased inactivation of endogenous bradykinin, resulting in decreased NO levels. In contrast, increased shear stress reduces ACE-gene expression and results in increased NO activity.<sup>116</sup> Since NO has profound effects on vascular structure and remodeling, exercise induced changes in blood flow may affect NO levels through changes in ACE-activity, with resultant favorable changes in vascular structure. While there is some experimental evidence that mechanism is important in animal models of arteriosclerosis (i.e., normalization of vascular structure and increased inner arterial lumen diameter)<sup>117</sup>, there are no data that support this mechanism in experimental or clinical heart failure.

### Abnormalities of Vascular Smooth Muscle Responsiveness in Chronic Heart Failure

Beyond impaired endothelium-dependent vascular responses, it is possible that the responses of the underlying vascular smooth muscle to vasodilators, such as nitric oxide or

**FIGURE 17-7** Shows the effect of 4 weeks of physical training on flow-dependent, endothelium-dependent vasodilation (FDD) in patients with chronic heart failure. Bar graphs indicate percent change of radial artery diameter during FDD before (baseline) and after training (training) and 6 weeks after end of the training. (Modified from Hornig B, Maier V, Drexler H. Physical training improves endothelial function in patients with chronic heart failure. *Circulation* 1996;93:210-214.)

adenosine, is altered in severe chronic heart failure. Nitric oxide stimulates the guanylyl cyclase in vascular smooth muscle cells and the resultant increase in cGMP leads to muscular relaxation, causing vasodilation. It is conceivable that a reduced responsiveness of this system to nitric oxide stimulation also could contribute to vasodilator dysfunction in chronic heart failure. A reduced response to nitroglycerin was first observed by Zelis et al<sup>15</sup> in their landmark study of the peripheral circulation in 1968. Some more recent studies did not find significant differences in the vascular responses to direct-acting donors of nitric oxide or endothelium-independent vasodilators; however, the clinical characteristics of these patients were different (i.e., less edematous and in a more compensated state). The initial observations were confirmed in patients with severe heart failure (i.e., nitroglycerin resulted in a significantly smaller increase in mean blood flow velocity of the superficial artery after intraarterial infusion in patients with chronic heart failure as compared with control subjects). Therefore a reduced responsiveness of vascular smooth muscle to nitric oxide-dependent cGMP-mediated or nonspecific vasodilation appears to represent a contributing factor in severe chronic heart failure.

Beyond impaired vasodilator capacity in heart failure, enhanced synthesis and release of vascular vasoconstricting factor may emerge in heart failure (i.e., originating from the cyclooxygenase metabolic pathway).<sup>59,118,119</sup> In this respect, patients with chronic heart failure showed a blunted response to acetylcholine as compared with control subjects.<sup>34</sup> When these experiments were repeated after cyclooxygenase inhibition with indomethacin, the vasodilator responses to acetylcholine were unchanged in normal subjects, but significantly increased in patients. Despite this improvement, the response still was significantly attenuated compared with normal subjects.<sup>34</sup> In addition, intra-arterial infusion of sodium-nitroprusside in chronic heart failure patients treated with aspirin resulted in significantly greater vasodilation as compared with patients not pretreated with aspirin.<sup>17</sup> Both findings are compatible with the view that an abnormal production of cyclooxygenase-dependent vasoconstricting factor(s) seems to be present in the peripheral circulation of patients with chronic heart failure. Such an effect may blunt the vasodilatory effects of both endogenous nitric oxide liberated by endothelial agonists such as acetylcholine and exogenous nitric oxide derived from nitric oxide donors such as sodium nitroprusside or nitroglycerin.

Thus there is abundant evidence that chronic heart failure is associated with impaired endothelium-dependent vasodilator function of peripheral resistance and conduit arteries. This impaired endothelium-dependent vasodilation is to a large extent secondary to a reduced bioavailability of nitric oxide. Nevertheless, it appears that the impaired endothelial function in chronic heart failure is multifactorial, including reduced expression of endothelial nitric oxide synthase, L-arginine substrate limitations, activation of the renin-angiotensin system, and enhanced oxidant stress, further reducing nitric oxide availability.

## POTENTIAL FUNCTIONAL IMPLICATIONS FOR PATIENTS WITH CHRONIC HEART FAILURE

Because endothelial vasodilator function is involved in the control of tissue perfusion, the question arises whether impaired exercise-induced release of nitric oxide contributes to reduced aerobic exercise capacity and worsening LV remodeling in patients with chronic heart failure. Moreover, it would be important to know whether improved endothelial function increases exercise capacity in chronic heart failure.

### Endothelial Function in Heart Failure

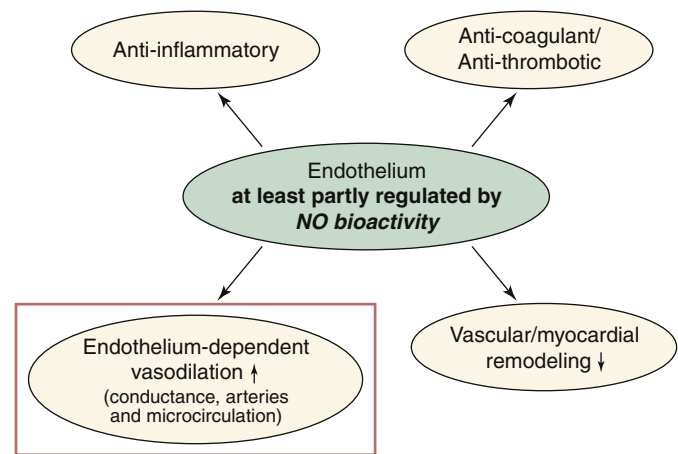

FIGURE 17-8 Role of endothelial function in heart failure.

If so, the endothelium would represent an attractive therapeutic target in these patients (Figure 17-8).

The beneficial effects of physical training in patients with chronic heart failure are established and are associated with improved endothelial vasodilator function. Several mechanisms have been proposed to account for the clinical benefit of physical training, including improvement of left ventricular diastolic function, autonomic balance, and ventilatory and/or skeletal muscle function. In particular, skeletal muscle atrophy, impaired metabolism, and reduced skeletal muscle oxidative capacity appear to contribute to the reduced exercise capacity in chronic heart failure. Exercise training improves force of contraction, metabolism, and oxidative capacity of skeletal muscle. Force of contraction in skeletal muscle is modulated by nitric oxide through reduced  $\text{Ca}^{2+}$  activation of actin filaments, resulting in decreased myofibrillar calcium sensitivity.<sup>120</sup> Skeletal muscle fibers express two isoforms of the nitric oxide synthase: neuronal and endothelial. In chronic heart failure, expression of the inducible nitric oxide synthase has been shown to emerge in skeletal muscle of patients.<sup>121</sup> Therefore, increased nitric oxide availability within the skeletal muscle may reduce the contractile force in these patients. In addition, endogenous nitric oxide released from microvascular endothelium plays an important role in the modulation of cellular respiration in skeletal muscle.<sup>122</sup> The suppression of tissue oxygen consumption in response to bradykinin (presumably stimulating endothelial release of nitric oxide) is blunted in the skeletal muscle of dogs with heart failure,<sup>123</sup> indicating a defective endogenous nitric oxide-mediated modulation of tissue oxygen consumption in skeletal muscle after development of heart failure. It is conceivable that defective biosynthesis of nitric oxide in skeletal muscle can be improved by physical training. Interestingly, the preservation of endothelial vasodilator function by physical training is associated by preserved resting hemodynamics and alleviation of clinical manifestations of heart failure,<sup>124</sup> consistent with the ideas that the beneficial effects of physical training are mediated in part by endothelial mechanisms.

The significant relationship between improvement of endothelial function and exercise capacity supports the notion that improved endothelial function contributes to increased exercise capacity, particularly since there is experimental evidence suggesting that limb blood flow during exercise is dependent on nitric oxide.<sup>125</sup> However, improved endothelial function can probably account only for a small incremental increase in exercise capacity. A complex physiology exists for hyperemia, exercise, and nitric oxide. The role of nitric oxide in exercise-induced increase in blood flow still remains controversial and the effects of inhibition

of nitric oxide synthesis in this respect are modest at best. Increases in blood flow during exercise or following arterial occlusions are mediated by several mediators and blockade of several systems is necessary to attenuate reactive hyperemia. In normal individuals, peak vasodilatory capacity can be increased by physical training without influencing basal or stimulated activity of the nitric oxide vasodilator system,<sup>126</sup> although exercise training undoubtedly augments endothelial nitric oxide synthesis and flow-dependent dilation of skeletal muscle arterioles through nitric oxide and prostaglandins.<sup>127</sup> Following physical training, an increase in flow reserve or reactive hyperemia has been observed both in animals and in humans. In fact, physical training in patients has been associated with increases in skeletal muscle blood flow during exercise, reactive hyperemia, and peak oxygen consumption possibly by enhancing vascular conduction and growth.<sup>128</sup> However, increased metabolic vasodilation in response to arterial occlusion may not be associated necessarily with increased training-induced endothelium-dependent vasodilation during exercise in chronic heart failure. Indeed, a recent study observed that the increased vasodilatory responses following arterial occlusion and endothelium-dependent stimuli following physical training in patients with chronic heart failure do not correlate, suggesting that the determinants of peak reactive hyperemic blood flow and endothelium-dependent vasodilation are not linked.<sup>109</sup> However, increased availability of nitric oxide during exercise provided by regular physical training may contribute to exercise capacity without affecting total increases in skeletal muscle blood flow by affecting the distribution of blood flow within the skeletal muscle. Interestingly, a recent pilot study has suggested that intense aerobic interval exercise training is substantially more effective as compared with continuous moderate exercise in restoring endothelium-dependent vasodilation in patients with CHF<sup>109a</sup>; however, this has to be confirmed in a larger study. Intense exercise training was also associated with a more pronounced beneficial effect on cardiac remodeling.<sup>109a</sup>

In chronic heart failure, skeletal muscle underperfusion emerges predominately in oxidative working muscle.<sup>8</sup> Inhibition of nitric oxide synthesis by L-nitro-arginine methyl ester (L-NAME) is most effective in limiting blood flow to oxidative working muscles, but the inhibitory effect of L-NAME on blood flow in these muscle fibers appears to be attenuated in chronic heart failure.<sup>129</sup> Thus redistribution of blood flow within skeletal muscle appears to emerge in heart failure caused by endothelial dysfunction possibly secondary to chronic deconditioning. It may be speculated that improved oxygen delivery with physical training is related partially to the reversal of impaired endothelium-dependent relaxation within oxidative muscle fibers. In this respect, it is noteworthy that activity of the neuronal NO synthase can be upregulated by endurance training.

Nitric oxide also is involved in the central regulation of sympathetic outflow, raising the possibility that both neuronal and endothelial nitric oxide synthesis may contribute to the regulation of vasomotor tone.<sup>130</sup> It is possible that the sympathoinhibitory effects of nitric oxide may be reduced in chronic heart failure and thus contribute to sustained sympathetic activation.

Several other interventions targeting the endothelium have been studied in chronic heart failure. ACE inhibition has been shown to improve endothelium-dependent vasodilation.<sup>69,131</sup> Accordingly, it is conceivable that the related beneficial effects of ACE inhibitors on exercised-induced blood flow and exercise capacity in heart failure<sup>9</sup> is, in part, caused by improved endothelium-dependent vasodilation. Antioxidants such as vitamin C are effective in restoring endothelium-dependent vasodilation<sup>53</sup>; however, their potential to improve exercise capacity is limited.<sup>132</sup>

In conclusion, endothelial dysfunction may play a role in the redistribution of blood flow during exercise and adversely

**FIGURE 17-9** Effect of endothelial function on prognosis in heart failure. Endothelial dysfunction (i.e., impaired endothelium-dependent vasodilation) has been associated with a markedly adverse outcome in patients with CHF in several studies. The figure shows the relationship between endothelium-dependent vasodilation (measured at the radial artery) and cardiovascular events (cardiac death, hospitalization due to worsening of heart failure—NYHA class IV/pulmonary edema, or necessity for heart transplantation) in the follow-up of patients with CHF. The study cohort was divided into those with flow-dependent vasodilation (FDD), greater median (6.2%) and lesser median. (Modified from Fischer D, Rossa S, Landmesser U, et al. Endothelial dysfunction in patients with chronic heart failure is independently associated with increased incidence of hospitalization, cardiac transplantation, or death. *Eur Heart J* 2005;26(1):65-69.)

affect exercise capacity. Conditions such as chronic heart failure that reduce the availability of endothelium-derived nitric oxide also impair the normal exercise-induced blood flow response. This in turn may lead to diminished exercise capacity.

## PROGNOSTIC IMPLICATIONS OF ENDOTHELIAL DYSFUNCTION

There is now accumulating evidence suggesting that an impaired nitric oxide-mediated vasodilation may have prognostic implications in patients with CHF. Indeed, impaired endothelium-dependent vasodilation was associated with an increased risk of hospitalization for heart failure and death in patients with CHF (Figure 17-9).<sup>133-135</sup> Thus in a limited number of patients with chronic heart failure and endothelium-mediated vasomotion studies, a correlation of endothelial dysfunction with future cardiovascular outcome has been shown by several authors using different techniques to characterize endothelial function. It should be noted, however, that the number of cardiovascular events was rather small in all of these studies.

Experimental data, however, suggest that endothelial NO synthase (and consequently endothelial function) is important for outcome in postmyocardial infarction. In this respect, a recent experimental study showed that mice lacking endothelial NO synthase have a substantially reduced survival rate after a myocardial infarction.<sup>136</sup> Moreover, we have observed that statin-induced beneficial effects on outcome after myocardial infarction were dependent on endothelial NO synthase, since they were not observed in eNOS-deficient animals.<sup>137</sup>

Summary, 298

Importantly, decreased glomerular filtration rate (GFR), usually estimated with creatinine-based equations, has emerged as a powerful independent predictor of outcomes in patients with heart failure (HF) (Figure 18-1).<sup>1-4</sup> In addition, deteriorating renal function and diuretic resistance during HF therapy are prominent therapeutic challenges (see also Chapter 44).<sup>5-7</sup> Indeed, the requirement to maintain a sufficient renal perfusion pressure is an important limitation to the dosing of vasodilating drugs that are commonly used for the treatment of congestive heart failure (CHF).

Here we will review the basic physiology and pathophysiology of the kidney in heart failure, discuss the emerging concept of the “cardiorenal syndrome,” and finally focus on novel therapeutic strategies that enhance pathways based on the second messenger cyclic guanosine monophosphate (cGMP).

## THE RENAL REGULATION OF SALT AND WATER

The kidneys control intravascular volume through the regulation of salt and water excretion and receive about 25% of the cardiac output. A kidney can be divided anatomically and physiologically into the cortex, outer medulla, and inner medulla. The single renal nephron (Figure 18-2), one of several hundred thousands that make up a kidney, is the basic functional unit of the kidney and includes the glomerulus, which filters the blood delivering plasma ultrafiltrate to the renal tubule.<sup>8</sup> The normal glomerulus is impermeable to macromolecules, and only in disease states becomes permeable to molecules such as albumin, which when lost in the urine impairs the ability to regulate intravascular volume through reductions in plasma oncotic pressure. The loss of plasma oncotic pressure favors edema formation as occurs in disease states such as in the nephrotic syndrome and has been reported in severe CHF with increases in renal venous pressure. Indeed, the high prevalence of CHF in chronic kidney disease may in part be mediated by increased glomerular permeability with microalbuminuria, the latter of which is a robust signature of increased cardiovascular risk.<sup>9</sup>

Glomerular function is also regulated by glomerular hydrostatic pressure, which is controlled by arterial blood pressure and segmental vascular resistances at the level of preglomerular and postglomerular vessels (i.e., afferent and efferent arterioles). Renal perfusion pressure can be reduced by systemic arterial hypotension as in HF or by renovascular disease (i.e., renal artery stenosis).

Importantly, the role of increased renal venous pressure has recently been highlighted. Damman et al and Mullens et al reported that central venous pressure was a more important factor in determining reduced GFR and worsening renal function than renal blood flow or cardiac index (Figure 18-3).<sup>10-12</sup> Indeed, prior physiological studies had indicated that increasing renal venous pressure in volume-expanded healthy canines increased renal interstitial pressure and decreased fractional excretion of sodium, glomerular filtration rate, and renal blood flow (Figure 18-4).<sup>13</sup> While increasing renal venous pressure would be expected to increase hydrostatic pressure in the glomerulus and thus promote filtration, given the tight renal capsule it can also compress the tubules, which would reduce the hydrostatic pressure gradient across the glomerular membrane.<sup>14</sup> Prospective studies are needed to assess whether tailoring therapies according to renal venous pressure (via central venous pressure) improves outcomes. Neurohumoral factors also regulate glomerular function either by altering glomerular pressure via hemodynamic actions or by direct action on the glomerular membrane. Glomerular filtration rate can also be reduced if the number of nephrons is reduced due to intrinsic renal disease, even though remaining nephrons can compensate somewhat.

From the glomerulus, the filtrate flows successively through the proximal tubule, the loop of Henle, the distal tubule, and finally the collecting duct to reach the renal pelvis as urine. The sections of the tubule vary in permeabilities for water and solutes due to the differential expression of transporters and channels, the activity of which can be affected by hormones and drugs (see Figure 18-2). The proximal tubule is regulated by hormonal and physical factors in the control of sodium reabsorption.<sup>15</sup> It is a key site also associated with enhanced reabsorption of sodium in overt CHF, thus contributing to sodium retention and edema formation. The juxtaglomerular apparatus is the location of renin-secreting cells and the macula densa and lies at the junction between the loop of Henle and the distal nephron at which the tubule comes in close proximity to the afferent arteriole.<sup>16</sup> The juxtaglomerular apparatus and macula densa

sense alterations in intratubular sodium concentration, which depends on GFR and proximal reabsorption. Increased delivery of sodium to the macula densa and juxtaglomerular apparatus decreases renin secretion, whereas decreased sodium delivery as a result of decreased GFR or increased proximal reabsorption as would occur in CHF, increases renin releases

**FIGURE 18-1** Proportional relationship of calculated glomerular filtration rate (using the Cockcroft-Gault equation) with mortality in Cox-adjusted survival analysis. Patients had heart failure (New York Heart Association class III or IV, left ventricular ejection fraction <35%) and were enrolled in the Second Perspective Randomized study of Ibopamine on Mortality and Efficacy (PRIME-II) trial, which investigated the oral dopamine agonist ibopamine. (With permission from Hillege HL, Girbes AR, de Kam PJ, et al. Renal function, neurohormonal activation, and survival in patients with chronic heart failure. *Circulation* 2000;102(2):203-210.<sup>1</sup>)

and activate the renin-angiotensin-aldosterone (RAAS) cascade.<sup>17</sup> The loop of Henle is therefore an important segment of the renal nephron and is responsible for reabsorption of sodium through direct alterations in sodium transport, and through changes in renal medullary blood flow. The final mediator of renal sodium regulation is the collecting duct, which is under the influence of both natriuretic and antinatriuretic factors.<sup>18</sup> These include aldosterone, which promotes active sodium reabsorption, and arginine vasopressin, which regulates the reabsorption of water. Natriuretic factors, such as the cardiac peptides ANP and BNP (see later discussion), also act primarily in the distal nephron. In overt CHF, this segment is overwhelmed by sodium-retaining factors to overcome the natriuretic effects of ANP and BNP, resulting in profound reabsorption of sodium and further edema formation and congestion. Understanding the single nephron in both structure and function provides insights into therapeutic approaches to enhance GFR, decrease sodium and water reabsorption, and therefore restore proper sodium and water homeostasis. With regard to therapy, it should be noted that loop diuretics act in the loop of Henle but not in the distal tubule or collecting duct, so that some of the sodium delivered to the distal nephron will be reabsorbed there. Indeed, chronic loop diuretic therapy can lead to hypertrophy and hyperplasia of distal nephron segments.<sup>71</sup> Furthermore, addition of thiazide-like diuretics, which act in the distal nephron, to loop diuretics can induce a powerful diuresis (“sequential nephron blockade”).

## THE “CARDIORENAL SYNDROME”

Given the interdependence of the heart and kidney and the apparent worse outcome of HF patients with coexisting renal dysfunction, the concept of a “cardiorenal syndrome” (CRS)

**FIGURE 18-2** Schematic of a single nephron with major sites of action of some conventional diuretics and the natriuretic peptides. The juxtaglomerular apparatus, located at the junction of the afferent arteriole and the distal tubule, contains renin-secreting cells. Natriuretic peptides have diverse renal actions: they can (1) increase glomerular filtration, (2) oppose proximal reabsorption of sodium by opposing angiotensin II and the sympathetic nervous system, (3) inhibit tubuloglomerular feedback and the secretion of renin, (4) inhibit sodium reabsorption in the distal tubule, and (5) promote free water excretion by opposing arginine vasopressin. *Aldo*, aldosterone; *AQP-2*, aquaporin 2 water channel; *AVP*, arginine vasopressin; *ENaC*, epithelial sodium channel; *MR*, mineralocorticoid; *V<sub>2</sub>-Receptor*, vasopressin 2 receptor.

was proposed.<sup>19</sup> In a broader sense it could be defined as a syndrome in which either the heart or the kidney fails to compensate for the functional impairment of the other organ, resulting in a vicious cycle that will ultimately lead to decompensation of the entire circulatory system. In a narrower sense, CRS could be defined as worsening renal function or diuretic resistance in patients treated for HF. Given that the term is somewhat vague and not consistently defined, Ronco et al recently suggested the following classification:<sup>20</sup>

Type 1 CRS: abrupt worsening of cardiac function (e.g., acute cardiogenic shock or decompensated CHF) leading to acute kidney injury

Type 2 CRS: chronic abnormalities in cardiac function (e.g., chronic CHF) causing progressive chronic kidney disease

Type 3 CRS: abrupt worsening of renal function (e.g., heart failure, arrhythmia, ischemia)

Type 4 CRS: state of chronic kidney disease (e.g., chronic glomerular disease) contributing to decreased cardiac function, cardiac hypertrophy, and/or increased risk of adverse cardiovascular events

Type 5 CRS: systemic condition (e.g., sepsis) causing both cardiac and renal dysfunction

Of course, CRS types could overlap. While the usefulness of this classification for patient treatment or clinical trial

**FIGURE 18-3** Prevalence of worsening renal function (defined as an increase of serum creatinine of 0.3 mg/dL) during hospitalization according to categories of admission central venous pressure (CVP), cardiac index (CI), systolic blood pressure (SBP), and pulmonary capillary wedge pressure (PCWP). (With permission from Mullens W, Abrahams Z, Francis GS, et al. Importance of venous congestion for worsening of renal function in advanced decompensated heart failure. *J Am Coll Cardiol* 2009;53(7):589-596.<sup>12</sup>)

**FIGURE 18-4** Relationship of renal venous pressure and renal interstitial pressure (left panel) and renal interstitial pressure and fractional excretion of sodium (right panel) in volume-expanded healthy canines. (With permission from Burnett JC Jr, Knox FG. Renal interstitial pressure and sodium excretion during renal vein constriction. *Am J Physiol* 1980;238(4):F279-F282.<sup>13</sup>)

**FIGURE 18-5** Simplified schematic of guanylyl cyclase (GC) pathways, which have cyclic guanosine monophosphate (cGMP) as their second messenger. Nitric oxide is produced by endothelial cells and activates soluble GC in the target cell. ANP and BNP stimulate GC-A (also called NP receptor A), while CNP stimulates GC-B (also called NP receptor B). DNP is a GC-agonist first discovered in snake venom. CD-NP is a chimeric peptide composed of the ring structure and amino terminus of CNP and the carboxyterminus of DNP; it activates both GC-A and GC-B. Natriuretic peptides also bind to the non-GC-linked natriuretic peptide C receptor, the biological significance of which beyond NP clearance is currently unclear. Cyclic GMP modulates cGMP-dependent protein kinase G, cGMP-regulated PDEs, and cGMP-regulated cation channels. The cGMP signal is terminated by PDEs that hydrolyze cGMP to GMP, or by extrusion into the extracellular space. The NPs are degraded by a variety of peptidases. Cyclic GMP signaling can be enhanced by (1) the use of NO mimetics such as nitrovasodilators, (2) direct sGC stimulators, (3) exogenous NPs, (4) inhibiting NP degrading enzymes, and (5) inhibiting the activity of cGMP-hydrolyzing PDEs. ANP, atrial natriuretic peptide; BNP, B-type natriuretic peptide; cGMP, cyclic guanosine monophosphate; GMP, guanosine monophosphate; GC, guanylyl cyclase; DNP, *Dendroaspis* natriuretic peptide; DPP4, dipeptidyl peptidase IV; NEP, neutral endopeptidase; NO, nitric oxide; PDE, phosphodiesterase; PKG, protein kinase G; R<sub>A</sub>, natriuretic peptide receptor A; sGC, soluble guanylate cyclase.

design remains to be established, it illustrates the scope of the problem of cardiorenal disease.

Recognizing that hemodynamic interaction between kidney and heart are not sufficient to explain the poor prognosis of coexisting renal and cardiac dysfunction, Bongartz et al highlighted “cardiorenal connectors” (i.e., factors that adversely affect both the kidney and the heart).<sup>21</sup>

- The renin-angiotensin-aldosterone system (RAAS).
- Relative deficiency of nitric oxide (NO) compared with reactive oxygen species (ROS)
- Inflammation
- The sympathetic nervous system

There is substantial overlap and mutual reinforcement among these factors, contributing to accelerated cardiorenal deterioration on many different levels, such as sodium retention, inflammation, fibrosis, and left ventricular hypertrophy. One therapeutic strategy would be to block some or all of these factors. An alternative strategy would be to enhance endogenous pathways that oppose these factors. Increasing evidence points to the renal cGMP system as fundamental in the regulation of sodium excretion and GFR. Later we will discuss what is known about cGMP and therapeutic strategies to improve renal function and the cardiorenal axis in CHF by targeting cGMP pathways especially in the kidney.

## THE CARDIORENAL AXIS AND CYCLIC GMP

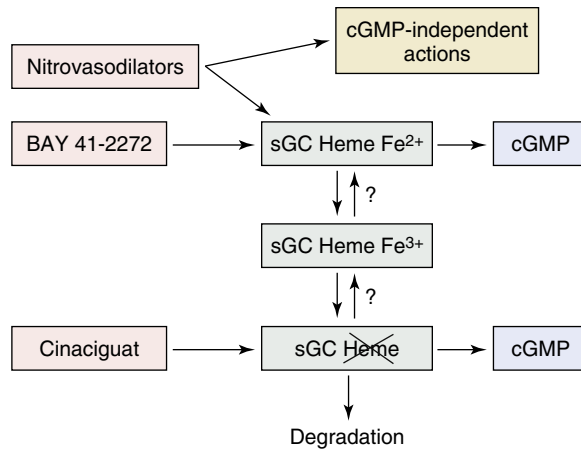

3', 5'-cyclic guanosine monophosphate (cGMP) is the second messenger of signaling systems that use distinct guanylyl cyclases (GCs; E.C. 4.6.1.2), which convert guanosine 5'-triphosphate (GTP) to cGMP.<sup>22</sup> Currently, one cytosolic (soluble) and seven membrane-bound (particulate) GCs have been identified. As illustrated in Figure 18-5, they are soluble GC (nitric oxide (NO)-sensitive GC) with its endogenous ligand NO, GC-A (also called natriuretic peptide A receptor [NPR-A]) with its endogenous ligands ANP and BNP, and

GC-B (also called NPR-B) with its endogenous ligand CNP. Other GCs are GC-C (ligands: guanylin and uroguanylin, heat-stable enterotoxins) and GC-D, -E, -F, and -G for which the endogenous ligands remain unknown. Cyclic GMP affects the activity of effector molecules, specifically cGMP-dependent protein kinases (PKG), cGMP-regulated phosphodiesterases (PDEs), and cGMP-regulated cation channels. Further, cGMP itself is also a substrate of several PDEs, which hydrolyze cGMP to GMP and thus terminate the cGMP signal.<sup>23</sup>

It is important to recognize that despite having a common second messenger, activating different cGMP-dependent pathways will not necessarily result in similar actions. Specifically, receptors can differ both in their tissue and their intracellular distribution. Within the cell GC-A activation as compared to sGC stimulation increases distinct cGMP pools that are compartmentalized by the activity of PDEs.<sup>24</sup> These findings are consistent with the observation of distinct action profiles. Specifically, ANP, BNP, and NO have vasodilating actions, but only ANP and BNP are natriuretic. Regarding renal function, intrarenal administration of the NO synthase inhibitor N<sup>G</sup>-monomethyl-L-arginine (L-NMMA) in experimental acute CHF reduces renal blood flow without affecting GFR and sodium excretion, whereas natriuretic peptide receptor blockade does not affect renal blood flow but decreases GFR and sodium excretion.<sup>25</sup> It should also be noted that there can be reciprocal regulation of different cGMP pathways such that in vascular smooth muscle cells activation of GC-A leads to an attenuated response to sGC and vice versa.<sup>26</sup>

## THE NO-sGC-cGMP PATHWAY: A POTENT RENOVASODILATING MECHANISM

Soluble GC (sGC) is a heterodimeric heme enzyme consisting of an  $\alpha$ - and  $\beta$ -subunit and a prosthetic heme group with a ferrous iron.<sup>27</sup> Binding of NO to the heme iron modifies the enzyme and increases its catalytic activity. The bioavailability of NO is frequently reduced in CHF due to oxidative stress

**FIGURE 18-6** Schematic illustrating three different forms of soluble guanylate cyclase and their respective responsiveness to nitrovasodilators, heme-dependent sGC stimulators (e.g., BAY 41-2272), and heme-independent sGC activators (e.g., cinaciguat [also known as BAY 58-2667]). Nitric oxide (NO) and nitrovasodilators only stimulate sGC when it contains the heme moiety with a ferrous iron ( $\text{Fe}^{2+}$ ); furthermore, NO and nitrovasodilators have cGMP-independent actions. BAY 41-2272 also activates only the NO-sensitive sGC but without the cGMP-independent actions of NO and nitrovasodilators. Cinaciguat activates heme-free sGC, which is insensitive to NO, and also inhibits its degradation. The question marks indicate that little is known about the transition between the different forms, their prevalence in health and disease, and their potential restoration to the reduced, NO-sensitive form. cGMP, cyclic guanosine monophosphate; Fe, iron; sGC, soluble guanylate cyclase. (From Boerrigter G, Burnett JC Jr. Soluble guanylate cyclase: not a dull enzyme. *Circulation* 2009;119(21):2752-2754.<sup>70</sup>)

leading to attenuated NO/sGC/cGMP signaling in vascular and renal tissues contributing to endothelial dysfunction. Furthermore, recent studies showed that the heme of sGC can be oxidized or removed, rendering the enzyme insensitive to endogenous NO or conventional nitrovasodilators (Figure 18-6). This endothelial or vascular dysfunction provides a rationale for the therapeutic enhancement of the NO/sGC/cGMP pathway, which is discussed later with conventional and novel sGC activators.

Soluble GC stimulation with nitrovasodilators has been used for over a century.<sup>28</sup> Importantly, long-term administration of nitrovasodilators is associated with the development of tolerance and cGMP-independent actions, which may have beneficial but also detrimental actions. The detrimental actions of nitrovasodilators include oxidative stress, mitochondrial toxicity, endothelial dysfunction, and protein nitrosation.<sup>29-31</sup> These adverse effects can partially be prevented by hydralazine, which possesses antioxidant properties. This may explain the results of clinical trials in which patients who received a combination of a nitrate (isosorbide dinitrate) and hydralazine had improved outcomes compared with a placebo before the introduction of ACE inhibitors and more recently in African Americans even on top of therapy with ACE inhibitors and  $\beta$ -blockers.<sup>32,72</sup>

In a key study Ko et al reported in 1994 that the molecule YC-1 activates sGC directly (i.e., independently of NO), prompting studies to develop such agents for cardiovascular therapeutic purposes such as CHF.<sup>33</sup> Two new classes of direct sGC stimulators, one NO-independent but heme-dependent, the other both NO- and heme-independent, have been developed and are potent renal and systemic vasodilating compounds. The former class only stimulates sGC if the heme iron is in the ferrous state ( $\text{Fe}^{2+}$ ), whereas the latter class stimulates the enzyme preferentially when the heme is absent.<sup>34</sup>

The first orally available NO-independent but heme-dependent sGC stimulator to be described is BAY 41-2272.<sup>35</sup> This novel agent binds to a regulatory site on sGC and activates it synergistically with NO and can thus be considered an

“NO sensitizer.” In experimental CHF induced by rapid right ventricular pacing, BAY 41-2272 decreased mean arterial pressure, pulmonary capillary wedge pressure and systemic and renal vascular resistances and increased cardiac output and renal blood flow.<sup>36</sup> The hemodynamic actions were similar to nitroglycerin with the important exception of right atrial pressure, which decreased with nitroglycerin but was unchanged with BAY 41-2272. This difference could be explained by recognizing that BAY 41-2272 acts synergistically with NO, which may be more abundant in arteries than veins. In contrast, nitroglycerin is bioactivated preferentially in the veins. Further drug optimization led to the development of riociguat, which is currently in clinical trials for pulmonary hypertension.<sup>37</sup>

The first reported NO- and heme-independent sGC activator is cinaciguat (also referred to as BAY 58-2667), which activates sGC as it competes with and replaces the heme moiety, which in the non-nitrosylated state inhibits enzyme activity.<sup>38</sup> Interestingly, heme-oxidized sGC is usually ubiquitinated and destined for proteosomal degradation; however, cinaciguat stabilizes the heme-free enzyme and prevents its degradation.<sup>39</sup> Stasch et al reported that in various experimental cardiovascular disease conditions the potency of nitrovasodilators was reduced, whereas it was increased for cinaciguat, strongly suggesting an increased prevalence of oxidized or heme-free sGC.<sup>40</sup> These findings provide evidence for a potential additional pathophysiological mechanism contributing to renal and systemic endothelial and vascular smooth muscle cell dysfunction in CHF.

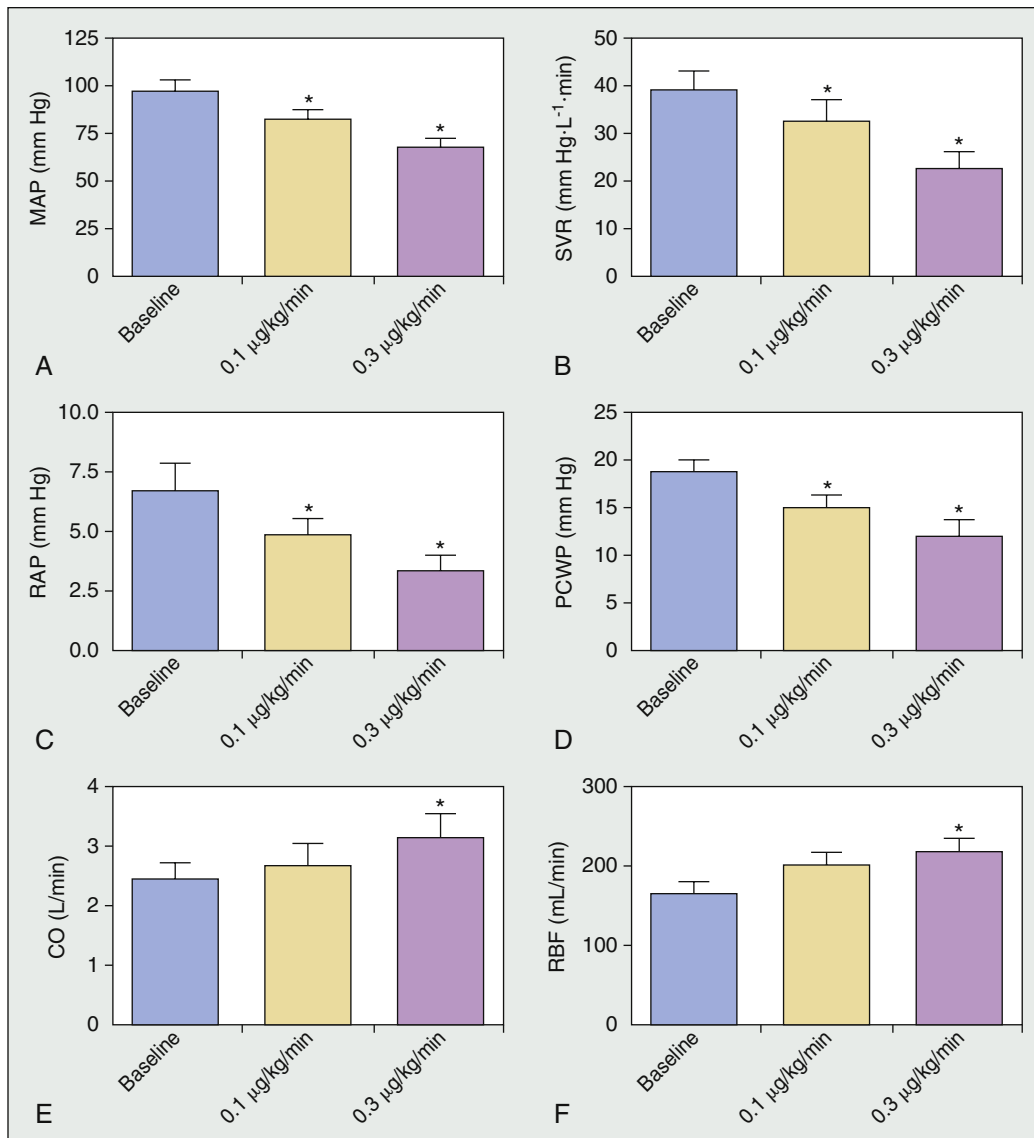

Cinaciguat also has an additive effect with NO and lowers blood pressure in rats and healthy canines. In experimental pacing-induced CHF, cinaciguat was a potent renovasodilator and had hemodynamic actions similar to nitroglycerin with reductions in mean arterial and pulmonary capillary wedge pressure, systemic and renal vascular resistance, and increases in cardiac output and renal blood flow (Figure 18-7).<sup>41</sup> Unlike BAY 41-2272, cinaciguat decreased right atrial pressure. GFR and urinary sodium excretion were preserved despite the hypotensive actions. There was also no activation of renin or aldosterone, whereas ANP and BNP decreased, consistent with cardiac unloading.

Cinaciguat therefore displays promising cardiorenal properties in experimental CHF and preserves renal function. Most recently, an unblinded, uncontrolled proof-of-concept study was reported. Specifically, Lapp et al assessed the effect of cinaciguat on hemodynamic and symptomatic status in patients admitted to the hospital with acute decompensated CHF, NYHA class III/IV symptoms, PCWP of 18 mm Hg or more, parenteral pharmacotherapy, and invasive hemodynamic monitoring.<sup>42</sup> Cinaciguat significantly reduced PCWP, right atrial pressure, and systemic and pulmonary vascular resistances, while cardiac output increased. A PCWP reduction of 4 mm Hg was achieved in 53%, 83%, and 90% after 2, 4, and 6 hours, respectively, which was associated with an improvement in symptomatic status as assessed by a dyspnea score. This study shows that also in human CHF there exists a pool of oxidized or heme-free sGC that can be activated by cinaciguat with favorable cardiac preload and afterload reduction, warranting further studies especially looking at the kidney.

## THE NATRIURETIC PEPTIDE PATHWAYS: ACTIVATORS OF RENAL PARTICULATE GUANYLYL CYCLASES

The natriuretic peptides ANP and BNP are secreted by the heart in response to cardiac overload such as CHF and via the GC-A stimulate the production of cGMP. They have natriuretic, diuretic, vasodilating, and renin- and aldosterone-suppressing actions that help to unload the heart. Moreover, ANP and BNP have antihypertrophic, antifibrotic,

**FIGURE 18-7** Effect of cinaciguat (BAY 58-2667) administration on (A) mean arterial pressure (MAP), (B) systemic vascular resistance, (C) right atrial pressure (RAP), (D) pulmonary capillary wedge pressure (PCWP), (E) cardiac output (CO), and (F) renal blood flow (RBF). \* Indicates  $P < .05$  compared with baseline. (From Boerrigter G, Costello-Boerrigter LC, Cataliotti A, et al. Targeting heme-oxidized soluble guanylate cyclase in experimental heart failure. *Hypertension* 2007;49(5):1128-1133.<sup>41</sup>)

and positive lusitropic properties.<sup>43-45</sup> CNP of endothelial origin functions via activation of NPR-B and is a more autocrine/paracrine peptide in endothelial cell/vascular smooth muscle cell control, with vasodilating actions, especially in the venous circulation.<sup>46</sup> CNP, however, is not natriuretic. Importantly, in more advanced CHF stages, the response to endogenous and exogenous NPs is blunted, which can at least partially be overcome by administration of exogenous NPs, providing a rationale for pharmacologically augmenting the NP system. This is possible in various ways (e.g., administration of exogenous NPs or prolonging the bioactivity of endogenous NPs by inhibiting their degradation [see Figure 18-2]).

## B-TYPE NATRIURETIC PEPTIDE

Supporting the use of BNP as a therapy in human CHF were studies in experimental CHF, one of which reported that BNP augmented the diuretic and natriuretic response to furosemide, increased GFR, and prevented an increase in aldosterone induced by furosemide alone.<sup>47</sup> Nesiritide is a recombinant form of human BNP and was approved for the

treatment of acute decompensated CHF in the United States in 2001 (see also Chapters 43 and 44). In the VMAC trial, which led to BNP approval by the FDA, nesiritide resulted a larger decrease in pulmonary capillary wedge pressure at 3 and 24 hours as compared with a placebo and nitroglycerin, although symptomatic status was not improved compared with nitroglycerin.<sup>48</sup> It should be noted that subsequent meta-analyses of publicly available studies suggested that nesiritide was associated with an increase in serum creatinine and mortality.<sup>49,50</sup> The mechanism for these findings is unclear but possibly the nesiritide dose administered, particularly the bolus, may have contributed to hypotension, which due to BNP's half-life would be more prolonged as compared with, for example, nitroglycerin. Subsequent small studies reported no indication for detrimental or beneficial renal effects of nesiritide in acute decompensated CHF.<sup>51-54</sup>

Supporting the use of BNP as a therapy in human CHF were studies in experimental CHF, one of which reported importantly, in the NAPA trial, nesiritide or placebo ( $n = 138$ ) was given to patients with a left ventricular ejection fraction of 40% or less undergoing bypass surgery with anticipated cardiopulmonary bypass (Figure 18-8).<sup>55</sup> Patients

**FIGURE 18-8** Adjusted mean maximum decrease in glomerular filtration rate (GFR) from baseline through hospital discharge or by study day 14, whichever came first, using an analysis of covariance model. Error bars indicate standard error of the mean (A). Kaplan-Meier survival curve to day 180 by treatment group in the “safety population,” which is a subset of the total study population added during the study to assess long-term safety (B). BL, Baseline; GFR, glomerular filtration rate; sCr, serum creatinine. (From Mentzer RM Jr, Oz MC, Sladen RN, et al. Effects of perioperative nesiritide in patients with left ventricular dysfunction undergoing cardiac surgery: the NAPA trial. *J Am Coll Cardiol* 2007;49(6):716-726.<sup>55</sup>)

randomized to nesiritide had a smaller rise in serum creatinine, larger urine output, shorter hospital stay, and a lower 180-day mortality. Similarly, in a study of patients with reduced renal function undergoing cardiac bypass surgery, randomization to nesiritide as compared with control improved postoperative renal function.<sup>56</sup> Another possible indication where studies are pursued is nesiritide as a treatment to ameliorate remodeling after a myocardial infarction in an effort to reduce CHF, which is supported by a recent report demonstrating cardioprotective properties of BNP in human MI.<sup>57</sup> Importantly, a 7000-patient acute CHF trial (ASCEND) is nearing completion addressing the safety and efficacy of BNP.<sup>58</sup>

### CHIMERIC NATRIURETIC PEPTIDES: CD-NP

Snake venom has been the source of several peptides that have been useful in the development of cardiovascular drugs and include agents such as the ACE inhibitor captopril and the glycoprotein IIb/IIIa antagonist eptifibatide. Schweitz et al reported the in vitro biological actions of a newly discovered peptide, *Dendroaspis* natriuretic peptide (DNP), which was isolated from the venom of the green mamba. DNP, like ANP and BNP, activates GC-A and binds to the natriuretic peptide clearance receptor, but it does not activate GC-B. GC-A and the natriuretic peptide clearance receptor, but not GC-B.<sup>59</sup> We reported that DNP in vivo was potently natriuretic and diuretic and possessed cardiac unloading actions but with

significant hypotensive properties.<sup>60,61</sup> These in vivo actions of DNP are consistent with GC-A activation as such effects mimic ANP and BNP but not CNP.

A structural feature of DNP is that it possesses the longest C-terminus of the known natriuretic peptides consisting of 15 amino acids (AA) as compared with 5 AA for ANP, 6 AA for BNP, and none for CNP. This long C-terminus of DNP may make DNP highly resistant to degradation by neutral endopeptidase, which is highly expressed in the kidney, contributing to potent natriuretic and diuretic actions.<sup>62</sup> Further, the lack of a C-terminus for CNP may explain the observation that of the three known endogenous natriuretic peptides CNP is the most susceptible to degradation by NEP, which could limit its renal actions.<sup>63</sup>

We recently reported that fusion of the 15 AA C-terminus of DNP onto the C-terminus position resulted in a synthetic chimeric NP that in vivo possessed the cardiac unloading actions of CNP with minimal hypotensive properties compared with BNP together with the additional renal effects of natriuresis and diuresis (Figure 18-9).<sup>64</sup> We also observed that this designer peptide called CD-NP retained properties of CNP in vitro in activating cGMP in cardiac fibroblasts and inhibiting cell proliferation. Further, in vitro studies also reported that CD-NP activates both GC-A and GC-B (B>A).<sup>65</sup> Thus this chimeric NP possesses potentially beneficial efficacy and safety for the treatment of cardiorenal disease states such as CHF. A first-in-human study was recently completed in normal human subjects and demonstrated activation of plasma and

**FIGURE 18-9** CD-NP is a chimeric peptide consisting of the amino terminus and ring structure of C-type natriuretic peptide and the carboxy terminus of *Dendroaspis* natriuretic peptide.

urinary cGMP, natriuresis, and aldosterone suppression with minimal actions on arterial pressure.<sup>66</sup> Human trials in CHF are currently under way.

## PHOSPHODIESTERASE INHIBITION

It is now well established that the cGMP signal is effectively terminated by the action of specific phosphodiesterases (PDEs) that hydrolyze cGMP to GMP. Inhibition of the isoenzyme PDE5 (e.g., with sildenafil, vardenafil, tadalafil) reduces vascular tone particularly in the corpus cavernosum and the pulmonary vasculature, leading to its application in erectile dysfunction and pulmonary arterial hypertension. In a mouse model of pressure overload due to aortic banding, chronic sildenafil attenuated cardiac hypertrophy, dilation, and fibrosis, and improved cardiac function.<sup>67</sup> Importantly, cardiac hypertrophy was not only prevented but, once established, could be reversed with sildenafil. This was associated with decreased activation of hypertrophic factors such as calcineurin, the mitogen-activated kinase ERK1/2, Akt, and PI3Kα.

In experimental CHF, chronic PDE5 inhibition with sildenafil reduced systemic vascular resistance and increased cardiac output but did not affect cardiac filling pressures or renal function.<sup>68</sup> In addition, chronic PDE5 inhibition augmented the renal response to acutely administered BNP. This combined therapy augmented GFR, further reduced tubular reabsorption of sodium, and increased sodium and water excretion. An emerging strategy for optimizing renal function in CHF is to activate GC receptors linked to the NPs and to inhibit the degradation of cGMP by PDE5. Indeed, we have reported the increase in renal PDE5 activity in experimental CHF underscoring the rationale for combined NP and PDE5 inhibition in CHF to enhance renal function.<sup>69</sup>

## OPTIMIZING sGC-pCG SIGNALING IN THE KIDNEY IN CHF

As illustrated in Figure 18-5, cGMP is generated by activation of pGC receptors to which the NPs bind or by stimulation of sGC by NO. We recently investigated the contribution of the renal NP/pGC/cGMP and NO/sGC/cGMP pathways in preserving renal function in acute CHF in which there are acute increases in the circulating NPs together with an intact renal NO system.<sup>25</sup> We used a large animal model of acute CHF. Renal hemodynamic and tubular function were assessed in the presence and absence of antagonism of the

endogenous GC receptors or inhibition of NO release. Particulate GC antagonism reduced GFR and sodium excretion but did not alter renal blood flow. In contrast, NO inhibition only decreased renal blood flow and did not alter either GFR or urinary sodium excretion. These studies demonstrate distinct roles for cGMP pathways (pGC vs. sGC) in the preservation of renal function in CHF in which GFR and sodium reabsorption are more linked to the NPs and pGC while renal blood flow is more linked to NO and sGC. These studies support the concept of “physiological compartmentalization” of cGMP in the kidney. Thus optimization of the cGMP pathways in the kidney would involve targeting GC-A/-B and sGC with inhibition of PDE5. Such a strategy is currently being defined in experimental CHF with severe renal dysfunction.

## SUMMARY

Renal dysfunction is an important independent predictor of adverse outcomes in CHF and frequently poses a therapeutic challenge, underscoring the need for new treatment strategies. Cyclic GMP in the kidney is a second messenger vital in the optimal regulation of renal function. Novel drugs are now available to enhance this signaling pathway with novel NO-independent and dependent sGC stimulators, GC-A and GC-B agonists, and PDE inhibitors. Given promising preclinical and clinical data, it is likely that the cGMP system will remain an attractive area of research and drug development. Indeed, in strategies targeting cardiorenal function in CHF, the focus has been on antagonizing endogenous neurohumoral systems. Cyclic GMP research has now opened a new direction in CHF therapeutics with an innovative way to enhance signaling pathways that possess properties of cardiorenal protection warranting further basic and clinical research.

## Alterations in Diaphragmatic and Skeletal Muscle in Heart Failure

Thierry H. Le Jemtel and Donna M. Mancini

Skeletal and diaphragmatic muscle alterations have been extensively reviewed in patients and experimental models of heart failure (HF) due to left ventricular (LV) systolic dysfunction.<sup>1-7</sup> Accordingly, the first aim of this chapter is to provide a concise summary of the vascular atrophic and meta-

Stage A attests to a high risk of developing HF; Stage B includes LV remodeling in the absence of symptoms<sup>20</sup>; Stage C is defined by the occurrence and progression of symptoms; Stage D denotes the presence of a low cardiac output. From a clinical standpoint, SM alterations are most relevant at stage C where both enhancement of LV systolic function and reversal of SM alterations are required for sustained functional improvement while at stage D enhancement of LV systolic function alone results in immediate functional improvement. In summary, partial or complete reversal of SM alterations is required at stage C to restore the functional capacity of HF patients to that of age- and gender-matched controls.<sup>21</sup>

### Vascular Alterations

While lower limb blood flow may increase up to 20 times from rest to peak exercise in healthy subjects, lower limb flow can increase only 2 to 3 times in patients with advanced HF due to LV systolic dysfunction.<sup>11,22</sup> Thus the vasodilatory response of the lower limb SM beds to exercise is relatively much more impaired than that of the cardiac output in severe HF. Some investigators have failed to observe a limited vasodilatory response of SM beds to exercise in patients with severe HF.<sup>23-25</sup> Cause of HF (primarily due to valvular disease rather than end-stage cardiomyopathy), and technical issues in the measurement of skeletal muscle blood flow (use of single thermistor for the thermodilution technique and measurement of blood flow draining other tissues than skeletal muscles) may in part explain the disparate findings. At stage C of HF, SM perfusion during exercise is primarily limited by an impaired vasodilatory response of lower limb SM beds and not by the cardiac output response to exercise. At stage D of CHF, SM perfusion during exercise is limited by the cardiac output response as it is in normal subjects.<sup>22</sup> The findings regarding SM microcirculation are controversial in severe HF.<sup>4</sup> Capillary density has been reported to be normal or decreased depending on normalization to

bolic skeletal muscle (SM) alterations that have been reported in patients with HF. The second aim is to review recent human and experimental investigations that have focused on the underlying mechanisms of SM alterations and possible novel therapeutic strategies. The third aim of the chapter is to provide an update on diaphragmatic muscle alterations in HF and the impact of diaphragmatic muscle alterations on the symptomatic progression of HF syndrome.

### SKELETAL MUSCLE IN HEART FAILURE

The view that alterations of skeletal muscle (SM) vasculature metabolism and mass play an important role in limiting peak functional capacity in patients with heart failure (HF) is now well accepted.<sup>8,9</sup> Vascular metabolic and atrophic alterations have been thoroughly documented in skeletal and diaphragmatic muscle of patients with HF.<sup>10-14</sup> However, the cascade of events and mechanisms that are responsible for SM alterations remain somewhat controversial in HF. Most investigators agree that reduced physical activity (disuse) plays an important role in the pathogenesis of SM alterations in HF and that HF-related SM alterations do not substantially differ from those observed in other chronic conditions, such as chronic obstructive pulmonary disease (COPD) or chronic kidney disease (CKD).<sup>15</sup> Paradoxically, while disuse was becoming increasingly recognized as an important determinant of HF-related SM alterations, alleviating disuse by exercise training was recently reported to have a modest impact on SM alterations as assessed by the change peak functional capacity in the HF-ACTION trial (see also Chapter 57).<sup>16</sup> Confronted with exercise training's limited benefits, investigators are seeking novel approaches to reverse or better prevent the development of SM alterations in patients with HF. Investigative efforts focusing on molecular pathways that mediate SM alterations in patients with CHF are presently under way with the aim of developing innovative therapeutic strategies.

Besides disuse, HF is associated with low-level systemic inflammation (see also Chapter 11) that fosters development of SM alterations. (see also Chapter 57)<sup>17,18</sup> As SM alterations become more severe, inflammatory mediators are released into the circulation, thereby deepening systemic inflammation that in turn promote SM atrophy. Accentuation of the muscle mechanoreflex in HF heightens sympathetic nervous activation (SNA) during exercise, resulting in vasoconstriction and metabolic derangements that may exacerbate SM alterations.<sup>19</sup> Progression of SM alterations in HF appears to be largely dependent on local factors and is not directly related to deterioration of LV systolic or diastolic function.

### Skeletal Muscle Alterations and Stages of Heart Failure

Skeletal muscle alterations develop and worsen concomitantly to the occurrence and deterioration of symptoms in patients with HF. Progression of HF due to LV systolic dysfunction is currently being summarized in four stages:

the muscle fibers' number and size. Duscha et al measured vascular density in the skeletal muscle of patients with HF.<sup>26</sup> Using cell-specific antibodies to measure vascular density, these investigators found decreased numbers of endothelial cells per fiber, which indicates a reduced capillary density. However, since capillary density varies with fiber type, and fiber-type switching is a dynamic process in patients with HF, studies on capillary density ratio should be interpreted with caution. Other investigators have reported a normal skeletal muscle capillary density in patients with HF.<sup>27</sup> Thickness of the capillary basement membrane is increased in the pronator teres muscle of patients with HF.<sup>28</sup> Finally, the resistance of the microvasculature is only minimally increased in the cutaneous tissue in patients with HF.<sup>29</sup> Of note, although vascular endothelial dysfunction (an important determinant of capillary behavior during exercise) is impaired in HF, oxygen extraction by exercising SM is nearly complete in severely symptomatic patients.<sup>30</sup> Similarly, reduced SM oxidative capacity does not limit oxygen extraction by exercising muscles in HF.<sup>31</sup> The oxygen content of the deep femoral vein that exclusively drains skeletal muscle is less than 1 to 2 mL/100 mL in patients with severe HF.<sup>30</sup> In summary, while skeletal muscle capillary density is likely to be altered in HF and oxidative capacity is reduced, they do not limit oxygen extraction by exercising muscles.

The mechanisms of vascular SM alterations are incompletely understood in HF. Few studies have dealt with vascular smooth muscle function while vascular endothelial function and particularly nitric oxide (NO)-mediated control of vasomotor tone has been extensively studied in HF.<sup>32-35</sup> Endothelial function was first evaluated in the upper limb vasculature by measuring forearm blood flow in response to methacholine, an endothelium-dependent dilator, and nitroprusside, an endothelium-independent dilator.<sup>35</sup> Blood flow was measured by venous plethysmography. The response to methacholine was significantly lower in patients with HF, when compared with age-matched controls, while the response to nitroprusside tended to be lower, although it did not reach statistical significance. The blunted response to methacholine implies that patients with HF have an impaired reserve of vascular endothelium. Endothelial function was studied in the lower limb vasculature of patients with HF using Doppler ultrasonography of the superficial femoral artery.<sup>34</sup> Patients did not have comorbid vascular disease that could have contributed to endothelial dysfunction. The maximal velocity of blood using a volume sampler positioned in the center of the vessel was evaluated during intraarterial administration of acetylcholine, an endothelial-dependent dilator, and nitroglycerin, an endothelial-independent dilator. Maximal blood flow velocity did not increase in response to acetylcholine at concentrations of 10-5M, while it increased by fivefold in healthy subjects. Maximal blood flow velocity in response to nitroglycerin at 10-7M was substantially reduced in patients when compared with the response elicited in healthy subjects. Following administration of a dose of nitroglycerin at 5 to 10 M, patients with HF experienced an increase in maximal blood flow velocity similar to that produced by nitroglycerin at 7 to 10 M in healthy subjects. The lack of response to acetylcholine clearly demonstrates the absence of functional reserve of the vascular endothelium in patients with HF. However, reduced vascular endothelial function in patients with HF may in part be due to reduced functional integrity of the cyclic GMP pathway that is evidenced by the depressed response to nitroglycerin. The mechanisms that are responsible and mediate the progression of vascular endothelial function in patients with HF are still poorly understood. Furthermore, the state of vascular function under basal conditions in patients with CHF is still debated. Administration of L-NMMA (N-monomethyl-L-arginine), a selective inhibitor of the production of NO from arginine, yielded similar

forearm blood flow decreases in patients with CHF and in healthy subjects.<sup>36,37</sup> However, others observed the expected decrease in blood flow following administration of L-NMMA in healthy subjects, but did not observe a decrease in patients with CHF.<sup>38</sup> Experimental data indicate that increases in oxidative stress associated with heart failure may accelerate NO degradation, and thus may impact on NO availability.<sup>39</sup>

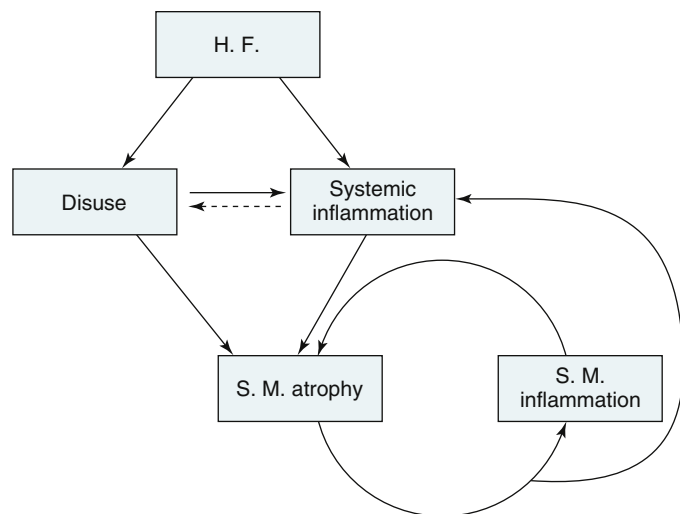

In the rat model, heart failure induced by ligation of the left anterior descending artery causes progressive peripheral vascular endothelial dysfunction.<sup>40</sup> The systemic vascular response to acetylcholine was not decreased until 4 weeks after coronary ligation and progressively worsened through week 16. Similar data are not available in human subjects. The mechanisms that mediate vascular endothelial dysfunction early in the course of heart failure are likely to be different from those responsible at later stages. In patients with symptomatic HF, the improvement induced by vitamin C administration and subsequent decreased extracellular SOD (superoxide dismutase) activity implies that increased oxidative stress may accelerate NO degradation, and may be partially responsible for vascular endothelial dysfunction.<sup>41</sup> Our data suggest that there is increased expression of endothelial NO synthase (eNOS) when normalized to Von Willebrand factor in the vastus lateralis muscle of patients with CHF.<sup>42</sup> Increased eNOS endothelial expression implies the development of an adaptive mechanism to compensate for accelerated NO degradation.

## Skeletal Muscle Mass

Calf muscle mass was reported to be significantly lower in patients with severe HF as evidenced by a peak  $\dot{V}O_2$  of 13 mL/min/kg when compared with age- and gender-matched controls. Approximately two thirds of these patients have a reduced calf mass that correlates only weakly ( $r = 0.48$ ) with peak oxygen uptake.<sup>10</sup> Overall the data regarding SM mass are disparate in patients with HF with some investigators reporting a normal muscle mass in patients with average peak oxygen uptake of 13.4 mL/kg/min while others are reporting a reduced muscle mass in patients with average peak oxygen uptake of 18.0 mL/kg/min.<sup>43</sup> In contrast to the controversial data on muscle mass, most investigators report decreased muscle strength when normalized to fiber cross-sectional areas in patients with HF.<sup>4</sup> Slowing of relaxation and steady decline in strength have been reported during low-frequency stimulation of slow-twitch muscles in rats with congestive HF.<sup>44</sup> Reduced isometric force and calcium-activated actomyosin (AM) ATPase activity in patients with HF may be due to a decline in density of contractile proteins, in the rate of cross-bridge attachment, or in both.<sup>45</sup> A reduction in contractile protein content appears to be the most likely explanation of reduced muscle strength since SM contractile protein function has been reported to be unaltered in patients with HF.<sup>46</sup>

Exertional shortness of breath and fatigue are the cornerstones of the clinical syndrome of HF. Exertional symptoms induce physical inactivity that results in disuse. The syndrome of HF is a low level inflammatory state. Both disuse and systemic inflammation are initially responsible for loss of SM mass and atrophy in patients with HF (Figure 19-1). Thereafter, SM atrophy steadily progresses in the absence of intervention. The progression of SM atrophy appears to be more closely related to an ongoing interaction between atrophy and local inflammation than to deterioration of LV dysfunction and HF (see Figure 19-1). The lack of correlation between progression of SM alterations and deterioration of LV function accounts in part for the discordant reports of SM alterations in HF due to LV systolic dysfunction. Furthermore, SM alterations are not easily quantifiable in patients and many SM parameters have no direct clinical correlates.

**FIGURE 19-1** Heart failure (HF) results in reduced physical activity (disuse) as shortness of breath and fatigue during exercise tend to limit physical activity. Patients with HF exhibit a low-level inflammatory state as evidenced by mildly elevated levels of circulating inflammatory mediators. Both disuse and systemic inflammation promote skeletal muscle (SM) atrophy that leads to SM inflammation and further loss of SM mass. In addition, SM inflammation fosters systemic inflammation that combined with disuse exacerbates SM atrophy. Disuse is associated with systemic inflammation that may negatively impact on functional capacity. Once loss of SM mass occurs, it tends to progress independently from the initiating cause.

Skeletal muscle atrophy promotes local inflammation that in turn exacerbates SM atrophy via multiple mechanisms. In addition, SM inflammation exacerbates systemic inflammation that results in further muscle atrophy. Akin to LV remodeling, which may progress independently from the initial cardiac event and is influenced by the presence of comorbid conditions such as diabetes or hypertension, SM alterations develop and progress in HF independently from LV dysfunction. As previously mentioned, magnitude of SM alterations and severity of LV dysfunction are not closely related.

Although intuitively plausible, experimental data do not support disuse as a cause of SM atrophy in HF. In a rat coronary ligation model of HF, changes in SM morphology and gene expression could not be explained by reduced activity.<sup>47</sup> However, limited activity of animals housed in cages and sham thoracotomy in control animals may have substantially reduced the likelihood of recording different activity levels between failing and control animals. A strong argument for the role of disuse in the pathogenesis of SM alterations comes from the observation that conditions which share disuse as a common trait but are as different as COPD, CKD, and chronic HF result in comparable SM alterations.<sup>48</sup> Physical inactivity in patients with CHF affect primarily the lower limb SM because patients—due to exertional shortness of breath and fatigue—curtail walking and climbing stairs long before they curtail physical activities involving the upper limbs when they experience symptoms at rest.<sup>49</sup> Thus studies of forearm SM in HF need to include a precise staging of symptoms and possibly the occupation of patients before they develop HF. Since these parameters are quite subjective and often poorly reported, the findings of forearm muscle studies in HF are commonly difficult to interpret.

The modest effect of exercise training on peak functional capacity in the HF-ACTION trial appears to argue against disuse playing an important role in the pathogenesis of SM alterations in HF. However, several carefully conducted single-center studies have thoroughly demonstrated the beneficial effects of exercise training on SM in patients with HF.<sup>50,51</sup> The unimpressive findings of the HF-ACTION trial underline how difficult it is to enforce strict adherence to exercise training

in a large study population. The findings of the HF-ACTION trial do not invalidate the previously well-documented beneficial effects of exercise training on functional capacity and SM mass in smaller populations of HF patients.

## Skeletal Muscle Fiber Composition

Adult human SM is composed of four fiber types: type I, IIa, IIb, and IIx. The fiber types are defined by their myosin heavy chain isoforms and are identified based on differential immunocytochemistry staining for myosin ATPase.<sup>52</sup> Type I fibers are slow-twitch fibers, so-called because they have a slowly propagated action potential. They develop low tension and primarily use aerobic or oxidative metabolism to generate ATP. They typically contain an abundance of mitochondria and use ATP very slowly, and are therefore fatigue-resistant fibers. Type I fibers are necessary for endurance activity; this includes posture, repetitive movements, and also long-distance exercise. In contrast, type IIb/x fibers are fast-twitch fibers that develop large tensions and rely on anaerobic metabolism to generate ATP. They have fewer mitochondria and use ATP very quickly. They are responsible for muscle power, in short bursts, but fatigue easily because anaerobic or glycolytic energy pathways are much less efficient in generating ATP. Type IIa fibers are a hybrid of fast and slow-twitch; they have the capacity to achieve great tension, but also have some measure of endurance. As expected, they rely on both aerobic and anaerobic metabolism to generate energy.<sup>52</sup> It may be that type IIa fibers are in the process of fiber type switching.

Patients with HF have an increased number of type IIb/x fibers (anaerobic, glycolytic) as compared with type I (aerobic, oxidative).<sup>12,14,54</sup> When compared with deconditioning-related SM atrophy, HF-related SM atrophy is more selective for type II. Mancini<sup>10</sup> et al reported an increased percentage of type IIb fibers and trends toward a decreased percentage of type I in the gastrocnemius muscle of patients with CHF. However, due to reduced areas of type IIb fibers, the relative contribution of each fiber type in a given cross-sectional area of muscle was not different between CHF patients and normal subjects. Interestingly, the percentage of type IIb fibers correlated inversely with peak oxygen uptake. Drexler<sup>14</sup> et al also found that fiber distribution was shifted toward type II fibers in the vastus lateralis of patients with HF. There was also decreased volume density of the mitochondria and surface density of the mitochondrial cristae, implying that oxidative transport coupling was compromised. Decreased mitochondrial density and surface density of mitochondrial cristae occurred mostly in patients with peak  $\dot{V}O_2$  averaging 12 mL/kg/min. Patients whose peak  $\dot{V}O_2$  was normal (more than 25 mL/kg/min) had normal mitochondrial parameters compared with controls. The decreased mitochondrial volume correlated with peak aerobic capacity, suggesting a major contribution of altered skeletal muscle metabolism to exercise intolerance. Recently, Mettauer<sup>55</sup> et al compared intrinsic mitochondrial function in the vastus lateralis muscle of patients with CHF to that of sedentary and active controls. The basal and stimulated oxidative parameters of the entire mitochondrial population were similar in CHF patients and sedentary controls, but were reduced when compared with the active controls. In agreement with previous reports,<sup>12,56</sup> the content of intramitochondrial Krebs cycle citrate synthase was lowest in HF patients. The level in sedentary subjects was also reduced, as compared with active subjects, but not as low as that found in patients with CHF. Total cytosolic creatine kinase (CK), skeletal muscle-specific CK (MM-CK), and lactate dehydrogenase (LDH) were lower in CHF patients. In experimental preparations, including myocardial infarction and moderate heart failure, angiotensin-converting enzyme inhibition completely prevents the fiber switch from type I to II in the skeletal muscle.<sup>57,58</sup> Similar observations were made

in the gastrocnemius muscle of patients with CHF following angiotensin-converting enzyme (ACE) inhibition or angiotensin receptor blockade for 6 months.<sup>59</sup>

## Skeletal Muscle Metabolism

Skeletal muscle metabolism has been studied by radioactive phosphorus nuclear magnetic resonance (31P-NMR) spectroscopy in patients with HF. Concomitant use of 31P-NMR to study SM metabolism and venous plethysmography to measure limb blood flow demonstrated that early SM acidosis during exercise occurs in the absence of an associated decrease in flow in patients with HF.<sup>60,61</sup> 31P-NMR spectroscopy consistently demonstrates the following abnormalities in the SM of patients with HF: accelerated rate of use of phosphocreatine (PCr, a high-energy phosphate), accumulation of inorganic phosphate (Pi, a by-product of ATP use), early intracellular acidification (low pH), and delayed PCr recovery after exercise. These abnormalities of SM metabolism were first reported in the forearm. Immediately after exercise, patients exhibited a greater than normal increase in the Pi/PCr ratio and a decrease in pH.<sup>62-64</sup> The lack of correlation between forearm blood flow assessed immediately after exercise by plethysmography and the previously mentioned metabolic abnormalities was offered as evidence that reduced SM perfusion is not responsible for the metabolic abnormalities.<sup>60,61,63</sup> Taking into account that forearm blood flow was most likely normal in the patients studied by 31P-NMR spectroscopy, a lack of correlation between flow and metabolism was expected. Thus the anticipated lack of correlation between SM blood flow and metabolism has no bearing on the pathophysiology of SM alterations in HF. It is likely that forearm SM metabolic alterations were related to some degree of deconditioning among the patients studied by 31P-NMR spectroscopy. Chati<sup>65</sup> et al have clearly demonstrated that the rate of use of PCr, accumulation of Pi, and intracellular acidification are not different in the SM of patients with HF and sedentary normal subjects. Adamopoulos<sup>66</sup> et al showed that physical conditioning substantially corrects SM metabolic alterations in patients with HF. After undergoing 8 weeks of home-based bicycle exercise training in a randomized-cross-over trial, patients exhibited less PCr depletion and faster PCr recovery. Acidification was unaffected by physical conditioning. Metabolic abnormalities similar to those documented in the forearm were subsequently demonstrated in the thigh and leg of patients with CHF.<sup>64,67</sup> On the basis of a significant correlation between the slope of PCr decrease when related to workload and peak oxygen uptake, Okita<sup>67</sup> et al concluded that the metabolic abnormalities in the thigh muscles limit exercise capacity in patients with HF. Studying the calf, Mancini<sup>64</sup> et al failed to observe a correlation between the slope of the Pi/PCr over  $\dot{V}O_2$  ratio and muscle enzyme activities. In summary, SM metabolic alterations have been thoroughly documented by 31P-NMR spectroscopy in patients with HF. Overall, patients with HF experience SM metabolic alterations that are similar to those reported after deconditioning. Extent of SM atrophy and severity of SM fibrosis and inflammation rather than impairment in SM metabolism are likely to underlie 31P-NMR spectroscopy SM metabolic alterations. In patients with HF, 31P-NMR spectroscopy findings need to be normalized to the amount of underlying intact SM and extent of SM fibrosis and fat deposits.

## Excitation Contraction Coupling

Excitation contraction (EC) coupling of the basic SM contractile unit of the sarcomere is abnormal in HF. Skeletal muscles from animals with HF exhibit  $Ca^{2+}$  spark frequency, decreased  $Ca^{2+}$  spark amplitude, and increased  $Ca^{2+}$  spark duration consistent with leaky sarcoplasmic reticulum (SR)  $Ca^{2+}$  release

and with decreased SR  $Ca^{2+}$  content.<sup>68</sup> Heart failure is associated with elevated levels of circulating catecholamines and widespread activation of adrenergic signaling pathways. The type 1 ryanodine receptor (RyR1) becomes leaky in HF as chronic adrenergic stimulation results in cAMP-dependent protein kinase (PKA) hyperphosphorylation of the channel, which in turn dissociates calstabin-1, the stabilizing protein that keeps the RyR1 channel in a closed state from the channel.<sup>68</sup> Whether  $Ca^{2+}$  leak has any clinical correlates remains to be demonstrated in patients with HF. Data regarding SR  $Ca^{2+}$  pumping in HF differ in fast- and slow-twitch muscles and according to the level of fatigue.<sup>44</sup> In agreement with data in aging, SR  $Ca^{2+}$  pumping appears to be most impaired in slow-twitch muscles of animals with HF. Data regarding SM protein and mRNA expression of sarcoplasmic reticulum calcium (SERCA) ATPase are divergent in HF.<sup>1,69</sup> Predominant muscle fiber composition and nature of the HF model may in part account for the disparate findings that have been occasionally correlated with early muscle fatigue.

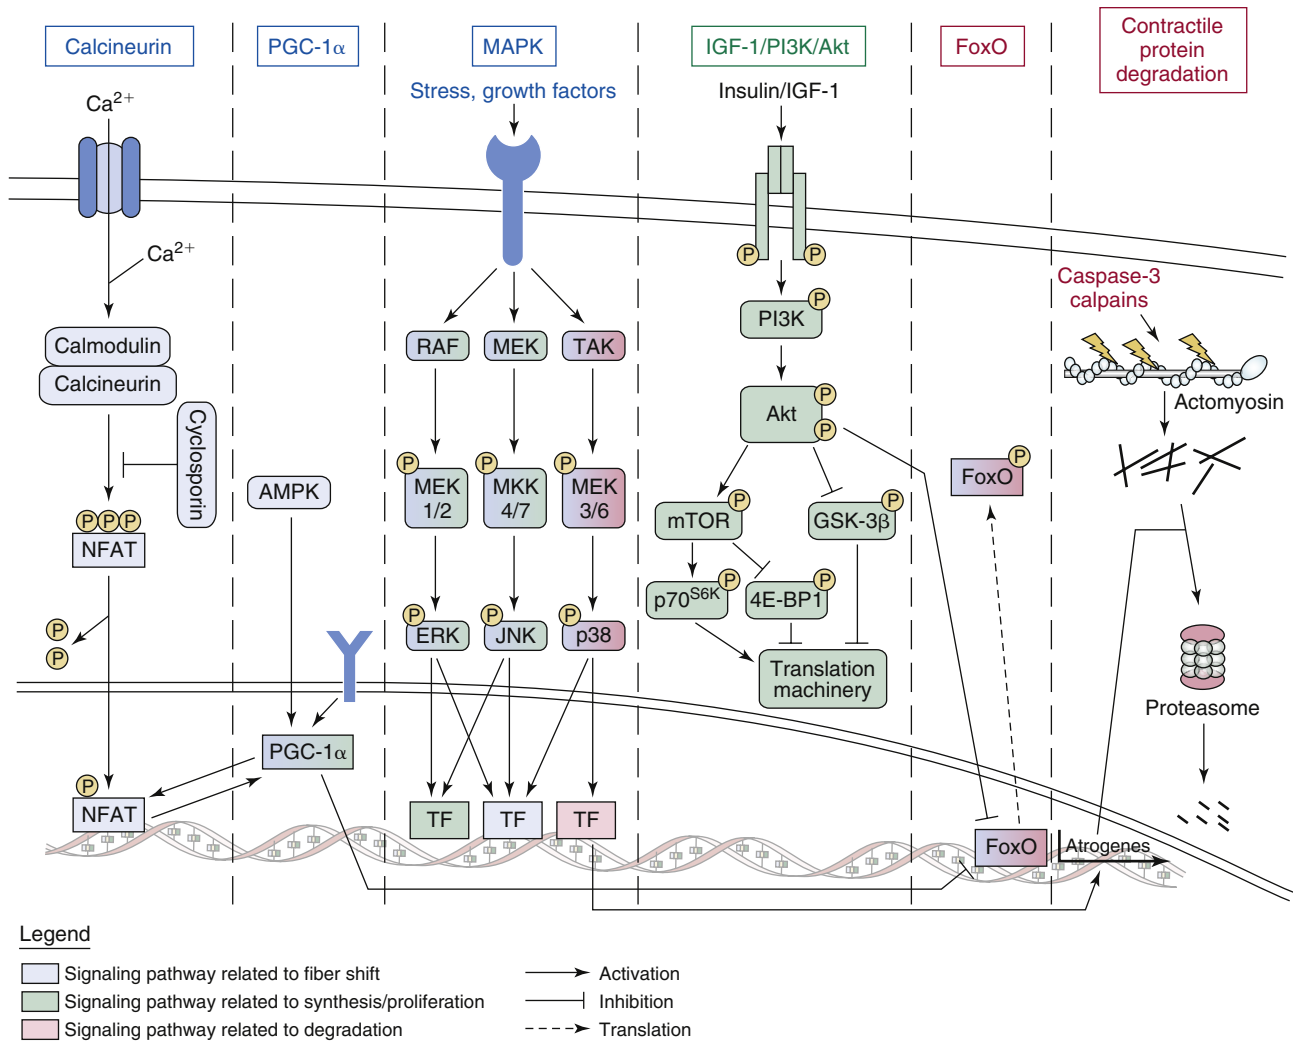

## Mechanisms of Skeletal Muscle Atrophy

The mechanisms that mediate SM wasting and atrophy have not been extensively investigated in patients with HF. Loss of SM mass can result from decreased protein synthesis, increased protein degradation, or both. Several key signaling pathways involved in protein degradation and synthesis are illustrated in Figure 19-2.<sup>70</sup> These pathways will be discussed in the following sections.

**Protein Degradation.** Recent experimental data in a mouse model of chronic HF due to ligation of the left coronary artery indicate that the ubiquitin-proteasome pathway plays an important role in HF-induced SM atrophy.<sup>71</sup> Ubiquitin protein ligases target specific proteins for ubiquitination. Proteins are marked by ubiquitin and subsequently rapidly degraded through the 26S proteasome, an ATP-dependent pathway that yields peptides and intact ubiquitin.<sup>4</sup> In experimental preparations, the ubiquitin-proteasome pathway was found to be activated as evidenced by selective induction of muscle-specific ubiquitin ligase atrogen-1 muscle atrophy Fbox (MAFbx), resulting in critical (FoxO) transcriptional factor activation.<sup>71</sup> Transgenic overexpression of MLC/mLgf-1 that encodes for a locally active isoform of IGF-1 prevents proteasome activation breakdown of SM structural proteins and atrophy.<sup>71</sup> Thus at least experimentally ubiquitin-mediated proteolytic degradation appears to be partly responsible for LV systolic dysfunction-related SM wasting. However, preliminary data from our laboratory did not support activation of the ubiquitin-proteasome pathway in patients with severe HF and overt SM atrophy. Whether the ubiquitin-proteasome pathway is activated at an earlier stage of HF when patients have not yet developed full-blown SM atrophy is currently unknown.

Experimental data regarding the seminal role of IGF-1 in the development of SM atrophy have been provided in a model of SM wasting induced by chronic administration of angiotensin II (AII).<sup>72</sup> The chronic AII administration model of SM wasting results in systemic AII levels that are similar to that measured in patients with decompensated HF who are not receiving ACE inhibitors. Chronic administration of AII downregulates IGF-1 signaling via the Akt/mTOR/p7056k pathway that is critical for caspase-3 activation, actin cleavage, ubiquitination, and apoptosis.<sup>72</sup> Caspase 3 activation is an essential step in muscle protein degradation. It cleaves actomyosin in proteins that are degraded by the ubiquitin-proteasome pathway.<sup>73</sup> Caspase 3 activation is blocked by muscle-specific expression of IGF-1 via the Akt/mTOR/p7056k pathway.<sup>72</sup>

In summary, experimental data support that AII-mediated downregulation of IGF-1 in SM is causally related to AII-induced muscle wasting.<sup>72</sup> Whether the beneficial effects of

**FIGURE 19-2** Signaling pathways underlying fiber type switching and protein synthesis and degradation in skeletal muscle.

Six potential signaling pathways are illustrated. The interaction between the pathways is not depicted.

1. Calcineurin, a calcium-activated phosphatase, modulates fiber shift by activating the nuclear factor of activated T-cells (NFAT) transcription factor.
2. Peroxisome proliferator-activated receptor- $\gamma$  (PPAR) coactivator 1 $\alpha$  (PGC-1 $\alpha$ ) is highly expressed in type I fibers and participates in the biogenesis of mitochondria to promote oxidative metabolism. It can be activated by cAMP and nuclear receptors such as PPAR.
3. The MAPK pathway can be divided into three distinct pathways (i.e., ERK, JNK, and p38), which activate common and distinct transcription factors. ERK and JNK pathways stimulate proliferation and a shift toward type I fibers. The p38 pathway decreases proliferation and promotes protein degradation.
4. The IGF-1/phosphatidylinositol 3-kinase (PI3K)/Akt pathway is a key regulator of protein homeostasis. When activated by IGF-1, Akt induces synthesis and survival signals through many targets, including mammalian target of rapamycin (mTOR), and glycogen synthase kinase-3 $\beta$  (GSK-3 $\beta$ ). Akt can phosphorylate and inactivate Forkhead box-containing protein O (FoxOs), thus contributing to reduced protein degradation.
5. FoxOs are a family of transcription factors that regulate the transcription of atrophying genes, such as Atrogin-1 and MuRF1. FoxOs also contribute to fiber shift.
6. The proteasome ensures degradation of intracellular protein using a two-step process. First, actomyosin is fragmented into polypeptides by caspase 3 or calpains, which are then ubiquitinated and degraded by the 26S proteasome enzymes. (From Caron M. Comparative assessment of the quadriceps and diaphragm in patients with COPD. *Appl Physiol* 2009;107:954.)

ACE inhibition on SM in HF patients are mediated through the IGF-1 pathway or result from a direct effect on SM vasculature via improvement of vascular endothelial function remains to be determined. In addition to AII elevated cytokines, SM levels can directly activate the ubiquitin-proteasome pathway and thereby result in SM protein degradation.<sup>74</sup>

**Protein Synthesis.** The syndrome of HF is associated with deficiencies in several anabolic hormones.<sup>75,76</sup> In male patients with HF deficiencies in circulating total testosterone, dehydroepiandrosterone (DHA) and IIGF-1 are common and correlate with a poor prognosis.<sup>76</sup> Testosterone produces SM hypertrophy by increasing fractional muscle protein synthesis.<sup>77</sup> The exact molecular pathways that mediate testosterone hypertrophic effects are incompletely understood. Testosterone appears to stimulate IGF-expression and downregulates

IGF-binding protein-4 in the muscle.<sup>78</sup> At supraphysiological doses, testosterone appears to act through androgen receptors' independent mechanisms. In most tissues, androgen receptors are either saturated or downregulated at the lower end of normal concentrations.<sup>78</sup> In patients with HF serum levels of free testosterone and dehydroepiandrosterone are decreased in proportion to HF severity<sup>76</sup> in a placebo-controlled trial of 70 elderly patients with moderately severe HF testosterone was recently shown to improve exercise capacity muscle strength glucose metabolisms and baroreflex sensitivity.<sup>79</sup> Despite beneficial effects on insulin resistance, testosterone had no apparent effects on myocardial performance and LV function. The increase in exercise capacity was related to serum levels of testosterone and not to changes in LV function. Independently of its possible effects on muscle metaboreflex that may contribute

to improved peak functional capacity, testosterone improved insulin sensitivity with an increase in total body mass and a decrease in fat mass.<sup>79</sup> Long-acting therapy seems to be well tolerated by elderly patients with moderately severe HF.

Besides their effects on SM protein degradation and cell death, growth hormone (GH) resistance and reduction in SM IGF-1 concentration contribute to SM atrophy in HF by directly reducing protein synthesis and by lessening muscle satellite cell recruitment and differentiation.<sup>80</sup> Cell-based therapy is presently under investigation for the treatment of muscular dystrophy.<sup>81</sup> Cell-based therapy is an attractive approach for SM regeneration in patients with disuse-induced atrophy.<sup>82,83</sup> Ghrelin, a novel GH-releasing peptide, stimulates physiological release of IGF-1 through a mechanism that is independent from hypothalamic GH-releasing hormone.<sup>84</sup> Administration of ghrelin for 3 weeks improves functional capacity and alleviates SM atrophy in patients with chronic HF and COPD.<sup>85</sup> Lastly the role of peroxisome proliferator-activated receptor  $\gamma$  coactivator 1 $\alpha$  (PGC1 $\alpha$ ) in the pathogenesis of disuse-induced SM atrophy remains to be investigated in patients with chronic HF or COPD.<sup>86</sup>

### Mechanisms of Skeletal Muscle Inflammation

Chronic HF is a low-level inflammatory state as evidenced by modest elevation of circulating IL-1 and IL-6 and TNF- $\alpha$  (see Chapter 11).<sup>17</sup> The initiating factors of SM inflammation are incompletely understood in HF. Disuse-induced atrophy promotes SM inflammation through activation of several signaling pathways (see Figure 19-2). Increased SNA promotes vasoconstriction and thereby reduces oxygen delivery to exercising SM. Concomitant activation of the renin-angiotensin system results in elevated A II SM concentration that increases local oxidative stress and lowers SM concentration of IGF-1. Reduced oxygen delivery and IGF-1 SM concentration combined with increased oxidative stress may accelerate protein degradation while decreasing protein synthesis. The increase in muscle SNA is mostly due to accentuation of muscle mechanoreceptors in HF while accentuation and desensitization of muscle metaboreceptors have been reported in HF depending on the severity of metabolic derangements, the degree of metaboreceptor desensitization, and the mode of exercise: static versus rhythmic.<sup>87-90</sup> Loss of SM mass, reduction in SM blood flow and blood flow distribution within SM, and fiber type composition contribute to muscle reflex alterations in HF.<sup>19</sup> In normal subjects, muscle reflex activation helps raise

blood pressure and thereby maintain muscle perfusion during muscle acidosis. In HF, muscle reflex activation occurs at the onset of exercise, resulting in vasoconstriction and limited SM perfusion. Increased SM SNA and AII concentration promote local inflammation by reducing O<sub>2</sub> delivery and local IGF-1 concentration and increasing oxidative stress. In turn SM inflammation upregulates expression of cytokines, especially IL-6 and TNF- $\alpha$  and expression of inducible nitric oxide synthase (iNOS).<sup>91</sup> Elevated IL-6 and TNF- $\alpha$  concentrations activates the NF  $\kappa$ B signaling pathway that modulates immune and inflammatory SM responses, thereby exacerbating SM wasting.<sup>92</sup> Increased SM IL-6 concentration has been associated with SM and diaphragmatic atrophy in rats and the Janus activated kinase (JAK)-I, activator of transcription (STAT) and cAMP-activated protein kinase (AMPK) signaling pathways.<sup>93</sup> Increased Akt activation increases activity of (FoxO) transcription factors, which control SM cell proliferation growth atrophy and metabolism.<sup>72</sup> As previously mentioned, increased FoxO activity precipitates SM protein degradation through the ubiquitin-proteasome pathway in rats with HF. SM inflammation exacerbates SM atrophy through stimulation of multiple cytokine-activated signaling pathways.

In summary, chronic conditions and particularly chronic HF are associated with reduced physical activity, resulting in disuse and low-level systemic inflammation (Figure 19-3). Both disuse and systemic inflammation promote loss of SM mass and ultimately SM atrophy. Continuous loss of SM mass activates multiple signaling pathways that mediate SM inflammation. In turn SM inflammation activates signaling pathways that promote further loss of SM mass and exacerbates local inflammation. The negative interaction between atrophy and inflammation within the SM appears to progress independently from the initial event and may be related to the presence of comorbid conditions, including hormonal deficiencies, diabetes mellitus, and obesity/sleep disorder breathing. An important goal of therapy in HF patients is to reverse or optimally prevent the development of SM alterations to restore a normal functional capacity.

### Diaphragm and Respiratory Muscle in Heart Failure

Skeletal muscles are not simply a mechanical system, but sensory organs that sense effort, tension, displacement, and fatigue via tendon organs, muscle spindles, joint receptors,

**FIGURE 19-3** Chronic conditions such as heart failure (HF), chronic obstructive pulmonary disease (COPD), and chronic kidney disease (CKD) have a substantial impact on skeletal muscles (SM). Patients with HF, COPD, or CKD experience SM wasting and ultimately atrophy. Besides abnormal excitation contraction (EC) coupling, atrophy is associated with increased sympathetic nervous activation (SNA), angiotensin II (Ang II), and oxidative (Ox) stress, reduced O<sub>2</sub> delivery, and IGF-1 concentration that mediate SM inflammation. In turn, SM inflammation is associated with increased cytokine levels, nuclear factor  $\kappa$ B (NF  $\kappa$ B) signaling, rate of apoptosis, and FoxO transcription factors. Whether the ubiquitin-proteasome pathway (Ub-P'some Path) is activated in patients with HF is unclear. Inflammation-related SM alterations foster SM atrophy and thereby a negative atrophy-inflammation interaction with SM. Whereas chronic conditions are initially responsible for SM atrophy, its progression appears to be largely dependent on local SM factors, including a negative atrophy-inflammation interaction and to a lesser extent on the deterioration of the initiating chronic condition.

and small nerve endings. It is the sensory aspect of skeletal muscles that mediates the symptoms of exercise intolerance in both healthy and disease states.<sup>7,94,95</sup> The first portion of this chapter focused on the limb skeletal muscle and we will now shift our attention to the respiratory muscles. Both groups of muscles are exposed to the same generalized heightened neurohormonal activation, cytokine release, and oxidative stress that is associated with the heart failure state, but unlike the limb musculature, which is underused with disease progression, the diaphragm and respiratory muscles encounter an ever-increasing workload as lung compliance decreases. **Table 19-1** contrasts the skeletal muscle characteristics of the locomotor and respiratory muscles in heart failure.

**Mechanism of Dyspnea**

A unified mechanism for dyspnea based on respiratory muscle function is that breathlessness occurs when the activity of the respiratory muscles is increased and/or the respiratory muscles are weak.<sup>7,94</sup> Varying respiratory muscle strength and workload will result in differences in perception of load and dyspnea.<sup>96-99</sup> Dyspnea is a conscious sensation that results from an unusual perception of discomfort during breathing.<sup>4-7</sup> As it is a sensation, it has a significant affective component that can be modified by cognitive and contextual influences. Dyspnea occurs in both normal and diseased states, and originates from the stimulation of mechanoreceptors, chemoreceptors, or proprioceptors. The magnitude of a stimulus to the receptor is transduced by the firing frequency in an afferent nerve to the central nervous system. The central impression constructed is interpreted based on past experience to generate a conscious sensation.<sup>7</sup>

Respiratory muscle fatigue may also contribute to dyspnea via biochemical changes in the muscles.<sup>100,101</sup> Dempsey et al have shown that fatiguing contractions of the inspiratory muscles result in an accumulation of metabolites that activate type IV phrenic afferents, resulting in an increase in sympathetic vasoconstrictor activity via a supraspinal reflex (i.e., inspiratory muscle metaboreflex).<sup>100</sup> This reflex is important during heavy sustained exercise and modulates the competition for blood flow between the respiratory and locomotor muscles. Activation of this reflex redirects blood flow from the periphery to the ventilatory muscles.

Additionally, increased respiratory drive during exercise may be due to metabolic stimuli arising from limb skeletal muscle.<sup>102,103</sup> Previous studies have demonstrated how changes in metabolism in skeletal muscle stimulate respiration. Oelberg et al<sup>104</sup> used magnetic resonance spectroscopy to demonstrate that skeletal muscle pH correlates with

minute ventilation (**Figure 19-4**). It is not clear whether such stimulation occurs through central or peripheral pathways.<sup>105</sup>

**Diaphragmatic Histochemical Changes in Heart Failure**

Histochemical and metabolic changes that occur in respiratory muscles may serve to accentuate the sensation of dyspnea in heart failure patients. A diaphragmatic myopathy has been demonstrated in an animal model of chronic heart failure<sup>106</sup> with decreased contractile and relaxation parameters.<sup>107</sup> Impaired diaphragmatic performance was correlated to a total cross-bridge number and altered calcium regulation.<sup>108</sup> Elevated tumor necrosis factor has been suggested to explain the diaphragmatic dysfunction.<sup>109</sup> Malnutrition has been shown to affect diaphragmatic weight and histochemistry.<sup>110,111</sup>

Various histologic abnormalities in the diaphragm of patients undergoing cardiac transplantation have been described.<sup>111-113</sup> In one study, costal diaphragmatic biopsies were obtained from 7 normal subjects and 10 patients at the time of transplant or LV assist placement.<sup>112</sup> The distribution of myosin heavy chain isoforms I, IIa, and IIb (MHC) by SDS gel electrophoresis was measured along with the activities of the oxidative (citrate synthase), lipolytic ( $\beta$ -hydroxyacyl CoA dehydrogenase), and glycolytic (lactate dehydrogenase) enzymes. In normal subjects, the distribution of MHC isoforms I, IIa, and IIb was 35%, 49%, and 17%, respectively, versus 54%, 40%, and 6% in the HF subjects. Therefore, in the patients with HF, slow myosin heavy chains were significantly increased ( $P < .01$ ) and glycolytic fast-twitch fibers significantly reduced compared with normal subjects ( $P < .01$ ). Additionally, oxidative and lipolytic enzymatic activities were greater and glycolytic enzyme activity was significantly less in HF than normal subjects (**Figure 19-5**) (all  $P < .01$ ). Thus in the diaphragm in HF, there is a shift from fast to slow myosin isoforms with an increase in oxidative capacity and a decrease in glycolytic capacity. These changes are consistent with those elicited by endurance training. The endurance changes described in the diaphragm probably were the consequence of the increased work of breathing that occurs in this patient population. These findings were subsequently found in animal models.<sup>106,107</sup>

However, despite the shift to more oxidative metabolism, evidence of decreased contractility and strength was

TABLE 19-1	Comparison of Locomotor and Respiratory Muscles

**FIGURE 19-4** The correlation between minute ventilation and quadriceps muscle pH (determined by magnetic resonance spectroscopy) during exercise in patients with heart failure. The data are from three exercise bouts in one subject. Bilateral lower extremity positive pressure of 45 Torr was used to separate out the effects of arterial pH, pain, or central motor command. (Modified from Oelberg D, Evans AB, Hrovat MI, et al. Skeletal muscle chemoreflex and pH<sub>i</sub> in exercise ventilatory control. *J Appl Physiol* 1998;84:676-682 with permission.)

**FIGURE 19-5** Abnormal costal muscle enzyme activity in patients with heart failure. Costal diaphragmatic biopsy samples were obtained from 7 normal subjects and 10 patients. Activity of citrate synthase (CS, a marker of oxidative metabolism) and B-hydroxyacyl-CoA dehydrogenase (BOAC, a marker of lipolytic enzymatic activity) were greater and glycolytic enzyme activity as assessed by the activity of lactate dehydrogenase (LDH) was significantly less in heart failure than normal subjects. (Modified from Tikunov B, Levine B, Mancini DM. Chronic congestive heart failure elicits adaptations of endurance exercise in diaphragmatic muscle. *Circulation* 1997;95:910-916 with permission.)

described in animal models. A rat HF model demonstrated similar histochemical changes as described in HF patients.<sup>114</sup> However, the mitochondrial function of the rat costal diaphragmatic muscle was reduced as measured in skinned muscle fibers using an oxygen electrode. ADP sensitivity of the mitochondria was increased but returned to normal in the presence of creatine. Decreased concentration of the mitochondrial isoform of creatine kinase has been previously demonstrated. Thus though the diaphragmatic muscle had an appropriate training response to the heightened work of breathing, the performance of the muscle was still attenuated due to the altered mitochondrial function.<sup>115</sup>

Myogenic regulatory factors regulate the expression of myosin heavy chains. In a rat model of heart failure, the expression of Myo D, myogenin, and MRF4 was examined in the diaphragm of heart failure and control rats. Myogenin is expressed at higher concentrations in slow-twitch muscle, whereas Myo D expression is increased in fast-twitch fibers. In the heart failure rats there was a selective downregulation of Myo D, leading to a lower percentage of fast-twitch fibers. The trigger for the downregulation of the Myo D is unknown but thought to be due to neurohormonal and cytokine activation.<sup>116</sup>

### Respiratory Muscle Function

Respiratory muscle function is commonly quantitated by measurement of respiratory muscle strength.<sup>117</sup> Maximal inspiratory pressure is measured with the subject inhaling against a resistance at functional residual volume to maximize the force-length relationship of the muscles. This measurement is volitional and as such may overestimate the degree of muscle weakness but this measurement has been shown to be reproducible. Inspiratory muscle weakness is arbitrarily defined as a maximum inspiratory pressure (P<sub>imax</sub>) less than 70% of predicted value. A reduction in inspiratory and expiratory respiratory muscle strength in patients with HF from both systolic and diastolic dysfunction has been shown in many studies.<sup>118-121</sup> Studies measuring diaphragmatic strength using esophageal and transdiaphragmatic pressure during maximal sniffs and phrenic nerve stimulation have also demonstrated reduction in diaphragmatic strength in HF patients.

When both respiratory muscle and limb muscle strength are measured in HF patients, a more marked reduction in respiratory rather than peripheral muscle strength has been observed. Chua et al failed to find a correlation between P<sub>imax</sub> and quadriceps strength.<sup>122</sup> Ambrosino<sup>121</sup> reported

reductions in maximal inspiratory and expiratory pressures that paralleled the severity of heart failure. HF patients with relatively preserved exercise capacity had reduced P<sub>imax</sub>.

P<sub>imax</sub> has been shown to have prognostic value independent of peak V<sub>O<sub>2</sub></sub>. Meyer et al<sup>123</sup> measured P<sub>imax</sub> in 244 consecutive HF patients and found this measurement to be a strong univariate and multivariate predictor of survival. Improvement in P<sub>imax</sub> has been found in patients with heart failure following initiation of angiotensin-converting enzyme inhibitor therapy, CPAP, and respiratory muscle training. However, serial changes in inspiratory strength were not predictive of prognosis.<sup>124</sup>

### Respiratory Muscle Perfusion

Limb skeletal muscle underperfusion has been described in patients with heart failure.<sup>125</sup> Animal and human studies suggest that with HF, respiratory muscle underperfusion may also occur. The diaphragm, the major respiratory muscle, has a complex and generous blood supply provided by the internal mammary, intercostal, and phrenic arteries and the costophrenic arcades. Because of its rich perfusion, the diaphragm is relatively resistant to ischemia, even during exercise, when large increases in perfusion of the diaphragm are needed. Examination of regional muscle perfusion in the dog during exercise has demonstrated that the muscle group with the largest increase in perfusion is the diaphragm.<sup>126</sup> In animal models of HF, the increase in diaphragmatic blood flow during submaximal exercise<sup>127</sup> was greatest in those animals with the most severe HF. Presumably the increased blood flow was required for increased work of breathing. During exercise, dramatic increases in blood flow occur in the diaphragm. This response is accentuated in HF.

Diaphragmatic ischemia and fatigue have been demonstrated in a canine model of cardiogenic shock produced by tamponade.<sup>128</sup> In spontaneously breathing dogs with tamponade, respiratory muscle failure preceded cardiac arrest. Preterminal increased neural excitation to the respiratory muscles was observed, implying an impairment of the contractile process. Diaphragmatic blood lactate was increased. Thus in this canine model of HF, respiratory muscle fatigue was probably due to respiratory muscle underperfusion.

Near-infrared spectroscopy is a technique that can be used to noninvasively assess skeletal muscle oxygenation.<sup>129</sup> This technique primarily relies on the optical properties of hemoglobin. Both oxygenated and deoxygenated forms absorb light at 800 nm, whereas at 760 nm absorption is primarily by the deoxygenated forms. By monitoring the difference between these two wavelengths, venous hemoglobin deoxygenation can be assessed.<sup>130</sup> Application of near-infrared spectroscopy during maximal exercise has demonstrated accessory respiratory muscle deoxygenation in HF but not normal subjects.<sup>131</sup>

Whether this respiratory muscle deoxygenation represents underperfusion, ischemia, and/or fatigue was investigated by measuring the development of low-frequency muscle fatigue following exercise in HF patients. Davies et al<sup>132</sup> demonstrated a decrease in maximum inspiratory and expiratory pressure following bicycle exercise in HF patients. This suggested respiratory muscle fatigue. However, measurements of maximal inspiratory and expiratory pressures are motivation dependent, and the observed reduction may have occurred from central mechanisms. To investigate objectively whether low-frequency diaphragmatic fatigue occurs in HF patients, supramaximal bilateral transcutaneous phrenic nerve stimulation before and after maximal bicycle exercise was performed.<sup>133</sup> Maximal transdiaphragmatic pressure was derived before and after exercise using the twitch interpolation technique. In both normal and HF subjects, maximal inspiratory and expiratory pressures decreased significantly with peak exercise. However, the maximal transdiaphragmatic pressure derived from the twitch interpolation technique

was unchanged in both normal and HF subjects. Thus low-frequency diaphragmatic muscle fatigue did not occur in patients with heart failure despite accessory respiratory muscle deoxygenation during exercise.

Increased activity of the respiratory muscles and/or respiratory muscle weakness rather than fatigue may be sufficient to evoke the sensation of dyspnea. Measurement of the tension-time index and thus the work of the diaphragm per breath demonstrated dramatic increases in patients with heart failure at rest and during exercise (Figure 19-6).<sup>133</sup> The tension-time index is calculated for each breath. It is the product of the ratio of the time in inspiration divided by the time per breath ( $T_i/T_{tot}$ ), and the ratio of the mean transdiaphragmatic pressure to maximal transdiaphragmatic pressure. It approximates the oxygen consumption of the diaphragm. Fatigue of the diaphragm is thought to occur when the tension-time index reaches a ratio of 0.15 or greater.<sup>134</sup> However, this fatiguing ratio may be lower in ischemic muscle, or with high tidal volumes, breathing frequency and minute ventilation. In the majority of the patients studied, the tension time index at end exercise was 0.1 and thus approached fatiguing levels.

The relationship between parameters of respiratory muscle function and ratings of perceived dyspnea during submaximal exercise was also examined.<sup>133</sup> Significant linear correlations were observed between a rating of perceived dyspnea (i.e., the Borg scale) at a fixed exercise workload (25 watts) and parameters of respiratory muscle strength (maximal inspiratory and expiratory pressures), and work (tension-time index), but not with lung volumes (tidal volume, minute ventilation). McParland also demonstrated a strong correlation between inspiratory muscle weakness and dyspnea during daily activities in stable ambulatory HF patients, as quantitated by the Dyspnea Index.<sup>118</sup>

The endurance of the respiratory muscles in HF patients is also diminished. Respiratory muscle endurance can be assessed by progressive isocapnic hyperpnea using a rebreathing circuit to measure maximal sustainable ventilatory capacity.<sup>135</sup> Both maximal voluntary ventilation and maximal sustainable ventilatory capacity are significantly reduced in HF patients compared with normal subjects consistent with lowered respiratory muscle endurance.

### Respiratory Muscle Training

Modification of respiratory muscle function with an appropriate shift in perceived dyspnea could demonstrate the importance of respiratory muscle function in the development of dyspnea. If respiratory muscles were a key modulator of the sensation of dyspnea, then selective respiratory muscle training should attenuate exertional dyspnea and may also improve exercise performance particularly in patients limited by dyspnea. Accordingly, the effect of selective respiratory muscle training on exertional dyspnea and exercise capacity has been examined in heart failure subjects. In our original series, we examined the effect of respiratory muscle training in 14 HF patients.<sup>136</sup> Supervised respiratory muscle training was performed for 3 months. Maximal sustainable ventilatory capacity, maximal mouth pressures, pulmonary function tests, and submaximal and maximal exercise capacity were measured before and after training.

As with aerobic training there are many different training regimens that can be employed involving either endurance or isometric type of exercise. The training protocol we devised included a variety of elements including isocapnic hyperpnea at a predetermined maximal sustainable ventilatory level, strength training with repetitive maximal inspiratory and expiratory mouth pressures, pulmonary rehabilitation exercises, and resistive breathing using a commercial available device (THRESHOLD Health Scan, Cedar Grove, NJ). Thus the impact of both strength and endurance training of

**FIGURE 19-6** Plot of tension-time index at rest and at submaximal and maximal exercise in normal subjects and heart failure (CHF) patients. The tension-time index is a measure of the work of the diaphragm per breath. (Modified from Mancini DM, Henson D, LaManca J, et al. Respiratory muscle function and dyspnea in patients with chronic congestive heart failure. *Circulation* 1992;86:909-918.)

the respiratory muscles in HF patients was investigated. Of the 14 patients enrolled in the study, only 8 completed the training protocol. The six dropouts were followed and comprised a comparison group by which to assess the reproducibility of the measurements. Respiratory muscle endurance was significantly improved with training as evidenced by increases in maximal sustainable ventilatory capacity of 57%. Respiratory muscle strength, and submaximal and maximal exercise capacity were also significantly improved with selective respiratory muscle training. Dyspnea was subjectively improved in the majority of trained patients. In contrast, no significant improvements in maximal sustainable ventilatory capacity, maximal mouth pressures, 6-minute walk, or peak  $\dot{V}O_2$  were observed in the six patients who did not complete the training program.

Since our initial study several other investigators<sup>137-142</sup> (Table 19-2) have studied respiratory muscle training in these patients using predominantly resistive pressure threshold load devices or computer-controlled biofeedback trainers. Training has been performed at a wide range of inspiratory pressure loads ranging from 15 to 60% of Pmax. Though the training regimens have varied the overall results have been consistent with demonstration of improvement in respiratory muscle strength, peak  $\dot{V}O_2$ , and 6-minute walk tests. The consistency of the improvement in overall peak  $\dot{V}O_2$  has led to studies to identify the mechanism for the enhanced exercise capacity.

Chiappa et al hypothesized that the improvement in peak  $\dot{V}O_2$  may result from a redistribution of blood from the lungs to the locomotor muscles.<sup>143</sup> Inspiratory muscle loading results in a reduction of blood flow to resting and exercising muscle, which following respiratory muscle training is alleviated in patients with HF and respiratory muscle weakness. Borghi Silva et al<sup>144</sup> also have demonstrated that unloaded ventilation improves submaximal exercise and skeletal muscle perfusion in nine patients with HF.

Conversely, if skeletal muscle metaboreceptors modulate the sensation of dyspnea, then selectively improving leg muscles may similarly alleviate dyspnea. As aerobic training results in training of both the leg and respiratory muscles, selective low-level leg training was performed in 17 HF patients. Low-level bicycle and treadmill exercise, where minute ventilation was below 25 L/min, was performed along with leg callisthenic exercises. Perceived dyspnea during submaximal exercise was reduced in patients with low-level training, suggesting that skeletal muscle function impacts this sensation.<sup>145</sup>

## CONCLUSION

Dyspnea is an extremely common symptom in patients with heart failure. In these patients, the increased work of breathing results from a combination of factors, including excessive ventilatory response during exercise, from increased dead space ventilation, and from ventilation perfusion mismatching; an increased impedance to breathing from bronchial hyperreactivity due to venous engorgement; and decreased lung compliance from elevated filling pressures and subsequent chronic fibrotic changes. This increased work of breathing is transduced into the sensation of dyspnea by stimulation of receptors in weak, atrophic, underperfused, and probably metabolically abnormal respiratory muscles. Additionally the atrophic and metabolically abnormal limb skeletal muscles may also exacerbate this sensation through an excessive muscle reflex activity.

In conclusion, the symptoms of fatigue and dyspnea both largely originate in skeletal muscle. The size, histology, metabolism, and vasculature of the skeletal muscle are all impacted by the neurohormonal, cytokine, and inflammatory activation that characterize heart failure and results in the classic symptoms of this disease.

## Summary and Outlook, 326

This chapter is based on two broad concepts. The *first concept* considers the heart as an efficient converter of energy.<sup>1</sup> It addresses the hypothesis that defective energy metabolism is a cause for contractile dysfunction of the heart (see Chapter 7). The *second concept* considers heart failure as a systemic disease that begins with adaptation and ends with maladaptation of the heart in response to different stimuli. This chapter covers the entire spectrum, from altered energy metabolism to cardiac hypertrophy and failure. It also addresses the hypothesis that metabolism not only provides energy for contraction, but also generates signals that regulate cardiac-specific gene programs, including programs of adaptation and maladaptation of the heart to environmental stimuli (Figure 20-1).

By definition, energy is the capacity for doing work. The transfer of energy includes ATP and phosphocreatine, but it is not limited to energy-rich phosphate compounds. A discussion of myocardial energy metabolism in heart failure should therefore include a brief review of normal energy transfer in the heart, a review of methods used to detect abnormal energy transfer in the heart, and of evolving paradigms on metabolic adaptation and maladaptation of the failing heart. An inevitable question is whether metabolic derangements are causes or consequences of heart failure. The answer is clear in cases of myocardial ischemia and in the relatively rare cases of genetically determined cardiomyopathies. The answer is less clear in the majority of patients suffering from dilated cardiomyopathies.

Over the years, it has been speculated that the failing heart is “energy starved (see Chapter 7).”<sup>2</sup> Although <sup>31</sup>P-NMR spectroscopy can detect metabolic abnormalities already in asymptomatic patients with cardiomyopathy, the concept of energy starvation has rested primarily on a reductionist approach focusing on some of the final reactions (e.g., the creatine kinase reaction). In this chapter, we use a more inclusive perspective that encompasses consideration of

likely sites for defective metabolism. In the heart, defective energy metabolism has been characterized best in the case of myocardial ischemia, where the lack of oxygen results in severe impairment of the efficient system of oxidative phosphorylation. Drugs that target specific “bottleneck” reactions in intermediary metabolism of the heart hold the promise of improving cardiac function in ischemic heart disease and in dilated cardiomyopathies (see Chapter 50). Although conceptually attractive, this concept may be an oversimplification. In the following section, we will see why.

## PERSPECTIVES

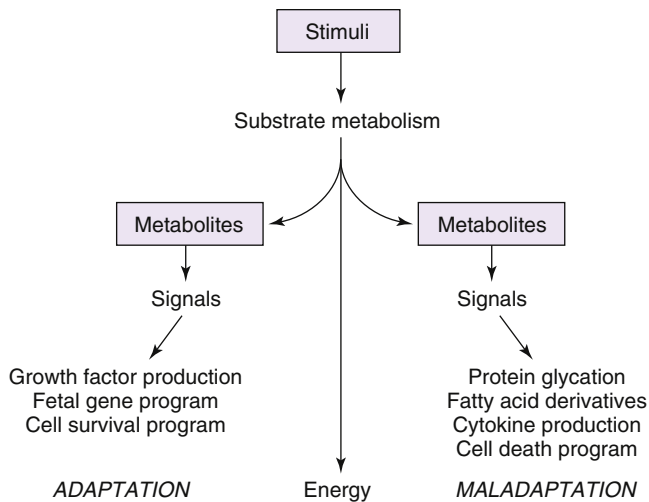

### Metabolism and Function Are Tightly Coupled

Catabolic energy substrate metabolism transfers energy from chemical bonds to ATP, the immediate precursor for conversion to mechanical energy. Heart muscle derives its energy for contraction from the oxidation of a variety of fuels, including glucose, lactate, and especially long-chain fatty acids.<sup>5</sup> When fatty acids are abundant, the myocardium increases fatty acid metabolism, which suppresses glucose metabolism. Conversely, myocardial fatty acid oxidation is suppressed when higher fuel efficiency (from glucose metabolism) is required.<sup>6,7</sup>

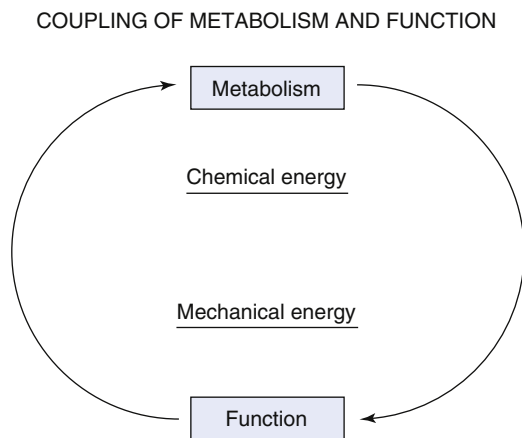

Metabolism is an integral part of the heart's physiological function (Figure 20-2). A decrease in energy demand and contractile function (e.g., during sleep or with  $\beta$ -adrenergic receptor blockade) results in a decrease in energy turnover. Vice versa, as first shown by Langendorff's classic studies in the isolated perfused cat heart, a decrease in energy supply (e.g., during ischemia) results in a decrease in contractile function.<sup>8</sup> Because the heart can store only a small amount of energy (and because energy is the capacity for doing work), it follows that supply of, and demand for, energy-providing substrates in the heart are finely regulated and need to be in balance. The tight coupling of contractile function and myocardial oxygen consumption in the mammalian heart has been known for nearly a century.<sup>9</sup> The evidence of this relationship between function and metabolism

all energy-metabolizing pathways. Such an approach seems justified in light of (1) emerging pharmacological and surgical strategies directed at shifting substrate flux through specific metabolic pathways, (2) the rapidly emerging concepts of peroxisome proliferator activated receptor signaling in the control of cardiac energy metabolism,<sup>3</sup> and (3) metabolically inducible forms of heart failure.

The complex and highly regulated systems of energy transfer have been the subject of biochemistry studies for most of the past century<sup>4</sup> and provide many

**FIGURE 20-1** The pleiotropic role of metabolites in energy metabolism, substrate storage, cell structure, cell signaling, gene expression, and apoptosis (programmed cell death). See text for discussion. (Adapted from Young ME, McNulty P, Taetgmeyer H. Adaptation and maladaptation of the heart in diabetes: Part II. Potential mechanisms. *Circulation* 2002; 105:1861-1870).

**FIGURE 20-2** The metabolic machinery in the heart converts chemical energy into mechanical energy. The tight coupling of energy substrate metabolism and contractile function of the heart underlies a system of high adaptability and efficiency. (Adapted from Taetgmeyer H. Cardiac metabolism as a target for the treatment of heart failure. *Circulation* 2004; 110(8): 894-896.)

and function is seen routinely in the clinical practice of cardiology (e.g., the hearts of patients with a decreased supply of oxygen [ischemia] exhibit decreased contractile function). In simple terms: The prerequisite for normal contractile function is the normal flux of energy, a concept already known to the ancient Greeks: *παντα ρει*, meaning “all is in flux” (Heraclitus, 540-475 BC).

Heart muscle derives its energy from the oxidative metabolism of fuels (for review, see Taetgmeyer).<sup>1</sup> Because the heart is capable of oxidizing a variety of biological fuels, we have termed it a “metabolic omnivore”. The essence of energy substrate metabolism in the heart is to maintain a dynamic state of equilibrium. Heart muscle burns chemical energy (fuels) and converts it into physical energy (pump function). In doing so, the heart distributes energy in the form of substrates and oxygen to the rest of the body. Hence the concept that heart failure is a disease of impaired energy transfer, beginning and ending with the heart.

It goes without saying that when the heart’s ability to convert chemical into mechanical energy is impaired for any reason, the consequences affect every organ of the body. The general concept that the failing heart is in an energy-deprived

state helps us to understand why in a number of clinical trials inotropic agents failed to produce a beneficial long-term effect. These drugs improve symptoms of heart failure, but do so at the expense of cardiac energy expenditure, which can only be expected to worsen cardiac performance.

## The Plasticity of Cardiac Metabolism

As mentioned, the heart is able to use multiple different fuels for generation of ATP. Fatty acids (either from free fatty acids or hydrolyzed triglycerides) are the main substrate used and glucose is typically a secondary substrate, but the heart can also use ketones, lactate, and amino acids.<sup>1,10</sup> One of the main determinants of the heart’s substrate choice is substrate availability. Under resting conditions in the fed and immediate postprandial state, the fuel for respiration is influenced by the composition of the diet, which affects both blood hormone and substrate levels. For example, increases in postprandial plasma glucose and insulin levels increase the heart’s glucose uptake and use. During fasting, the main fuel of the heart is fatty acids.<sup>10</sup> During exercise, with increased lactate production, the heart increases lactate and glucose use.<sup>11</sup> Thus there is “plasticity” of the heart’s substrate metabolism (i.e., it can readily and rapidly switch substrate preference based on substrate availability under physiologic conditions). Special physiological conditions also influence substrate choice and a return to the fetal gene program and aging. In the fetal state, the heart uses predominantly glucose rather than fatty acids.<sup>12</sup> Interestingly, the aging heart is also associated with predominantly glucose use rather than fatty acid metabolism.<sup>13</sup> As discussed later, the failing heart (due to idiopathic cardiomyopathy) also predominantly uses glucose, like the fetal and aging heart.

## Energy Transfer in the Heart

The heart transforms chemical energy from its substrates into ATP and then uses ATP for cellular function. The main source of ATP is oxidative phosphorylation (see Chapter 2). The high rate of ATP turnover of the heart is reflected in the heart’s high rates of oxygen consumption, the high cellular density of mitochondria, and the high capillary density in heart muscle (2500 capillaries/mm<sup>3</sup> in the heart vs. 400 capillaries/mm<sup>3</sup> in red skeletal muscle). Mitochondria in heart muscle are not only more abundant but they also contain a far greater number of cristae (the location of respiratory chain enzymes) than mitochondria of other organs. Classic studies on the ultrastructure of the normal rat myocardium have shown that mitochondria account for 35.8% of myocyte cell volume with a mitochondria/myofibril ratio of 0.75. This ratio increases in the early phase of hypertrophy induced by aortic constriction<sup>14</sup> and decreases below normal values with prolongation of pressure overload.<sup>15</sup> The latter decrease is due to a decrease in the volume fraction of mitochondria, in combination with an increase in the volume fraction of myofibrils.<sup>16</sup> Mitochondria isolated from hypertrophied, nonfailing rabbit hearts exhibit significantly increased respiratory activity compared with controls,<sup>17</sup> whereas mitochondria from failing hearts exhibit respiratory rates near or below normal values and decreased respiratory control.<sup>18</sup>

Although all of the mechanisms by which respiration is coupled to energy expenditure in vivo are not known, the efficacy of oxidative phosphorylation is well established. For example, one mole of glucose yields 36 moles of ATP when oxidized, whereas the same amount of glucose yields only 2 moles of ATP when metabolized to lactate under anaerobic conditions. In addition, this less productive anaerobic glycolysis is suppressed by oxygen.<sup>19</sup> In the context of oxidative metabolism, it is also well established that efficient energy transfer occurs through a series of moiety-conserved cycles (Figure 20-3).<sup>1</sup> In the heart, these moiety-conserved cycles begin with the circulation itself, continue with the cyclic

**FIGURE 20-3** A series of moiety-conserved cycles underlies the efficient energy transfer from substrates to work. The moiety-conserved cycles can be likened to the wheels of a bicycle and provide a mechanism for immediate response to changes in energy demand. The higher the flux of energy, the greater the rate of turnover of the cycles. The concentration of cycle intermediates (moieties) remains stable over a wide range of energy fluxes. (Adapted from Sherma S, Androgue JV, Goldman L et al: Energy metabolism of the heart: from basic concepts to clinical applications. *Curr Prob Cardiol* 1994; 19:57-111.)

metabolic processes in the cell, and end with the cycling of the actin and myosin cross-bridges. Moiety-conserved cycles can be likened to the wheels of a bicycle because these cycles of energy are much more efficient than linear pathways (e.g., anaerobic glycolysis), just as the wheels of a bicycle are more efficient mechanism for locomotion than the more linear mechanism of walking.<sup>20</sup>

In addition to the concept of interconnected cycles, it is a convenient practice to divide energy transfer into three stages (Figure 20-4). Stage 1 involves the uptake of substrates into the cell, their conversion into acetyl-CoA, and oxidation in the Krebs cycle. Stage 2 consists of the final acceptance of electrons from reducing equivalents to molecular oxygen in the respiratory chain, which is coupled to the rephosphorylation of ADP to ATP in the proton motive force. Stage 3 is the transfer of energy from the mitochondria to the rest of the cell for contractile and other work. This division of substrate metabolism into stages helps to define sites at which energy transfer may become impaired and to identify potential sites for pharmacological intervention. In short, each stage can be the site of a metabolic block causing impaired energy transfer and contractile dysfunction. For example, impaired uptake of glucose is a feature of the heart, in type 1 diabetes,<sup>20</sup> impaired oxidation of long-chain fatty acids is a feature of lipotoxic heart failure,<sup>21</sup> impaired Krebs cycle flux is a feature of limited cofactor availability for certain dehydrogenases,<sup>22</sup> and impaired respiratory chain flux is a feature of ischemia with a redirection of metabolic fluxes from aerobic to anaerobic metabolism.<sup>23,24</sup> These concepts will be expanded upon in the section on metabolic adaptation and maladaptation.

Lastly, for practical purposes it is also useful to distinguish between *control* and *regulation* of metabolism. *Metabolic control* is the power to change the state of metabolism in response to an external signal, whereas *metabolic regulation* is geared toward maintaining a constant internal state.<sup>25</sup> In such a system, large changes in flux through metabolic pathways correspond to small changes in myocardial metabolite concentrations.<sup>26</sup> It follows that regulatory sites of metabolism, or “pacemaker” enzymes,<sup>27</sup> are not only targets for the change of metabolic fluxes by physiological effectors, but also emerging targets for pharmacological agents. Examples include the “fuel gauge” 5′-AMP-dependent protein kinase (AMPK) and the evolving class of partial fatty acid oxidation inhibitors (and other metabolically active drugs) in the management of ischemic heart disease. In the former case, AMPK is the primary

sensor of energy charge in the mammalian cell.<sup>28</sup> Most effectors of intracellular ATP depletion are probably mediated through this kinase pathway rather than through direct effects of adenine nucleotides. AMPK promotes glucose uptake and long-chain fatty acid oxidation by different mechanisms,<sup>29</sup> and the activity of this kinase can be altered both acutely (e.g., increased workload) and chronically (e.g., ischemia and pressure-overload-induced hypertrophy).<sup>30</sup> In the latter case, partial inhibition of fatty acid oxidation shifts the fuel balance to the energetically more efficient oxidation of glucose.

## METHODS FOR DETECTING DEFECTIVE SUBSTRATE METABOLISM IN THE FAILING HEART

### Substrate Uptake by Arteriovenous (AV) Differences

At the beginning of the past century, the oxygen requirement of the mammalian heart was established by the German physiologist Hans Winterstein.<sup>31</sup> The British physiologist C. Lovatt Evans studied the effect of various mechanical conditions on the gaseous metabolism and efficiency of the mammalian heart.<sup>32</sup> However, it was not until the advent of cardiac catheterization and cannulation of the coronary sinus that the hypothesis of defective energy metabolism in the failing heart could be tested in earnest. The results firmly established that heart muscle derives its energy for contraction from the oxidation of energy-providing substrates<sup>33</sup> and suggested that oxygen consumption is an index of energy production. Despite decreased efficiency of the failing human heart, the results were disappointing because no qualitative change in substrate metabolism was observed through measurement of AV differences.<sup>34</sup> These early studies found that like the normal human heart, the failing heart under fasting conditions derived about 30% of its energy requirements from carbohydrates, 5% from amino acids, 7% from ketone bodies, and the remaining 58% from fatty acids.<sup>34</sup> Thus, these early measurements of AV differences of substrates failed to provide insight into mechanisms of impaired cardiac function. However, it should be noted that these early studies were limited in that they did not use nonradiolabeled tracer infusions, such as C-13 palmitate, which facilitate the discrimination of exogenous substrate use from endogenous substrate

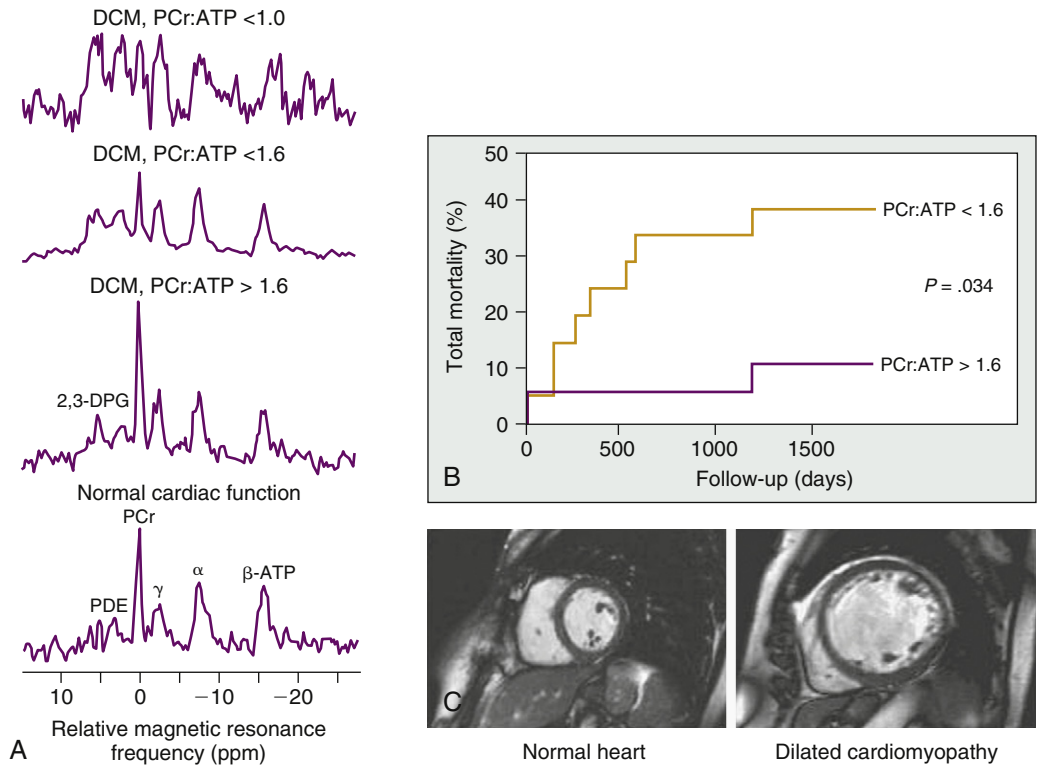

**FIGURE 20-4** Energy transfer in the cardiac myocyte occurs in three stages. Each stage may be the site of metabolic derangements causing or accompanying contractile dysfunction of the heart. The first stage is substrate uptake and metabolism (outlined in red). In this stage substrates are broken down by  $\beta$ -oxidation and glycolysis to form acetyl coenzyme A (CoA), from which the Krebs cycle produces NADH and  $\text{CO}_2$ . The second stage is energy production through oxidative phosphorylation (outlined in blue). Respiratory chain complexes in the mitochondria transfer electrons from NADH to oxygen. This creates a proton electrochemical gradient ( $\Delta\mu \text{H}^+$ ) across the inner mitochondrial membrane in addition to water and NAD. This gradient drives ATP synthase. Uncoupling proteins (UCPs) use this electrochemical gradient to create heat instead of ATP. The third stage is energy transfer via the creatine kinase shuttle (outlined in green). ATP is transferred to and consumed by myofibrillar ATPase and other reactions. GLUT, glucose transporter;  $P_i$ , inorganic phosphate; ANT, adenine nucleotide translocase; PCr, phosphocreatine; Cr, free creatine;  $\text{CK}_{\text{mito}}$ , mitochondrial creatine kinase isoenzyme; and  $\text{CK}_{\text{MM}}$ , myofibrillar creatine kinase isoenzyme. (Reproduced with permission from Neubauer S. The failing heart—an engine out of fuel. *N Engl J Med* 2007;356:1140-1151.)

production. More recent A-V balance studies have taken advantage of this technique to evaluate myocardial uptake and use of exogenous versus endogenous substrates.<sup>12</sup> In addition, some of the early AV balance studies of heart failure did not evaluate substrate metabolism in patients with concomitant diabetes or obesity, which would be expected to affect substrate delivery and thus myocardial substrate use.

### NMR Spectroscopy (see Chapter 7)

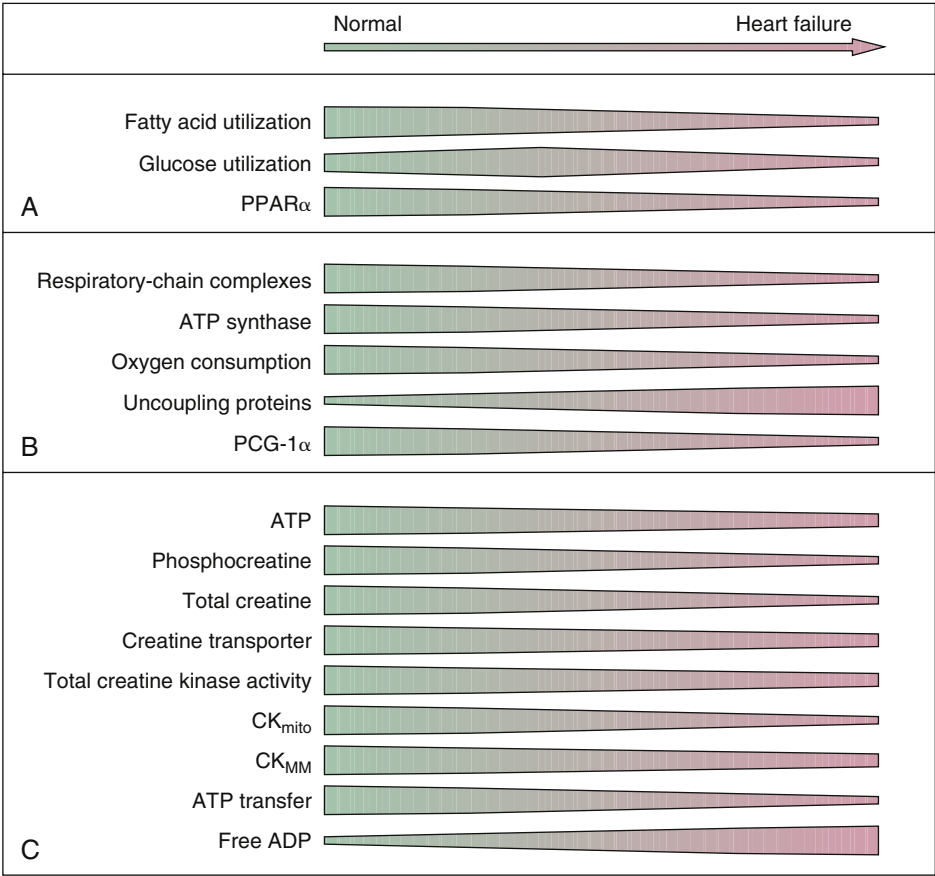

NMR spectroscopy of energy-rich phosphates and other biological compounds detects the magnetic spin of atomic nuclei and is used to monitor changes in metabolic content and enrichment in the intact heart. Commonly used nuclei include  $^1\text{H}$ ,  $^2\text{H}$ ,  $^{13}\text{C}$ ,  $^{15}\text{N}$ ,  $^{17}\text{O}$ ,  $^{31}\text{P}$ ,  $^{23}\text{N}$ , and  $^{39}\text{K}$ .  $^{31}\text{P}$  NMR spectroscopy is one of the most commonly used types of NMR spectroscopy, which yields distinct quantitative resonance peaks for mono-phosphate esters, inorganic phosphates, phosphocreatine, and the three phosphorus atoms of ATP ( $\gamma$ -ATP,  $\alpha$ -ATP, and  $\beta$ -ATP). The sizes of these peaks are related to the concentration

of these metabolites. A decrease in the myocardial PCr/ATP ratio occurs relatively early in heart failure and results from a decrease in creatine transporter function, which leads to lower [Cr] and [PCr] levels. A decreased PCr/ATP ratio ( $<1.6$ ) is a predictor of mortality in patients with dilated cardiomyopathy (Figure 20-5).<sup>35</sup> Decreased PCr/ATP ratio is also an early finding in inherited hypertrophic cardiomyopathy, even without frank left ventricular (LV) hypertrophy.<sup>36</sup> Heart failure impairs the creatine kinase energy-transfer mechanism, reducing ATP flux rates by approximately 50% in mild to moderate heart failure. ADP concentrations increase in heart failure.<sup>2</sup> A decrease in myocardial ATP level generally only occurs in advanced heart failure. An overview of the evolution of changes in high-energy phosphate metabolism created by heart failure (along with the changes in myocardial metabolism and oxidative phosphorylation) is shown in Figure 20-6. Although most clinical  $^{31}\text{P}$  NMR studies of heart failure have measured the PCr/ATP ratio, it is possible to quantify concentrations of myocardial metabolites by normalizing their NMR signal to that of a standard of known concentration.

**FIGURE 20-5** A, Illustrates top to bottom: a <sup>31</sup>P-NMR spectra in a normal human, a patient with dilated cardiomyopathy but a favorable PCr/ATP ratio of greater than 1.6, a patient with dilated cardiomyopathy and an unfavorable PCr/ATP ratio less than 1.6, and a cardiomyopathy patient with a severely decreased PCr/ATP (<1.0), who died within 7 days after this image was taken. B, A Kaplan-Meier analysis showing prognosis differences based on PCr/ATP. C, Shows magnetic resonance imaging (MRI) of a normal heart compared with a dilated cardiomyopathy. (Reproduced with permission from Neubauer S. The failing heart—an engine out of fuel. *N Engl J Med* 2007;356:1140-1151.)

**FIGURE 20-6** Cardiac metabolism in heart failure. B, Shows the heart failure-induced changes in oxidative phosphorylation. There is decreased energy production. C, Demonstrates the changes in high-energy phosphate metabolism. (Reproduced with permission from Neubauer S. The failing heart—an engine out of fuel. *N Engl J Med* 2007;356:1140-1151.)

$^1\text{H}$ -NMR spectroscopy is useful for assessing myocardial fatty acid metabolism both in animal models and in humans with heart failure.<sup>37</sup> The spectra generated from  $^1\text{H}$ -NMR are used to determine intramyocellular triglyceride deposition (as opposed to flux). The spectra are acquired from a region of interest in the interventricular septum to avoid contamination from epicardial fat. As shown in Figure 20-7, the spectral peak due to water is very large in comparison with the peaks due to myocardial triglycerides. However, the agreement between  $^1\text{H}$ -NMR spectroscopy measurement of myocardial triglycerides and traditional biochemical methods is very good, and  $^1\text{H}$ -NMR spectroscopy is reproducible. The amount of myocardial triglyceride deposition correlates with increased ventricular mass, concentric remodeling, and decreased regional systolic function (Figure 20-8).<sup>37</sup> This noninvasive technique is particularly valuable for the robust myocardial phenotyping of patients with heart failure due to different causes and for monitoring responses to metabolic modulation therapies.

### Radionuclear Imaging: A Focus on Positron Emission Tomography

Tracing metabolic pathways with short-lived radionuclear tracers has found more widespread clinical applications than NMR spectroscopy, mainly in the diagnosis and management

of ischemic heart disease. Although single-photon emission computed tomography (SPECT) imaging can be used to evaluate myocardial glucose or fatty acid metabolism, SPECT cannot quantify myocardial metabolism rates, so its utility for measuring metabolism has been limited. In contrast, positron emission tomography (PET) can be used to quantify myocardial oxygen and substrate metabolism (see also Chapter 36). In general, two types of positron-emitting tracers are used in PET imaging: generator-derived substrate analogs, such as [ $^{18}\text{F}$ ]2-deoxy-2-fluoro-D-glucose (FDG), and cyclotron-derived [ $^{11}\text{C}$ ]-labeled tracers, such as [ $1\text{-}^{11}\text{C}$ ]-glucose. The main advantages of generator-produced tracers are that an onsite cyclotron is not needed and the cost is often cheaper than cyclotron-produced tracers. The main advantage of cyclotron-produced tracers is that (in conjunction with compartmental modeling) they can provide more comprehensive information about intracellular myocardial metabolism. While complete detail on all metabolic tracers ever used or being developed for myocardial metabolic measurements is beyond the scope of this chapter, it is important to note that clinically the most commonly used metabolic tracer is FDG. The method for calculation of myocardial glucose metabolism rates using FDG requires use of a “lumped constant” that represents the ratio of the use of 2-deoxyglucose relative to glucose. The uptake and retention of FDG is linear with time and follows zero-order kinetics.<sup>38</sup> For research purposes, more detailed measurements of metabolism and intracellular fate of substrates is now possible using [ $1\text{-}^{11}\text{C}$ ]-labeled glucose, fatty acids, and lactate due to the development of new compartmental models that are used in conjunction with the PET-derived time-activity curves from the myocardium and the blood.<sup>39</sup> For example, clearance of labeled long-chain fatty acids is biexponential, suggesting both rapid and slow turnover pools.<sup>40</sup> The size and slope of the exponential components of the  $^{11}\text{C}$  time-activity curve reflect immediate and delayed oxidation of labeled fatty acids. Most recently, a methodology designed to measure endogenous triglyceride oxidation in animals using [ $1\text{-}^{11}\text{C}$ ] palmitate and 3-dimensional PET has shown promise for the potential use of PET for the noninvasive measurement of endogenous triglyceride oxidation.<sup>41</sup>

Still, the most important clinical use for metabolic PET imaging is the assessment of myocardial viability (see Chapter 36).<sup>42</sup> Regional responses in substrate metabolism to myocardial ischemia can be visualized entirely noninvasively. The basis of viability studies is the finding that ischemic, non-contractile, *but viable* myocardium has markedly impaired blood flow but normal or enhanced glucose metabolism due to a return to the fetal gene program.<sup>43</sup> Thus demonstration of enhanced FDG uptake and normal or decreased coronary

**FIGURE 20-7** Far left: Magnetic resonance image of the heart showing a region of interest in the ventricular septum. The  $^1\text{H}$ -NMR spectra generated from the region of interest are next to the MRI image. The largest peak is from water. The myocardial triglyceride peaks have been enlarged. 318 flow (metabolism/perfusion mismatch) is the current gold standard for identification of potentially reversible contractile dysfunction with revascularization (Figure 20-9).

CH 20

Results from PET studies of myocardial metabolism in nonischemic heart failure in nonobese, nondiabetic patients are somewhat mixed but generally demonstrate a shift toward glucose and away from fatty acid metabolism.<sup>44</sup> For example, in a PET study of human idiopathic cardiomyopathy using [<sup>11</sup>C] palmitate, the mean LV myocardial use of fatty acids was significantly less than that of control subjects.<sup>45</sup> In heart failure from a different cause (i.e., due to genetic defects in fatty acid oxidation), it is not the total fatty acid use that is altered as much as the rates of  $\beta$ -oxidation of fatty acids are decreased.<sup>46</sup> In contrast, in one study of hypertrophic cardiomyopathy due to a particular mutation (Asp175Asn in the  $\alpha$ -tropomyosin gene), myocardial oxygen consumption and fatty acid metabolism were increased.<sup>47</sup> Taken together, these studies demonstrate that all heart failure is not created equally in terms of myocardial metabolism. Different causes lead to different patterns of myocardial metabolic substrate preference even if decreased function is common to all. This suggests that myocardial metabolic changes observed in heart failure are not solely in response to functional changes. Moreover, it suggests that new treatment strategies aimed at improving myocardial metabolism will have to be *individualized* to the metabolic pattern peculiar to a particular cause of heart failure.

Treatment of heart failure patients with standard heart failure medications aimed at the neurohormonal axis may also have effects on myocardial metabolism and energetics. For example, the  $\beta$ -blocker carvedilol leads to a readily detectable decrease of fatty acid uptake by the heart and an increase in glucose uptake, suggesting increased reliance on glucose an energy-providing substrate. ACE inhibitor therapy also appeared to improve myocardial energetics in heart failure. The findings are consistent with the concept of a change in the biological properties of the failing human heart with  $\beta$ -blockade that includes substrate preference<sup>48</sup> and substrate-induced improvement in cardiac efficiency.<sup>49</sup>

**FIGURE 20-9** Assessment of myocardial viability. The top short axis positron emission tomography (PET) images show uptake of FDG in all myocardial segments, consistent with intact glucose metabolism. The bottom images show markedly decreased perfusion in the inferior wall (white arrows) assessed by thallium-201 uptake. Demonstration of enhanced FDG uptake and normal or decreased coronary flow (metabolism/perfusion mismatch) is the current gold standard for identification of potentially reversible contractile dysfunction with revascularization. (Reproduced with permission from Cornel JH, Bax JJ, Fioretti PM, et al. Prediction of improvement of ventricular function after revascularization. 18F-fluorodeoxyglucose single-photon emission computed tomography versus low-dose dobutamine echocardiography. *Eur Heart J* 1997;18(6):941-948.)

## Transcript Analyses

Another dimension in the evaluation of metabolic disturbances underlying heart failure is the assessment of gene expression in myocardial biopsy samples. With the exception of rare disorders such as glycogen storage disease and lipotoxic heart disease (see later discussion), histology and immunocytochemistry have limited usefulness as tools for diagnosing metabolic disturbances of the failing heart. As outlined previously, the use of AV differences, <sup>31</sup>P-NMR, and PET have brought to light a number of defects in energy substrate metabolism. These findings and the concept of energy starvation of the failing heart are now the basis for further studies examining cardiac gene expression of key regulators in energy substrate metabolism. Moreover, the advent of quantitative RT-PCR and targeted gene expression arrays have facilitated a more complete assessment of metabolic gene expression changes in the failing heart.

Consistent with the observed reduction in fatty acid oxidation capacity in heart failure from dilated cardiomyopathy, the mRNA expression of enzymes that mediate long-chain fatty acid metabolism is downregulated<sup>50,51</sup> (Figure 20-10). Similar downregulation in the expression of genes encoding fatty acid oxidation enzymes is observed in animal models of hypertrophy and heart failure.<sup>52</sup>

Many of the genes for proteins of fatty acid uptake and oxidation are regulated by the nuclear receptor peroxisome proliferator activated receptor  $\alpha$  (PPAR $\alpha$ ).<sup>53</sup> This transcription factor forms a heterodimer with the retinoic X receptor  $\alpha$  (RXR $\alpha$ ) and complexes with coactivators, most prominently PGC1 $\alpha$ .<sup>54</sup> One of the natural ligands for PPAR $\alpha$  was recently determined to be 16:0;18:1 glycerol-3-phosphocholine; however, other fatty acid moieties may also be able to activate this nuclear receptor. In animal models of cardiac hypertrophy, gene expression and DNA binding activity of PPAR $\alpha$

Fatty acid oxidation enzyme gene expression is downregulated in the failing heart. *Circulation* 1996;94:2837-2842.)

decrease as does the expression of various enzymes involved in  $\beta$ -oxidation,<sup>53</sup> suggesting a possible transcriptional mechanism for diminished rates of fatty acid oxidation. These observations are consistent with data demonstrating that PPAR $\alpha$  is downregulated in the failing human heart.<sup>55</sup> In addition to PPAR $\alpha$ , the heart also expresses high levels of the nuclear receptors PPAR $\beta/\delta$  and ERR $\alpha$ . Although the regulation of these transcription factors in heart failure is less clear, both PPAR $\beta/\delta$  and ERR $\alpha$  upregulate many of the same fatty acid oxidation genes as PPAR $\alpha$ .<sup>56</sup> In addition, PPAR $\beta/\delta$  and ERR $\alpha$  are distinct from PPAR $\alpha$  in that they induce genes involved in glucose uptake and mitochondrial oxidative phosphorylation, respectively. Mice overexpressing PPAR $\beta/\delta$  in the myocardium are resistant to high-fat diet-induced cardiomyopathy and show increased protection from ischemia reperfusion injury.<sup>56</sup> In contrast, animals with a cardiac-specific deletion of PPAR $\beta/\delta$  develop cardiomyopathy.<sup>57</sup> These data are consistent with the concept that PPAR $\beta/\delta$ -induced transcriptional programs are cardioprotective. ERR $\alpha$  also plays a protective role when the heart is exposed to stresses such as pressure overload, as evidenced by the rapid development of heart failure in ERR $\alpha$  knockout mice subjected to aortic banding.<sup>58</sup> Recent evidence also suggests that ERR $\alpha$ -regulated pathways are downregulated in humans with heart failure.<sup>59</sup>

In contrast to long-chain fatty acids, the transcriptional regulation of glucose metabolism in heart failure is less well understood. Cardiac hypertrophy is associated with increased reliance on glucose oxidation,<sup>60</sup> whereas late-stage cardiomyopathy is associated with decreased glucose uptake.<sup>61</sup> Recent studies suggest that glucose transporters 1 and 4 are both downregulated in patients with end-stage heart failure at the transcriptional level.<sup>51</sup> In addition, pacing-induced heart failure in a canine model caused decreased mRNA levels of lactate dehydrogenase. In the same model, the activities of 3-phosphoglycerate kinase and pyruvate kinase were also downregulated,<sup>62</sup> consistent with an impairment of glucose use in the later stages of heart failure. Thus not only do different causes of heart failure affect the heart's substrate metabolism profile, but severity of heart failure also affects it.

In addition to changes in transcript levels of enzymes regulating energy substrate metabolism, genes controlling the transfer of high-energy phosphates across the inner mitochondrial membrane also show alterations in the failing heart. For instance, a recent report showed a downregulation of adenine nucleotide translocator 1 (ANT1) in a rodent model of chronic heart failure.<sup>63</sup> In contrast, others have found that hearts from patients with dilated cardiomyopathy have decreased transcript levels of adenine nucleotide translocator 2, whereas adenine nucleotide translocator 1 protein content increased.<sup>64</sup> Overall, these findings suggest that in the failing heart, changes in expression of regulators of energy transfer pathways are likely contributors to the progression of contractile dysfunction.

Transcripts for mitochondrial proteins are also decreased in the failing heart. For instance, in a mouse model of heart failure, mitochondrial DNA-encoded gene transcripts, including the subunits of complex I (ND1, 2, 3, 4, 4L, and 5), complex III (cytochrome b), complex IV (cytochrome oxidase), and rRNA (12S and 16S) are all decreased. These transcriptional changes were accompanied by changes in the enzymatic activity of complexes I, III, and IV.<sup>65</sup> These findings are consistent with other observations of decreased mitochondrial respiration in the failing human heart, and defective mitochondrial structure and function in animal models of heart failure.<sup>66</sup> However, with the exception of certain inherited cardiomyopathies exhibiting mutations for mitochondrial enzymes of long-chain fatty acid metabolism,<sup>50</sup> it cannot be determined with certainty whether mitochondria play a primary or a secondary role in contributing to heart failure.

The regulation of genes involved in both fatty acid oxidation and mitochondrial oxidative capacity/biogenesis are controlled by the nuclear receptor coactivators PGC-1 $\alpha$  and  $\beta$ .<sup>67</sup> These proteins are highly expressed in the heart where they direct gene expression through interactions with nuclear receptor (PPAR $\alpha$ , PPAR $\beta/\delta$ , ERR $\alpha$ ) and nonnuclear receptor transcription factors (NRF-1/2, MEF2). The highly inducible nature of these proteins allows them to rapidly reprogram metabolism in response to a variety of stressors. In both humans and animal models of hypertrophy and heart failure from dilated cardiomyopathy PGC-1 coactivators are downregulated. This is further supported by the observation that mice lacking both PGC-1 isoforms die of heart failure early in life.<sup>68</sup> Thus although a metabolic shift toward glucose metabolism and away from fatty acid metabolism may in some ways be adaptive (e.g., glucose metabolism is more oxygen efficient than fat metabolism), a marked decrease fatty acid metabolism appears to be maladaptive. The decrease in fatty acid metabolism may be detrimental because the heart can produce more ATP from each long-chain fatty acid compared with each glucose molecule. So, a marked downregulation of myocardial fatty acid enzymes and fatty acid metabolism would result in less energy production for the failing heart.

## Genomic Analysis

Genomic analysis of enzymes of lipid metabolism has the potential to contribute to both diagnosis and prognosis in heart failure. At least a dozen separate inherited disorders of mitochondrial fatty acid  $\beta$ -oxidation have been described in humans (Table 20-1).<sup>69</sup> The severe clinical manifestations of these inborn errors in human fatty acid oxidizing enzymes include dilated cardiomyopathy and sudden death, underlining the importance of *normal* fatty acid metabolism for *normal* function of the *normal* heart.<sup>70</sup> The most commonly recognized defect is medium-chain acyl-CoA dehydrogenase (MCAD) deficiency. In addition, polymorphisms of the PPAR $\alpha$  gene have been shown to influence human LV growth

**TABLE 20-1 Defects of Mitochondrial Fatty Acid Oxidation**

Fatty acid oxidation defect

Abbreviations: CPT, carnitine palmitoyltransferase; CPT II, carnitine palmitoyltransferase II; CPT I, carnitine palmitoyltransferase I; MCAD, medium-chain acyl-CoA dehydrogenase; LCAD, long-chain acyl-CoA dehydrogenase; ETF, electron transfer flavoprotein; QO, ubiquinone oxidoreductase; SCAD, short-chain acyl-CoA dehydrogenase; LCHAD, long-chain 3-hydroxyacyl-CoA dehydrogenase; SCHAD, short-chain 3-hydroxyacyl-CoA dehydrogenase.

in response to exercise and hypertension<sup>71</sup> and to modify the response to  $\beta$ -blockers in patients with recent myocardial infarction.<sup>72</sup> Further characterization of the phenotypic impact of polymorphisms within metabolic regulatory proteins has prognostic and therapeutic potential for patients with heart failure.

## METABOLIC ADAPTATION AND MALADAPTATION OF THE HEART

Perhaps one of the most exciting developments in the field of cardiac metabolism is the recognition that the heart possesses defined mechanisms to adapt to external stimuli. Sustained and/or multiple stimuli may also lead to metabolic remodeling and maladaptation of the heart.

### Steps Leading to Metabolic Remodeling

Studies carried out in isolated perfused heart preparations have shown that the heart responds to changes in its environment by redirecting substrate fluxes through those pathways that are energetically most efficient in a given metabolic or physiological environment. Examples are the suppression of glucose oxidation when there is an oversupply of fatty acids, and conversely, the suppression of long-chain fatty acid oxidation in the presence of high concentrations of glucose and insulin.<sup>5</sup> An acute increase in the workload of the heart results in instantaneous mobilization and oxidation of glycogen and a shift from fat to carbohydrates (glucose and lactate) as the main fuel for respiration.<sup>73</sup> In the heart, *in vivo*, this shift is tied to greater efficiency of energy conversion.<sup>74</sup>

Sustained changes in the heart's environment, caused by altering substrate supply or by changing LV pressure, induce isoform-specific switches in sarcomeric and metabolic proteins.<sup>75</sup> Qualitative and quantitative changes in metabolic gene expression result in a shift from fat to glucose in the hypertrophied and atrophied heart.<sup>76</sup> In contrast, the heart in obesity and diabetes further increases its reliance on fatty acids as fuel for respiration,<sup>77</sup> changes that are orchestrated at least in part through altered expression of metabolic genes.

The dynamic nature of this oscillation between uses of different substrates is not always appreciated. As outlined previously, this adaptation can either be acute (alterations in preexisting proteins) or chronic (alterations in gene expression, remodeling), depending upon the intensity and duration of the stimulus.<sup>60</sup> It is reasonable to propose that metabolic adaptation often precedes or parallels functional adaptation of the heart. While this metabolic change may initially be generally adaptive to a stimulus in the short-term, it may also have detrimental effects over the long-term and lead to contractile dysfunction and failure (maladaptation).

### Hypertrophy from Pressure Overload

The impact of workload on cardiac metabolism, gene expression, and function has been intensely studied. Alterations in workload on the heart have both acute and chronic effects on myocardial metabolism. When the workload is increased, the heart rapidly responds by increasing the flux of carbon through metabolic pathways. In doing so, the heart balances the rates of energy-generating reactions (e.g., oxidative phosphorylation) with that of energy-consuming reactions (e.g., cross-bridge cycling). More specifically, increased workload on the heart rapidly results in increased glucose uptake, glycolysis, glycolytic flux, and pyruvate oxidation (whether derived from extracellular glucose, extracellular lactate, or intracellular glycogen), with little effect on fatty acid oxidation.<sup>78</sup>

If the increased workload on the heart is sustained, the heart responds with characteristic alterations in morphology, increased cell size, and gene expression (e.g., reexpression of fetal genes), paralleled by a process of metabolic remodeling. In general terms, the hypertrophied heart increases its reliance on glucose as a fuel, while decreasing fatty acid oxidation.<sup>79</sup> This upregulation of glucose metabolism occurs even before there is an increase in LV mass.<sup>80</sup> Somewhat unexpectedly, with a sustained *decrease* in workload, the heart also responds with an upregulation of glucose metabolism.<sup>76</sup> It appears that any sustained changes in workload results in similar patterns of metabolic remodeling and in a switch from an energetically less efficient (fatty acids) to an energetically more efficient (glucose) fuel for respiration.

Two important questions arise when considering metabolic adaptation of the hypertrophied heart. (1) What is the mechanism for substrate switching and (2) why does substrate switching occur? In the past, mechanistic studies of substrate switching have focused on the regulation of the pyruvate dehydrogenase complex (PDC). Recent evidence suggests, however, that the nuclear receptor PPAR $\alpha$  plays a key regulatory role in substrate switching,<sup>81</sup> whereas PDC activity remains relatively unaffected in response to sustained pressure overload. PPAR $\alpha$  binds to the promoter of, and subsequently induces the transcription of, multiple genes encoding for proteins involved in fatty acid metabolism. These include fatty acid translocase (FAT/CD36), heart-specific fatty acid binding protein (hFABP), acyl-CoA synthetase I (ACSI), malonyl-CoA decarboxylase (MCD), muscle-specific carnitine palmitoyltransferase I (mCPTI), medium-chain acyl-CoA dehydrogenase (MCAD), and long-chain acyl-CoA dehydrogenase (LCAD). PPAR $\alpha$  is itself activated by fatty acids, thereby forming a positive feed-forward mechanism for fatty acid-induced fatty acid oxidation. Pressure overload represses this mechanism by decreasing the expression of PPAR $\alpha$  itself, and its coactivator, PGC1. PPAR $\alpha$ -DNA binding activity is also reduced through covalent modification (phosphorylation) in response to pressure overload. The result is decreased expression of fatty acid metabolizing genes in the hypertrophied heart, and therefore decreased fatty acid oxidation capacity. In addition, several other transcription factors (e.g., Sp1, Coup-TF) known to be activated in the response to pressure overload have been implicated in the repression of fatty acid oxidation genes.<sup>82</sup> What is less clear is the mechanism by which reliance on glucose as a metabolic fuel increases in the hypertrophied heart. One possibility is that the increased glucose oxidation is the result of decreased fatty acid oxidation through a mechanism complementing the one described nearly 40 years ago by Randle and his group.<sup>7</sup> In the normal heart, fatty acids suppress glucose oxidation to a greater extent than glycolysis, and glycolysis to a greater extent than glucose uptake. Conversely, glucose also suppresses fatty acid oxidation<sup>5</sup> through a mechanism that involves malonyl-CoA-induced inhibition of the fatty acid transporter protein CPTI.<sup>83</sup> Although increased glycolytic rates in the hypertrophied heart are consistent with the Randle hypothesis, rates of pyruvate oxidation are not increased to the same extent,<sup>84</sup> and insulin's effects on glucose oxidation are attenuated.<sup>85</sup> Therefore, a loss of coordination between glucose oxidation and glycolysis exists. Other potential factors involved in increased glucose use in response to pressure overload include decreased expression of PDK4 (a PPAR $\alpha$  target gene), chronic activation of AMPK, and elevated cytosolic levels of Ca<sup>2+</sup>.<sup>86</sup>

Why does substrate switching occur in the hypertrophied heart? A classic explanation for this phenomenon is at the energetic level. Glucose is a more efficient energy source compared with fatty acids (i.e., more ATP generated per O<sub>2</sub> consumed). This is particularly important when oxygen demand outstrips oxygen supply, as may be the case in the

hypertrophied heart. Furthermore, evidence exists suggesting that glycolytically derived ATP is preferentially used by ion channels, the activities of which are increased in the hypertrophied heart. However, substrate switching may have roles beyond its stereotypical function as a provider of ATP, potentially creating essential signals within the cardiomyocyte required for adaptation and remodeling. For example, as mentioned previously, fatty acids affect the expression of several target genes through transcription factor activation. Work performed in the liver as a model system for metabolically controlled gene transcription has shown that glucose metabolites alter the expression of specific genes, such as pyruvate kinase, acetyl CoA-carboxylase  $\alpha$ , and fatty acid synthase.<sup>87</sup> Specific glucose-sensing transcription factors (e.g., SP1, USF) become activated through reversible covalent modification (phosphorylation and/or glycosylation) when glucose metabolites accumulate within the cell.<sup>88</sup> These transcription factors are present in the heart, and both are activated in response to pressure overload.<sup>75</sup> Evidence is accumulating for their involvement in the induction of several fetal genes.<sup>89</sup> Glucose has also been suggested to be involved in the induction of growth factors and the activation of translation factors, and may therefore be involved in the trophic response to pressure overload. Indeed, heart-specific overexpression of GLUT1 or the knockout of hFABP in the heart results in substrate switching and cardiac hypertrophy, suggesting increased glucose use is sufficient to trigger the hypertrophic response.<sup>90</sup>

As outlined previously, it appears that metabolic adaptation, including a switch to glucose use, may be important for the heart not only as a means of efficient ATP generation, but also for the generation of intracellular signals involved in the hypertrophic response to pressure overload. PPAR $\alpha$  plays a key role in this substrate switching, since activation of PPAR $\alpha$  in the hypertrophied heart prevents downregulation of fatty acid oxidation and blocks the increased reliance on glucose in response to pressure overload in rats.<sup>91</sup> Such PPAR $\alpha$  activation results in contractile dysfunction in the hypertrophied heart, supporting the idea that switching to glucose use is essential for the heart to maintain contractile function in response to pressure overload. Furthermore, the induction of the fetal gene skeletal  $\alpha$ -actin was abolished by PPAR $\alpha$  activation. The activation of this contractile protein in response to pressure overload has previously been shown to be dependent upon the activation of the glucose-sensing transcription factor, Sp1. Despite the block of metabolic and gene expression adaptation, the trophic response to pressure overload was unaffected by PPAR $\alpha$  activation.<sup>91</sup> Increased reliance on myocardial glucose metabolism therefore appears essential for the maintenance of contractile function and the initially adaptive trophic response to pressure overload.

## METABOLIC REMODELING OF THE HEART IN OBESITY, INSULIN RESISTANCE, AND DIABETES

### Adaptation and Maladaptation of the Heart in Obesity

There is increasing awareness of the link between obesity and cardiovascular disease (see Chapter 22), and cardiac remodeling in obesity.<sup>92</sup> Obesity is a growing public health concern, and affects approximately one third of the U.S. population and a growing percentage worldwide. Obesity is also a major risk factor for the development of heart failure. It is estimated that between 11% and 14% of all heart failure is due to obesity alone, and that a much greater percentage of all heart failure is due to obesity and its frequent comorbidities,

diabetes, hypertension, and coronary disease.<sup>93</sup> In morbidly obese patients, overfeeding the heart with energy-providing substrates results in the accumulation of triglycerides in cardiac myocytes and impaired contractile function. This is not a new concept. “Fat in all the wrong places”<sup>94</sup> was already described by Virchow who observed in his *Cellular Pathology* that “genuine fatty degeneration (metamorphosis) of the heart is a real transformation of its substance, going on in the interior of the fibers.”<sup>95</sup> Although extreme cardiac fatty metamorphosis (adipositas cordis), manifested by a heart so stuffed with lipids that it floats in water, is relatively rare, impairment of myocardial triglyceride and fatty acid metabolism on a more modest scale also appears to have deleterious effects on the function of the heart.<sup>96</sup>

“Lipotoxicity” in a general sense describes the effects of excessive uptake of fatty acids by the heart. When first described in animal models, however, lipotoxicity referred to a specific pathway in which increased fatty acid uptake exceeded  $\beta$ -oxidation and led to fatty acid *deposition*, ceramide production, increased iNOS activity, and apoptosis.<sup>75</sup> Since this initial description, it has been discovered that fatty acid *deposition*-induced apoptosis may also result from reactive oxygen species generation<sup>97</sup> (Figure 20-11). Excessive fatty acid *oxidation* may also play a role in the development of obesity-related cardiac dysfunction through pathways that do not result in apoptosis. For example, a study of *db/db* mice showed that increased myocardial fatty acid oxidation precedes contractile dysfunction, suggesting that excessive fatty acid oxidation may contribute to dysfunction. A mouse model with transgenic overexpression of a fatty acid transport protein in the heart also demonstrated increased cardiac fatty acid oxidation, leading to diastolic cardiac dysfunction.<sup>98</sup> Excessive free radical generation from oxidative processes in general may contribute to dysfunctional calcium handling and dysfunction rather than apoptosis-induced dysfunction.<sup>99</sup>

In humans, there is growing evidence that alterations in myocardial fatty acid metabolism accompany decreased cardiac function. Fat deposition has been demonstrated in pathological examination of failing human hearts from obese and diabetic patients.<sup>100</sup> This fat deposition can now be measured *in vivo* noninvasively, using <sup>1</sup>H-NMR as described previously.<sup>37</sup> Fat deposition may be reversible, as shown in one study of obese, diabetic patients placed on a very low-calorie diet, in whom a decrease in myocardial lipid accumulation was accompanied by an improvement in diastolic function.<sup>101</sup> Nonetheless, it remains unclear whether the lipid deposition *per se* results in human cardiac dysfunction, or if it is a marker of an altered metabolic milieu and myocardial metabolic metabolism that leads to dysfunction. Obesity and its frequent comorbidity, insulin resistance, also are associated with increased myocardial fatty acid uptake, use, and oxidation in asymptomatic young women without frank cardiac systolic dysfunction compared with age-matched controls.<sup>102</sup> Weight loss can decrease the high rates of myocardial fatty acid metabolism associated with obesity.<sup>103</sup> Weight loss (from bariatric surgery or diet therapy) also improves whole body metabolic abnormalities, cardiac diastolic dysfunction, and occasionally systolic function.<sup>104</sup> The fact that weight loss results in an improvement in diastolic and sometimes systolic dysfunction suggests that in humans, apoptosis is not likely the predominant mechanism by which obesity causes heart failure.<sup>105</sup>

### Adaptation and Maladaptation of the Heart in Diabetes

Although the question whether there is a diabetes-specific cardiomyopathy has been debated for decades (see Chapter 26), there is increasing evidence that diabetes has detrimental

**FIGURE 20-11** Cardiac hypertrophy and failure in a mouse heart model of lipotoxicity. The panels are (from left to right) serial 2-dimensional guided M-mode echocardiographic images obtained from wild-type (*upper panel*) and MHC-ACS1 07 (*lower panel*) mice at 2, 3, 4, and 6 weeks of age. Images shown are from a representative pair of age- and sex-matched wild-type transgenic animals. The last panel on the right is a transmission electronmicrograph of cardiac tissue from 18-day-old MHC-ACS mice shown at 15,000 $\times$  magnification. Numerous lipid droplets are observed in ventricular myocytes. Some droplets at this stage are surrounded by multiple concentric layers of membrane (*arrow*). (Modified with permission from Chiu HC, Kovacs A, Ford DA, et al. A novel mouse model of lipotoxic cardiomyopathy. *J Clin Invest* 2001;107:813-822.)

effects on cardiac function not accounted for by coronary or other cardiac disease. Patients with diabetes mellitus have an increased lifetime risk of congestive heart failure<sup>106</sup> and are overrepresented in large heart failure databases.<sup>107</sup> Other evidence for a “diabetic cardiomyopathy” in humans includes a number of morphological, functional, energetic, and biochemical observations. Moreover, heart disease in general is the leading cause of death among patients with diabetes mellitus. This excess heart disease is observed both in patients with type 1, characterized by severe impairment or absence of insulin secretion, and in patients with type 2, characterized by a combination of peripheral tissue insulin resistance and inadequate compensatory insulin secretion. Insulin resistance is a feature of both types of diabetes.

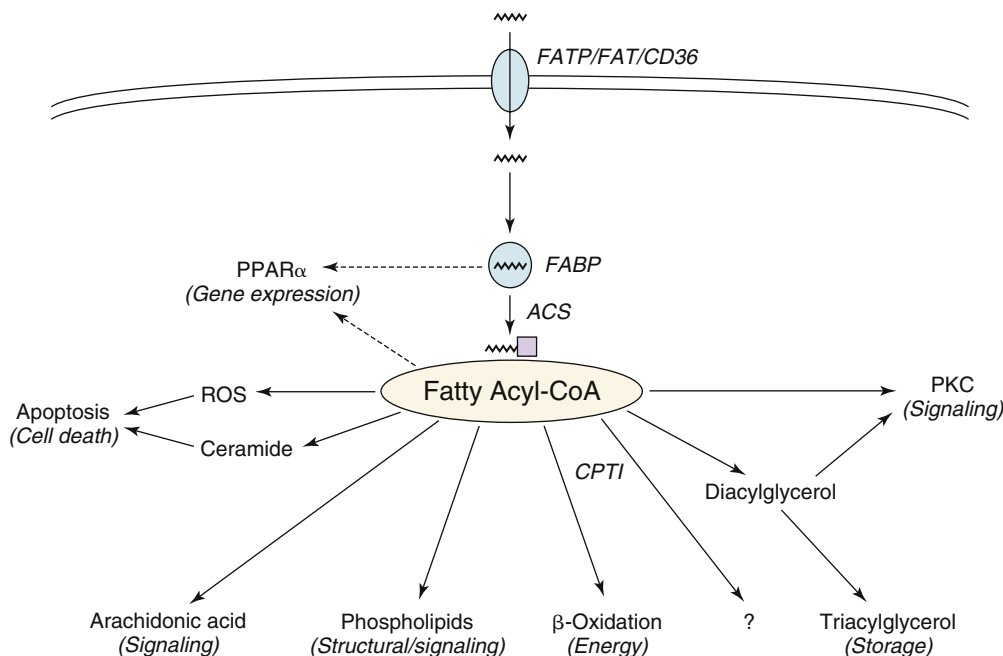

The prevalence of type 2 diabetes has increased dramatically in parallel with the obesity epidemic.<sup>75,108</sup> Thus the adaptation of the heart in diabetes warrants further discussion. There is a depression of glucose oxidation in the diabetic heart. This is likely due to inhibition of PDC. The activity of PDC is affected by both allosteric modulation and covalent modification. In the diabetic state, increased fatty acid and ketone body use results in increased intramitochondrial acetyl-CoA levels, which allosterically inhibit PDC. Furthermore, activation of PPAR $\alpha$  by fatty acids induces pyruvate dehydrogenase kinase 4 (PDK4), which phosphorylates and inhibits PDC.<sup>91</sup> Despite the apparent opposite metabolic adaptation, the heart in diabetes shows gene expression of myosin isoforms that is similar to that of the pressure-overloaded heart.<sup>109</sup> In pressure overload, the reexpression of these particular fetal genes is proposed to be due to increased glucose metabolites within the cardiomyocytes involved in the induction of fetal genes. At first sight this does not seem to be consistent with the diabetic heart’s metabolic profile. However, if there is hyperglycemia, the rate of glucose transport in the hearts of diabetic animals is often similar to that of normal animals because substrate use is very dependent on plasma substrate concentration. Due to the severe attenuation of pyruvate oxidation, glucose oxidation rates are lower than rates of glucose uptake, resulting in the accumulation of glycolytic intermediates in the heart during diabetes. Thus in diabetes, myocardial glucose uptake and oxidation are not as tightly coupled as in the normal heart, which has consequences on cardiac gene expression.

It is also very evident that diabetes is as much a disorder of fatty acid metabolism as it is a disorder of glucose metabolism.<sup>110</sup> Just like in the fasted state, the normal heart oxidizes predominantly fatty acids.<sup>111</sup> In the diabetic milieu, the increased fatty acid availability is accompanied by even greater rates of fatty acid oxidation.<sup>112</sup> Current concepts support the view that the greater reliance on fat oxidation in the diabetic heart is due to activation of PPAR $\alpha$  and subsequent induction of PPAR $\alpha$ -regulated fatty acid oxidation enzymes.<sup>113</sup> For example, induction of MCD in the heart of streptozotocin-induced diabetic rats (a model of type I diabetes) likely plays a role in the decreased malonyl-CoA levels (an inhibitor of fatty acyl-CoA entry into the mitochondrion) and increased fatty acid oxidation.<sup>114</sup> Models of type 2 diabetes also demonstrate an increase in myocardial fatty acid oxidation at a young age and lipid accumulation at older ages.<sup>115</sup> As mentioned in the section previously discussed on obesity, this increase in fatty acid oxidation and/or lipid accumulation may have direct, lipotoxic effects on cardiac function. However,  $\beta$ -oxidation of fatty acids may not always match excessive fatty acid delivery to the heart, resulting in subsequent elevation of intracellular fatty acids and lipids, which have been associated with diabetic cardiomyopathy in rodent models.<sup>116</sup> In this respect, the diabetic heart appears similar to the obese heart, although some studies suggest that the former has even greater fat accumulation (Figure 20-12).<sup>100</sup> There appear to be multiple mechanisms that contribute to this type of lipid accumulation-driven lipotoxicity, including chronically activated PKCs, generation of reactive oxygen species (ROS), and ceramide-induced apoptosis. In addition, it is not surprising that dysregulation of myocardial fatty acid metabolism may decrease cardiac function in the diabetic heart, since fatty acids and fatty acid metabolites have multiple cellular functions (Figure 20-13). They are mediators of signal transduction (e.g., activation of various protein kinase C (PKC) isoforms, initiation of apoptosis), ligands for nuclear transcription factors (e.g., PPAR $\alpha$ ), and essential components of biological membranes.

Some of the more recent studies of the human heart in diabetes demonstrate similar metabolic features as seen in animal models. In patients with type I diabetes, there is an increase in myocardial oxygen consumption and fatty acid metabolism, and a lower glucose use/level of plasma insulin,

**FIGURE 20-12** Cardiac lipotoxicity. *Top:* Photomicrographs of low, intermediate, and high lipid accumulation in the myocardium, as stained by Oil red O. *Bottom:* The amount of intramyocardial triglyceride in explanted hearts from nonfailing donors (NF) not suitable for transplant, nonobese heart failure patients (HF), obese heart failure patients (HF + O), and diabetic heart failure patients (HF + DM). The patients with diabetes and heart failure had higher intramyocardial fat levels (\*  $P < .05$ ). (Adapted from Sharma S, Androgué JV, Golfman L, et al: Intramyocardial lipid accumulation in the failing human heart resembles the lipotoxic rat heart. *FASEB J*. 2004; 18:1692-1700.)

**FIGURE 20-13** The multiple fates of activated fatty acids in the cardiac myocytes. See text for further discussion.

suggesting insulin resistance.<sup>117,118</sup> However, the myocardium can still respond to changes in insulin and free fatty acid levels by changing its substrate preference. This suggests that the metabolic regulatory phenomena such as the Randle cycle or “Randle phenomenon” still are germane to the diabetic heart. In patients with type 2 diabetes without heart failure, there is increased myocardial fatty acid use. In type 2 diabetics, there is also evidence of increased myocardial fatty acid accumulation.<sup>100</sup> As noted previously, lipid accumulation in diabetics without heart failure may be decreased with weight loss. Myocardial energetics in diabetes are also

altered, with decreased PCr/ATP compared with controls. Moreover, this detrimentally altered energetic state is *directly related to impaired diastolic function*.<sup>119</sup> At least one study has also related hyperglycemia with diastolic dysfunction as well.<sup>120</sup> Whether therapies aimed at manipulating diabetes-induced alterations in myocardial metabolism and/or energetics improves cardiac function is as yet unknown.

To make matters more complicated, diabetes is often associated with hypertension, obesity, and the metabolic syndrome.<sup>108</sup> The addition of other pathophysiological conditions (particularly hypertension) on top of diabetes

complicates and exacerbates its myocardial metabolic abnormalities. For example, induction of diabetes in rats with pressure-overload-induced hypertrophy results in rapid cardiac failure.<sup>121</sup> This phenomenon is similar to the observation that reactivation of PPAR $\alpha$  in the hypertrophied heart results in contractile dysfunction.<sup>91</sup> The attenuation of fatty acid oxidation due to pressure overload and increased fatty acid availability because of concomitant diabetes theoretically should accelerate lipid deposition within the cardiomyocyte, thereby accelerating lipotoxicity. Thus forcing a hypertrophied heart to use fatty acids in the diabetic milieu results in a maladapted heart, exhibiting contractile dysfunction.

## CROSSTALK BETWEEN CYTOKINE SIGNALING PATHWAYS, INNATE IMMUNITY, AND METABOLISM

### Nitric Oxide: Effects on Metabolism

Since the identification of nitric oxide (NO) as an endothelial-derived relaxation factor (EDRF), which is a mediator of various vasodilatory agents, including bradykinin, the role of NO has been implicated in various cellular systems.<sup>122</sup> NO is a simple free radical gas with a relatively short half-life in biological systems (estimated at approximately 4 seconds) due to its high reactivity.<sup>122</sup> The ability of NO to diffuse freely through membranes enables it to have paracrine and autocrine functions (see Chapter 17).

Nitric oxide is a modulator of cardiac metabolism, both oxidative and nonoxidative. In the former case, NO inhibits mitochondrial oxygen consumption through its effects on aconitase, complexes I and II of the electron transport chain, and cytochrome *c* oxidase, most likely due to a direct interaction of NO with these iron-containing proteins.<sup>123</sup> Exposure of the heart to NO donors has been shown to inhibit oxygen consumption.<sup>124</sup> Conversely, inhibition of NOS with L-arginine analogues increases mitochondrial oxygen consumption.<sup>124</sup> Selective NOS isoform knockout mice suggest that NO derived from eNOS, the most highly expressed NOS isoform in the heart, acts as a physiological inhibitor of mitochondrial oxygen consumption.<sup>125</sup>

NO also affects glucose uptake and glycolytic flux. In contrast to skeletal muscle, NO appears to inhibit cardiac glucose metabolism.<sup>126,127</sup> Exposure of the heart to NO donors decreases glucose uptake, while glucose uptake is stimulated by NOS inhibitors.<sup>126</sup> In addition, eNOS knockout mouse hearts have elevated rates of glucose uptake when perfused *ex vivo*, compared with wild-type hearts. It has been postulated that these effects of NO are mediated by cGMP. Inhibition of the glycolytic enzyme, phosphofructokinase, by NO is also due to elevated intracellular cGMP levels and subsequent activation of cGMP-dependent protein kinase (PKG).

Results of studies regarding the effects of NO on fatty acid metabolism are mixed. Indirect observations suggest that the NO may decrease fatty acid oxidation. For example, activation of acetyl-CoA carboxylase by NO results in increased intracellular levels of malonyl-CoA, an inhibitor of long-chain fatty acyl-CoA transport into the mitochondrion.<sup>126</sup> As mitochondrial fatty acid metabolism is an aerobic process, the inhibition of the mitochondrial electron transport chain components by NO would presumably contribute to inhibition of  $\beta$ -oxidation. However, studies in the dog heart show both an increase in free fatty acid uptake and a decrease in the respiratory quotient (RQ) in response to NO donors, indicative of increased reliance on fatty acid oxidation.<sup>124</sup> This increased reliance on fatty acid oxidation with NO would fit well with the known decrease in glucose metabolism with NO stimulation.

The physiological relevance of nitric oxide signaling in the myocardium has been underscored by the observation that  $\beta$ -3 adrenergic signaling in the heart activates NO-generating pathways. The activation of  $\beta$ -3 receptors on cardiac myocytes reduces contractility through an NO-dependent mechanism,<sup>128</sup> consistent with the described effects of NO on metabolism. Nebivolol is a third-generation  $\beta$ -blocker that is a highly selective  $\beta$ -1 antagonist, but also a  $\beta$ -3 receptor agonist. This drug produces NO-dependent vasodilation and cardiodepression,<sup>128</sup> which in some circumstances is thought to improve the balance between energy delivery and use. The SENIORS trial investigated this drug in elderly patients with clinical heart failure and demonstrated a significant improvement in clinical outcomes related to therapy with nebivolol.<sup>129</sup>

### Modulation of Myocardial Metabolism by Inflammatory Cytokines

In the past decade, it has been suggested that numerous cytokines are involved in the pathogenesis of heart failure.<sup>130</sup> Among these, tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) has received special attention (see Chapter 11). Although the precise mechanisms by which TNF- $\alpha$  and other cytokines elicit their effects on contractile function are still not fully understood, induction of apoptosis, uncoupling of  $\beta$ -adrenergic receptors from adenylate cyclase, and modulation of the extracellular matrix have emerged as possible candidates. In addition, cytokines have dramatic effects on cardiac energy metabolism.<sup>131</sup> Studies in cardiomyocytes have shown that both TNF- $\alpha$  and interleukin-1 $\alpha$  inhibit mitochondrial respiration and decrease PDC activity.<sup>132</sup> In addition, interleukin-1 $\beta$  increases nonoxidative glucose metabolism and decreases mitochondrial enzyme activity (complex I and complex II).<sup>133</sup> The exact mechanisms by which these cytokines modulate energy substrate metabolism are not known, but may depend on the production of NO, the effects of which were discussed previously.

The effects of inflammatory signaling on myocardial metabolism and function are readily apparent in the syndrome of septic shock. It is now recognized that more than 50% of patients with bacterial sepsis will develop inflammatory-induced transient myocardial dysfunction.<sup>129</sup> The inflammatory cascade responsible for the syndrome of gram-negative sepsis is triggered by the host receptor TLR4, which recognizes bacterial lipopolysaccharide (LPS).<sup>134</sup> In animal models of sepsis, the injection of LPS produces LV dysfunction that is dependent on TLR4 activation.<sup>146</sup> The cardiometabolic effects of LPS include decreased fatty acid oxidation capacity and myocardial triglyceride accumulation.<sup>147</sup> Consistent with these observations, LPS downregulates the expression of genes involved in fatty acid oxidation including PPAR $\alpha$ , ERR $\alpha$ , MCAD, and MCP-1.<sup>148</sup> In addition, the nuclear receptor coactivators PGC-1 $\alpha$  and PGC-1 $\beta$ , which regulate fatty acid oxidation and mitochondrial function pathways, are profoundly downregulated during TLR4-induced inflammatory stress. Recent data suggest that LPS-mediated modulation of myocardial metabolism occurs through a PGC-1-dependent mechanism.

The suppression of myocardial fatty acid oxidation pathways by inflammation has been further illustrated in a transgenic mouse with cardiac-specific overexpression of TNF- $\alpha$ .<sup>135</sup> Similar to the acute model of LPS stimulation, TNF- $\alpha$  transgenic mice have reduced fatty acid oxidation capacity and downregulation of the genes encoding PGC-1 $\alpha$ , PPAR $\alpha$ , and many FAO enzymes. In this system, TNF induction of TGF- $\beta$  was shown to mediate the observed downregulation of PPAR $\alpha$ -mediated gene transcription through a Smad3-dependent mechanism. Taken together, it is clear that inflammatory signaling reprograms myocardial metabolism, leading

to reduced rates of fatty acid oxidation. In addition to direct relevance to sepsis-induced myocardial dysfunction, the crosstalk between inflammatory and metabolic pathways illustrated by LPS and TNF stimulation models may also be salient to the metabolic reprogramming observed in chronic heart failure, which is often associated with increased inflammation, particularly in end-stage heart failure.

## Modulation of Programmed Cell Death and Cell Survival by Glucose and Fatty Acid Metabolites

Recent studies have shown that energy metabolism interacts with various pathways regulating programmed cell death and cell survival.<sup>136</sup> There is evidence to suggest that in the heart metabolites serve as signals for programs of adaptation and maladaptation (see Figure 20-1).<sup>137-139</sup> For example, the pleiotropic functions of glucose in the heart include a strong cardioprotective component. Provision of glucose during hypoxic stress,<sup>140</sup> overexpression of the glucose transporter GLUT1, and chronic hyperglycemia all reduce cardiac apoptosis.<sup>153,154</sup> With respect to the protective effects of glucose and insulin on cell function of the heart, three observations are of importance. First, in the reperfused heart, insulin itself increases postischemic cardiac power without increasing rates of glucose oxidation during early reperfusion.<sup>141</sup> This suggests that insulin itself improves the efficiency of the heart without a concomitant increase in rates of glucose oxidation and may be tied to the insulin signal transduction in cascade. Key regulators of this pathway are the insulin receptor, insulin receptor substrate (IRS), PI3 kinase, and Akt/protein kinase B.<sup>142</sup> PI3 kinase regulates cardiac growth,<sup>143</sup> while Akt activation reduces cardiomyocyte death and induces cardiac hypertrophy.<sup>144</sup> Downstream from the activation of mTOR and its targets is dependent on hexose 6-phosphate.<sup>145</sup> Akt is antiapoptotic and promotes both glucose uptake and glycogen synthesis.<sup>146</sup> Activation of Akt by insulin affords myocardial protection through the insulin signaling cascade,<sup>147</sup> and it appears that the inhibition of early apoptotic events by Akt is dependent upon the first committed step of glycolysis, and, more specifically, by the action of hexokinase II, which is bound to the mitochondria.<sup>148</sup> Increased hexokinase activity also protects against acute oxidant-induced cell death.<sup>149</sup>

Deletion of GLUT4 or glucose deprivation, on the other hand, enhances cardiac injury during ischemia.<sup>30,150</sup> Possible mechanisms by which glucose protects the cell from apoptosis include the prevention of intracellular  $\text{Ca}^{2+}$  accumulation, the activation of Akt,<sup>144</sup> and/or the upregulation of the antiapoptotic protein Bcl-2.<sup>151</sup> Three different pathways have been implicated in this response, including glucose deprivation-induced ATP depletion and stimulation of the mitochondrial death pathway cascade, hypoglycemia-induced oxidative stress and activation of the JNK/MAPK signaling pathways,<sup>152</sup> and glucose deprivation-induced stabilization of p53 leading to an increase in p53-associated apoptosis.<sup>152</sup>

In contrast to glucose, fatty acids are implicated in the induction of programmed cell death.<sup>21</sup> A study in Zucker diabetic fatty rats found that high levels of myocardial triacylglycerol were associated with increased DNA laddering (a marker of apoptosis).<sup>153</sup> Both myocardial triacylglycerol accumulation and DNA were attenuated by treating the animals with a lipid-lowering drug.<sup>154</sup> One proposed mechanism of lipoapoptosis is the increased synthesis of ceramide from palmitoyl acyl-CoA.<sup>153</sup> Ceramide is a potent inhibitor of complex III of the electron transport chain, and promotes the accumulation of reactive oxygen species (ROS).<sup>155</sup> Ceramide also upregulates iNOS expression, NO production, and peroxynitrite generation. The latter is an inducer of apoptosis.<sup>153</sup> Studies in cell culture have shown that fatty acid-induced apoptosis can also be regulated by ceramide-independent pathways. One such pathway appears to be mediated by the generation of ROS.<sup>97</sup>

## Metabolism as a Target for Pharmacological Intervention in Heart Failure (see Chapter 50)

The complex and highly regulated network of metabolic pathways provides many potential targets for drug interventions. Prominent among those are drugs directed at shifting the heart's energy supply from oxidation of fatty acids to the more energy efficient oxidation of glucose. This shift can be brought about by either lowering fatty acid availability in the plasma, by inhibiting fatty acid oxidation, or by direct targeting of mitochondrial metabolism. Lastly, drugs may be aimed at the restoration of moiety-conserved cycles.

### Trimetazidine

Trimetazidine, a piperazine compound, is an antianginal drug widely used in France, and belongs to the group of partial fatty acid oxidation inhibitors (so-called PFox inhibitors). Trimetazidine has cardioprotective effects in animal models of ischemia.<sup>156</sup> In clinical trials of chronic stable angina pectoris, trimetazidine was as effective as nifedipine and propranolol for the treatment of stable angina.<sup>157</sup> In contrast to nifedipine and propranolol, trimetazidine elicited beneficial effects independent of any hemodynamic changes.

Trimetazidine is cardioprotective because it modulates energy substrate metabolism, and it may also have antioxidative properties. Trimetazidine decreases long-chain fatty acid oxidation by inhibition of 3 ketoacyl-CoA thiolase.<sup>158</sup> This decrease in fatty acid oxidation leads to an increase in carbohydrate oxidation. This switch in energy substrate preference results in improved coupling between glycolysis and glucose oxidation, thereby decreasing proton and  $\text{Na}^+$  accumulation. There are a few small clinical trials showing that trimetazidine improves heart failure.<sup>159</sup> In one randomized study, those heart failure patients receiving trimetazidine realized improvements in their functional class and LV function. In a PET study, trimetazidine modestly decreased myocardial fatty acid oxidation without changing overall oxygen consumption, implying but not proving an increase in glucose oxidation.<sup>160</sup> However, trimetazidine has limited availability and is not FDA approved for use in the United States.

### Ranolazine

Like trimetazidine, ranolazine belongs to the family of piperazine derivatives, which partially inhibit fatty acid oxidation and hence enhance glucose oxidation.<sup>161</sup> There is also some evidence that ranolazine may reduce calcium overload in ischemic myocardium. Activity of PDC, a key regulator of glucose oxidation, increases after ranolazine treatment, most likely due to decreased inhibitory effects of end products of  $\beta$ -oxidation (NADH, acetyl-CoA)<sup>162</sup> or due to changes in the phosphorylation state. There are also data showing that ranolazine improves myocardial efficiency and LV systolic function in animal models of chronic heart failure.<sup>163</sup> To date there are no data on ranolazine's effects on myocardial metabolism in humans with heart failure, so it has no indication for heart failure treatment at present.

### Lipid-Lowering Agents

Drugs and other therapies, such as weight loss, that decrease fatty acid and/or triglyceride delivery to the heart are attractive targets for decreasing excessive myocardial fatty acid uptake and accumulation. Weight loss decreases myocardial fatty acid use in obese humans.<sup>103</sup> Thiazolidinediones (predominantly PPAR $\gamma$  agonists) reduce plasma lipid levels and (in one study) increase myocardial glucose use. However, results regarding their effect on steatosis are mixed,

with some studies demonstrating decreased and others showing increased lipid accumulation in nonadipose tissues.<sup>164,165</sup> Another drug, acipimox, known to markedly and acutely decrease plasma free fatty acid levels, impaired cardiac efficiency and cardiac work in dilated cardiomyopathy patients.<sup>166</sup> However, the patients in this study would not have been expected to have excessive cardiac fatty acid metabolism before treatment since they were not diabetic. Thus it is perhaps not surprising that they did not benefit. It may be that patients with heart failure related to underlying diabetes and obesity, who have marked myocardial lipid abnormalities at the outset, may have the most to gain from lipid-lowering therapies.

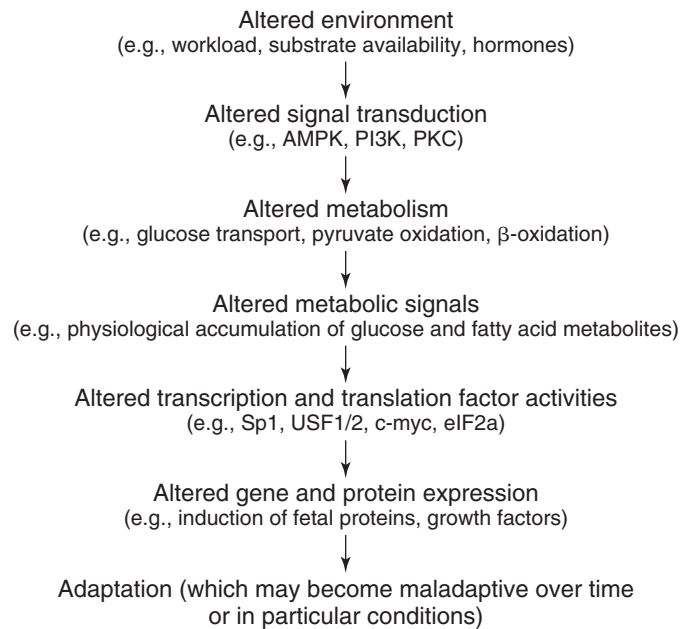

### Propionyl-L-Carnitine

Propionyl-L-carnitine (PLC) has been shown to improve postischemic contractile performance in the heart, presumably through redistribution of long-chain acyl-CoA esters to less toxic intermediates.<sup>167,168</sup> In the failing heart, PLC may improve energy metabolism by three possible mechanisms. First, PLC provides propionate. As a precursor of succinyl-CoA, propionate may replenish citric acid cycle intermediates.<sup>169</sup> Secondly, PLC may raise the levels of free CoASH and improves flux through  $\alpha$ -ketoglutarate dehydrogenase. Third, PLC may redistribute carnitine levels between cytosol and mitochondria and improve fatty acid oxidation in the stressed heart.<sup>170</sup> Collectively, it appears that PLC (and possibly also carnitine<sup>171</sup>) improves substrate flux, and possibly also contractile function of the heart. Indeed, alterations in substrate metabolism produced by carnitine deficiency result in inadequate ATP production under high workload conditions that cause impaired cardiac contractile performance, and carnitine deficiency may also induce a number of changes in gene expression of key enzymes required for normal cardiac function and metabolism.<sup>172,173</sup> Chronic cardiomyopathy has been described in children with a defect in carnitine uptake,<sup>174</sup> and systemic carnitine deficiency has been identified as a treatable cardiomyopathy.<sup>175</sup>

### SUMMARY AND OUTLOOK

The human heart is an efficient energy converter and consumes several kilograms of ATP each day.<sup>1</sup> ATP production is linked to a highly regulated system of energy substrate metabolism and is tightly coupled to both oxygen consumption and contractile function of the heart. Intermediary metabolites provide essential signals for pathways of adaptation and maladaptation of the heart to external stimuli (Figure 20-14).

Because heart failure is a systemic disease that begins and ends with the heart, an appreciation of the principles of myocardial energy metabolism seems critical for the understanding of heart failure. At the present time we possess a wealth of information on the biochemistry of the heart. To a large extent it still has to be determined how this information can be integrated into the diagnosis and management of heart failure. Defective energy metabolism of the heart is both cause and consequence of heart failure and can be detected in the whole heart by noninvasive methods, or in myocardial biopsy samples by gene or protein expression assays or by biochemical analyses. Pharmacological and nutritional interventions targeted at the specific myocardial metabolic alterations of particular causes of heart failure hold promise for reversing defective energy metabolism and improving contractile function of the heart. An appreciation of the pivotal role of metabolism in the process of adaptation and maladaptation of the heart to external stimuli provides essential clues for the pathophysiology and treatment of heart failure.

# Alterations in Nutrition and Body Mass in Heart Failure

Wolfram Doehner, Stephan von Haehling, and Stefan D. Anker

The treatment of chronic heart failure (CHF) has made significant advances over the past 2 decades. Even more so, our understanding of the disease has developed from a hemodynamic model of mere pumping failure to a complex approach, including multiple body systems and peripheral organs and tissues. Improved acute and chronic therapy and a steadily older growing population have resulted in an increasing prevalence and incidence of CHF.

The prevalence of CHF has been estimated at around 0.3% to 2.4%, which implies that 5 million people in the United States are affected.<sup>1</sup> Heart failure accounts for 970,000 hospitalizations and 12 to 15 million outpatient office visits in this country per year. Overall, the incidence of CHF is steadily increasing in most European countries and in the United States. Heart failure is primarily a diagnosis among the elderly and with the aging of the population a further increase in prevalence with epidemic proportion is anticipated. Current estimates

treatment. Although anorexia is certainly a common characteristic in HF and a contributing factor of weight loss, this feature alone cannot explain the metabolic changes observed during this perturbation. It is among the most common misconceptions that feeding and enhanced nutritional and caloric supplementation may be sufficient to adequately reverse the process of losing weight in patients with cachexia. Weight loss in the cachectic patient predominantly affects muscle protein; however, bone and fat tissue are likewise affected later in the course of the disease. The timelines differ widely between patients. We are only beginning to understand the factors that trigger the progression from clinically and weight-stable ambulatory CHF to cardiac cachexia. Cachexia is not a unique feature of CHF, but is also seen in advanced stages of a range of chronic illnesses, including cancer, chronic kidney and liver disease, rheumatoid arthritis, acquired immunodeficiency syndrome (AIDS), and others. Based on observed similarities in the signaling and regulatory processes in cachectic patients of varying origin, a common final pathway of weight loss in chronic disease has been hypothesized.<sup>5</sup>

In this chapter an overview of the current knowledge of metabolic imbalance, nutritional aspects, and the significance of cardiac cachexia in CHF is presented.

## BODY COMPOSITION AND HEART FAILURE FROM THE HISTORIC AND PUBLIC PERSPECTIVE: THE OBESITY PARADOX

Weight loss and the development of cachexia in association with cardiac illness have been known to physicians for centuries as a “signum mali ominis,” indicating end-stage disease and poor quality of life. Cachexia (Greek: *kakós* “bad”; *hexis* “condition”) constitutes its terminal phase and develops in advanced stages of various chronic illnesses (e.g., CHF, chronic obstructive pulmonary disease, or cancer). Already in ancient Greece, a picturesque clinical

amount to an overall incidence of 0.1% to 0.5% per year, with doubling of the numbers with each decade reaching 3% in those over the age of 75.

More patients survive acute cardiac events and live for a prolonged period of time in a state of compensated cardiac failure. Consequently, complications of long-term disease progression are increasingly coming to the fore in the clinical presentation of patients. Systemic metabolic impairment emerged as characteristic feature inherent to chronic heart failure. Imbalanced hormonal signaling leads to adaptive and eventually maladaptive changes in metabolic flux and hence in maintenance of structural tissue and energy storage. Weight loss and the development of cachexia in the course of disease have been recognized as a severe complication of CHF with further deterioration of clinical symptoms and a particular grave prognosis.

Despite improved medical and interventional therapy of cardiac disease, CHF mortality remains high and, in fact, is even increasing due to the factors indicated previously. About half of the patients with CHF die within 4 years of diagnosis.<sup>2</sup> This truly devastating prognosis is comparable to that of some types of cancer.<sup>3</sup>

The situation worsens considerably once cardiac cachexia has been diagnosed. Although a uniform definition of cardiac cachexia has been subject to debate over years (see later discussion), most researchers have unanimously agreed on the particular poor prognosis of the cachectic patient. In unselected patients with CHF, mortality rates were as high as 50% in the cachectic subset compared with 17% in the noncachectic subset at 18 months of follow-up.<sup>4</sup> Already a comparatively small amount of documented tissue loss is associated with a significant increase in mortality. Considerations of a certain cutoff for weight loss to identify patients at higher risk are of particular relevance for clinical evaluation and identification of patients with cachexia and are discussed in further detail later.

Cachexia is not only associated with poor outcome, but also with advanced symptomatic status, poor quality of life, and an unfavorable response to drug

description of cachexia was provided by Hippocrates: “The flesh is consumed and becomes water,... the abdomen fills with water, the feet and legs swell, the shoulders, clavicles, chest, and thighs melt away.... The illness is fatal.”<sup>6</sup> Despite the manifest change in the patient’s shape and appearance, a systematic investigation into this aspect was not extended beyond the state of mere observation until recently. Weakness and a reduced urge to eat were easily accepted as underlying mechanism of weight loss.<sup>7</sup> Increasing investigation of the significance and underlying mechanisms of weight loss and body composition changes in CHF revealed the significant impact of metabolic failure as a characteristic feature of CHF pathophysiology that contributes to both the morbidity and mortality of the patients.

Body weight is a dynamic parameter and has a certain rhythm over the life span.<sup>8</sup> Currently, public awareness of body weight and body composition is more concerned with overweight and weight gain than weight loss, and therefore most of the programs in adults are aimed at the reduction of body size.<sup>9</sup> In fact the aim to be slim and to lose weight has been thoroughly implemented in the public consciousness as surrogates for physical and mental well-being. This makes it hard to establish a more differential view on the association between body composition and morbidity and mortality. It should be noted, however, that the principles that have been proven for healthy populations may not be applicable in full in the setting of chronic diseased patients. In fact, convincing evidence has been accumulated that the WHO criteria of normal body mass index (BMI, Figure 21-1) may not be applicable to patients with CHF with regard to optimum survival.

More recent data from a collaborative analysis of 57 prospective studies with more than 890,000 participants, mostly in western Europe and North America, revealed also on an epidemiological level that BMI less than 22.5 kg/m<sup>2</sup> is associated inversely with overall mortality, mainly because of strong inverse associations with respiratory disease and lung cancer.<sup>10</sup>

In a number of CHF populations from large multicenter controlled studies, it emerged that patients with overweight and mild obesity have better survival rates than patients with the a BMI less than 25 kg/m<sup>2</sup>, the upper limit of normal according to WHO criteria. From the Digitalis Investigation Group (DIG) trial, 7767 patients were analyzed, showing a linear rather than a U-shaped association between BMI and survival.<sup>11</sup> Even after multivariable adjustment, overweight and obese patients were at lower risk for death (HR 0.88, 95% CI 0.80 to 0.96, and HR 0.81, 95% CI 0.72 to 0.92, respectively) compared with normal BMI. In the study population of the Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) program, 7599 patients with CHF (NYHA II-IV) with a broad spectrum of left ventricular ejection fraction (mean 39%) were analyzed for BMI and survival; 1831 patients died during follow-up (mean 37.7 months). Optimum survival was observed in the subgroup of patients with a BMI of 30 to 34.9 kg/m<sup>2</sup>, with a graded increase in mortality risk in the groups with lower BMI (see Figure 21-1).<sup>12</sup> Moreover, the increased risk of death in patients with BMI greater than 35 was not statistically significant. These associations were not altered by age, smoking, or LVEF.

In a post hoc analysis of 5010 patients from the Valsartan Heart Failure Trial (Val-HeFT), again, a stepwise linear association between BMI and mortality rate was observed (Table 21-1).<sup>13</sup> In a meta-analysis of nine observational trials in CHF populations, the affect of body weight on all-cause mortality was evaluated in a total of 28,209 patients with a mean follow-up period of 2.7 years.<sup>14</sup> The investigators reported the uniform finding that in all studies included in the analysis, overweight and obesity were associated with lower all-cause mortality and cardiovascular mortality rates.

**FIGURE 21-1** Mortality in the CHARM trial program in patient subgroups according to BMI. Lowest mortality was observed in the BMI subgroup 30 to 34.9, with a stepwise increase in risk in the lower BMI groups. (Adapted from Kenchaiah S, Pocock SJ, Wang D, et al. Body mass index and prognosis in patients with chronic heart failure: insights from the candesartan in heart failure: assessment of reduction in mortality and morbidity (CHARM) program. *Circulation* 2007;116:627-636.)

**TABLE 21-1** Mortality Rate on Patients with CHF in the Valsartan Heart Failure Trial (Val-HeFT)  $P < .0001$

BMI Subgroup	BMI (kg/m <sup>2</sup> )	Mortality Rate (%)
Underweight	<22	27.2
Normal weight	22-24.9	21.7
Overweight	25-29.9	17.9
Obese	>30	16.5

The constant finding that higher BMI is not associated with increased mortality in CHF is opposite to the U-shaped curve of the association between BMI and survival that is known from populational analyses. This finding led the researchers to coin the term “obesity paradox.”<sup>11</sup> Interestingly, the “paradox” aspect may be viewed as a reflection of the expectation that is fueled from the epidemiological studies in healthy subjects. An important conclusion from these findings is that metabolic balance and body composition need to be viewed from a different perspective in patients with a chronic disease such as CHF as compared with healthy subjects. Insights and “common knowledge” on weight and body composition from a normal healthy population may not be uncritically translated to such patient populations as significant differences may exist in the metabolic homeostasis in chronic patients.

## Definition of Cardiac Cachexia

Clinical decisions in modern medicine rely to a large degree on quantifiable variables as the basis for clear-cut definitions and guidelines for identification and management of medical conditions. Unfortunately, there is no universal definition available for appropriate identification of cachectic patients or patients at risk.<sup>15</sup> It remains hitherto at the discretion of the individual physician to observe this important aspect in the progression of the diseases. Additional confusion is caused by the inconsistent nomenclature used when describing body wasting. Indeed, descriptive terms such as “cachexia,” “anorexia,” “sarcopenia,” “malnutrition,” and even “hypercatabolism” are often used as synonyms. While

sarcopenia refers to age-associated “normal” muscle wasting,<sup>16</sup> weight may largely remain balanced because muscle is replaced by fat tissue. Opposite to cachexia, weight loss due to malnutrition and anorexia is fully reversible with adequate food intake. Loss of appetite or anorexia causes primarily loss of fat mass rather than muscle tissue. Malnutrition is also associated with body wasting, predominantly of fat tissue. Lastly, the term “hypercatabolism” cannot be evaluated during clinical examination and does not appreciate anabolic processes as the other side of the metabolic balance.<sup>17</sup>

Several definitions of cardiac cachexia have been put forward in different studies using a range of clinical tests such as skinfold thickness, fat tissue content, BMI, and others.

The recently proposed definition derived from the SOLVD (Studies of Left Ventricular Dysfunction) database seems most appropriate to meet the requirements of clinical usefulness and applicability.<sup>18</sup> In the SOLVD study population of 1929 patients with CHF, a nonedematous weight loss of greater than 6% of total body weight over a period of 6 or more months has been identified to be the strongest predictor of mortality among cutoffs from 5% to 15%. This finding had been validated in the study population of the V-HeFT II trial, confirming the strong and independent prognostic power of this cutoff to predict mortality in patients with CHF.

Several aspects are of importance to underscore applicability of this definition. First, the dynamic process of tissue loss rather than a single time BMI assessment is appreciated as the underlying principle of cachexia, avoiding bias from constitutional asthenic body composition. The observed weight loss carries the significant information of an ongoing detrimental spiral of tissue degradation (Figure 21-2).<sup>19</sup>

Second, a weight loss of greater than 6% of body weight is in comparison, a small difference that is in contrast to the rather traditional perception of cachectic patients. Further, the simple method to obtain a weight history ensures practicality and applicability of the definition in any clinical condition at no cost. Notably, the severity of cardiac cachexia may not always correlate with classic criteria of disease severity as a New York Heart Association (NYHA) functional class, left ventricular ejection fraction, or exercise duration.<sup>20</sup> Cardiac cachexia even may not be associated with morphological cardiac changes as seen by magnetic resonance imaging or echocardiography.<sup>21,22</sup>

A series of conferences was held in recent years aiming to achieve a consensus for a common definition of cachexia in chronic illness. According to the recently published consensus document resulting from these conferences,<sup>5</sup> cachexia has to be considered in adult patients with chronic illness, who experience weight loss of 5% or more in upto 12 months (or have a body mass index <20), and comply with at least three out of five clinical or laboratory criteria (Table 21-2). With this definition of cachexia, the interventional trial results will be more applicable to cachexia of different causes, and the quest for an effective treatment may be reaching some landmarks in the near future.

Mechanisms of Altered Body Composition in Chronic Heart Failure

Cardiac cachexia as a clinical entity is acknowledged as a complex syndrome with multiple factors mutually inter-related. Patients usually experience progressive weight loss with body composition alterations and disturbed homeostasis of several body systems. There is evidence for activation of neuroendocrine and inflammatory systems, increased lipolysis, muscle wasting, lack of appetite, and malabsorption.<sup>23,24</sup> The importance of individual pathways and their exact interplay are still incompletely understood.

FIGURE 21-2 Mortality of patients with CHF in subgroups according to BMI and with stable body weight (numbers show range of BMI per group) in comparison to patients with observed weight loss 7.5% of body weight (black curve). Best survival was seen in patients with mild obesity (BMI 28 to 32). However, highest mortality occurred in patients with documented weight loss. (Adapted from Davos CH, Doehner W, Rauchhaus M, et al. Body mass and survival in patients with chronic heart failure without cachexia: the importance of obesity. J Card Fail 2003;9:29-35.)

Nutrition and Regulation of Feeding

Loss of appetite and inadequate food intake are important components contributing to the development of weight loss and cachexia in CHF. This anorexia may occur as a consequence of symptomatic disablement of the patients from weakness, dyspnea, fatigue, or lethargy.<sup>25</sup> Also intestinal edema leading to nausea, diminished absorption, and protein-losing enteropathy have been described in this context.<sup>26</sup> Notably, iatrogenic factors may unfavorably contribute to the decreased appetite and food intake of patients as a consequence of multiple daily drug regimens. Also imposed dietary restrictions may have a role, which, in view of those previously mentioned, needs to be viewed with great care on an individual basis.

Regulation of feeding is a complex regulated balance within a satiety-hunger homeostatic model (Figure 21-3), with a multitude of factors involved. The fine-tuned regulation of appetite is characterized by pleiotropism and redundancy—two key principles in balanced physiology. Many of the factors involved are increasingly investigated and will briefly be discussed with reference to specific observations

**FIGURE 21-3** Basic regulation of food intake and energy expenditure. Mutual interaction, pleiotropism, and redundancy. *AgRP*, agouti-related protein; *CART*, cocaine and amphetamine-related transcript; *NPY*, neuropeptide Y; *POMC*, proopiomelanocortin; *MSH*, melanocyte-stimulating hormone; *LH*, lateral hypothalamus; *PYY*, peptide YY; *VMH*, ventromedial hypothalamus; *CCK*, cholecystokinin.

in CHF. The hypothalamus has been identified as the central regulating site of appetite with a lateral “feeding area” and a medial “satiety center.”<sup>27</sup> Stimulation of the first increased the urge for food intake; the latter triggers cessation of eating. Numerous mediators take part in controlling these centers in the hypothalamus. For a given person under normal conditions, a balanced equilibrium between both pathways results in an individually defined set point of fairly stable body weight and composition. Excessive fluctuations on either side, however, cause weight and body composition changes, which may develop into medical conditions or disease.

### Neuropeptide Y

Neuropeptide Y (NPY) is a neurotransmitter in the central and peripheral nervous system, which is stored mainly in the hypothalamus as the central site of appetite regulation.<sup>28</sup> NPY is a central player in appetite regulation with a potent orexigenic capacity (i.e., stimulating food intake). NPY excretion from the hypothalamus increases during fasting and exercise. Besides increased appetite, a range of pathways is modulated that starts a cascade of hormonal signaling. Parasympathetic activity and induction of corticotropin-releasing factor are stimulated, the latter yielding release of adrenocorticotrophic hormone and cortisol. Sympathetic activity and energy expenditure, on the other hand, are being suppressed. The NPY pathway in turn is suppressed by insulin and the adipocyte-derived polypeptide leptin (see later discussion).<sup>29</sup>

A study in 30 patients with CHF and 16 healthy controls demonstrated elevated plasma levels of NPY in the patients with CHF ( $P < .01$ ).<sup>30</sup> Although vasoconstriction is an effect of endogenous NPY, intravenous infusion of the peptide had no hemodynamic effect.<sup>31</sup>

### Leptin

Leptin (Greek: *leptos*, “thin”) was the first adipocyte-derived hormone to be discovered.<sup>32,33</sup> Leptin is produced exclusively by adipocytes and its identification surmounted the paradigm that fat tissue merely serves as a passive energy depot. Accordingly a close correlation exists between size of adipose

tissue and serum leptin levels with higher levels in women compared with men.<sup>34</sup> It circulates in the bloodstream either free or protein bound and can cross the blood-brain barrier. A large number of OBRb, one of five isoforms of the leptin receptor, the is expressed in the choroid plexus and hypothalamus, and hence leptin is viewed as the link between adipose tissue and central nervous system mediating the central regulation of satiety and energy metabolism. Beyond its central effects, leptin may have pleiotropic peripheral actions. Leptin receptors are also expressed in several peripheral tissues such as pancreatic islets, liver, kidney, lung, adrenal glands, heart, and skeletal muscle.<sup>35,36,37</sup> These would include interaction with several metabolic and hormonal pathways (e.g., lipogenesis in adipose tissue, growth hormone signaling, and insulin sensitivity).<sup>38,39</sup> In turn, leptin is under multihormonal control (such as insulin, glucocorticoids, catecholamines).

It is a key regulator of food intake and energy homeostasis. Leptin levels increase with accumulating fat tissue and decline during body fat deprivation. Indeed, it has been shown that a 10% reduction in body weight led to a 53% reduction in serum leptin, whereas a 10% body weight increase caused a 300% increase in serum leptin.<sup>40</sup> Leptin’s effects on body metabolism are mediated by multifactorial pathways including insulin, glucocorticoids, catecholamines, and in particular the melanocortin system. The activation of this system via pro-opiomelanocortin (POMC) cells,  $\alpha$ -melanocyte stimulating hormone (MSH), and the type 4 melanocortin receptor (MC4R) eventually leads to the suppression of food intake (antiorexigenic effect) and increases in energy expenditure. On the other hand, leptin suppresses the antagonistic (i.e., orexigenic) pathway of NPY/agouti-related protein (AgRP).<sup>41,42</sup> Additionally, both systems are targeted by several peripheral metabolic signals, including insulin, glucose, ghrelin, and peptide YY.<sup>43,44</sup>

In CHF, preserved<sup>45</sup> and even elevated leptin levels have been observed.<sup>46</sup> In cachectic patients serum leptin levels are significantly lower than in noncachectic patients, rather in the range of normal values.<sup>47</sup> Notably, the significantly reduced fat tissue amount in cachectic patients<sup>48</sup> may explain

the pseudonormal leptin levels. Indeed, adjustment for fat tissue amount reveals that both cachectic and noncachectic CHF patients are relatively hyperleptinemic.<sup>46</sup> These findings argue against a predominant role of leptin-regulated reduced appetite in the development of cardiac cachexia. Indirect effects of hyperleptinemia may nevertheless have a contributing role such as via insulin resistance and acquired growth hormone resistance, which are both observed to relate to hyperleptinemia in CHF.<sup>46,49</sup>

### Melanocortins

Melanocortins primarily stimulate the melanogenesis and/or steroidogenesis in melanocytes and adrenal cortical cells, respectively. Melanocortins can bind and activate five different melanocortin receptors.<sup>50</sup> Food intake and energy expenditure are mainly regulated through MC4R, which are widely distributed within the central nervous system, including the hypothalamus, the thalamus, and the spinal cord.<sup>51</sup>

Melanocortins are antiorexigenic and loss of normal melanocortin signaling leads to hyperphagia and obesity.<sup>52,53,54</sup> The overactivity of this system, on the other hand, would lead to suppression of food intake and upregulation of energy expenditure.<sup>55</sup> Evidence is mounting that increased melanocortin activity plays a role in the pathogenesis of cachexia.<sup>56,57</sup> This appears to be mainly due to an increased production of systemic proinflammatory cytokines.<sup>58</sup> In experimental settings in cancer or renal failure, melanocortin antagonists were shown to improve food intake and lean body mass. This approach seems feasible for cachexia therapy in chronic disease; however, studies are warranted to test applicability to humans.<sup>59</sup>

### Ghrelin

Ghrelin is mainly produced in the fundus region of the stomach,<sup>60,61</sup> but it is also expressed in other organs, including the duodenum, jejunum, ileum, and colon (with gradually decreasing expression), where it promotes gastric motility.<sup>60</sup> It is also found in the pancreas,<sup>62</sup> in the arcuate nucleus of the hypothalamus, in the kidneys,<sup>63</sup> and the placenta.<sup>64</sup> Active ghrelin binds to the growth hormone secretagogue receptor (GHS-R), a G protein-coupled receptor.<sup>65,66</sup> Physiologically, ghrelin induces the release of growth hormone and has appetite-regulating and antiinflammatory properties. Growth hormone is released in a dose-dependent manner from the pituitary gland upon binding of ghrelin to the GHS-R.<sup>60</sup> In humans, high doses of ghrelin also increase the levels of adrenocorticotrophic hormone—prolactin and cortisol.<sup>67</sup>

Ghrelin expressing neurons in the hypothalamus have direct contact with neurons containing NPY, agouti-related protein (AgRP), and proopiomelanocortin (POMC; see Figure 21-3).<sup>68</sup> Hence, ghrelin is likely to exert its effect on feeding by stimulating the release of NPY and AgRP,<sup>69</sup> while reducing the release of POMC.<sup>68</sup> Although peptides generally do not pass the blood-brain barrier, ghrelin injected into the periphery is able to stimulate the hypothalamus<sup>70</sup> and food intake.<sup>71</sup> The signaling of ghrelin via afferent nerve fibers of the vagus<sup>72</sup> has been observed, which among other target areas project to the stomach and bowel.

The ghrelin-induced inhibition of the expression of proinflammatory cytokines has been reported in a time- and dose-dependent fashion,<sup>73</sup> and downregulated proliferation of murine anti-CD3 activated T cells has been described.<sup>74</sup> Moreover, ghrelin accounted for downregulated circulating proinflammatory cytokines in a rat model of endotoxemia<sup>75</sup> and attenuated proinflammatory response in human endothelial cells.<sup>76</sup>

Elevated plasma ghrelin levels have been shown in cachectic heart failure patients compared with noncachectic CHF patients in association with elevated levels of growth hormone and TNF- $\alpha$ .<sup>77</sup> In an uncontrolled pilot study in predominantly

cachectic CHF patients, infusion of ghrelin showed promising cardiovascular results.<sup>78</sup> Intravenous ghrelin administration of 4  $\mu$ g/kg body weight resulted in increased food intake and lean body mass. LVEF increased and plasma levels of B-type natriuretic peptide decreased over the 3-week treatment period. Similar results regarding heart function, body weight, and body composition have been described in animal models of heart failure.<sup>79</sup> Currently, several trials aim to reproduce these data in a double-blind, placebo-controlled fashion but results are inconsistent<sup>80,81</sup> and further research is needed to establish the therapeutic potential of ghrelin.

### Adiponectin

Adiponectin is another fat tissue-derived hormone with feedback signaling function to regulate balanced energy substrate metabolism and body composition. Playing the counterpart to leptin, adiponectin plasma levels are inversely related to fat stores<sup>82</sup> and low adiponectin levels are associated with increased insulin resistance,<sup>83</sup> whereas high adiponectin levels indicate improved insulin sensitivity.<sup>84</sup> Adiponectin levels are increased in CHF.<sup>85,86</sup> Elevated adiponectin levels are directly related to symptomatic status<sup>87</sup> and severity of LV dysfunction,<sup>88</sup> and adiponectin has been identified as an independent marker of impaired prognosis in CHF.<sup>89</sup> This is somewhat surprising because CHF is commonly associated with impaired insulin sensitivity (see later discussion). More research is needed to uncover the pathophysiological relevance of adiponectin in CHF.

## Chronic Immune Activation (see Chapter 11)

The hormonal regulation of body composition, feeding, and metabolic flux as outlined previously has tight and multiple interconnections with chronic inflammatory activation, a commonly observed characteristic in CHF. Since the initial description of elevated TNF $\alpha$  levels in CHF,<sup>90</sup> a number of different hypotheses have been suggested to explain the origin of immune activation in this disease. The production of proinflammatory cytokines has been attributed to secretion by mononuclear cells, although the myocardium seems to be another important source. However, it appears that only the failing myocardium is capable of TNF $\alpha$  production.<sup>91</sup> Some evidence suggests that catecholamines augment myocardial cytokine release. Other concepts suggest a response to myocardial injury<sup>92</sup> and underperfusion of peripheral tissues<sup>93</sup> as underlying mechanisms. It has also been proposed that increased bowel wall edema may cause impairment of bowel wall barrier function. This leads to increased translocation of bacterial components, such as lipopolysaccharide (LPS), a cell wall component from gram-negative bacteria and one of the strongest inducers of proinflammatory cytokines and especially TNF $\alpha$ .<sup>94</sup> Indeed, it has been shown that very small (pathophysiological) amounts of this substance are capable of inducing TNF $\alpha$  secretion.<sup>95</sup> Notably, LPS levels are particularly elevated in the bloodstream of patients with CHF during edematous decompensation (i.e., when clinical signs of severe tissue congestion are present.<sup>96</sup> It is well possible that the aforementioned hypotheses rather complement than exclude one another, but it is certainly true that inflammatory activation is much more than an epiphenomenon in CHF.

## Anabolic Failure

### Growth Hormone (GH)

The peptide hormone from the anterior pituitary gland has a central role in the regulation of energy stores and exerts strong anabolic effects. The pleiotropic effects of GH are mediated by activation of insulin-like growth factor-1 (IGF-1) and somatomedins.<sup>97</sup> The main site of IGF-1 synthesis is the liver but peripheral tissues are also capable of its production.<sup>98</sup>

Direct actions of GH include an increase in muscle protein synthesis<sup>99</sup> but also effects on glucose, lipid, and sodium metabolism. Lipolytic effects account for enhanced fat use. Thus GH plays a significant role in the regulation of substrate metabolism and body composition in man.

Despite the plausible and intriguing therapeutic concept to prevent tissue wasting and cachexia by administration of recombinant GH, results from a series of studies were disappointing.<sup>100,101,102</sup> An explanation of the failing approach may come from an observation of an acquired GH resistance in CHF<sup>103</sup> characterized by a threefold increase in GH levels in cachectic patients compared with noncachectic patients with CHF and healthy subjects paralleled by lower than normal IGF-1 levels.

#### Insulin Resistance (see also Chapters 20 and 26)

Besides the central function as a regulator of glucose homeostasis, energy flux and substrate use in general, insulin is the strongest anabolic hormone in human physiology. In the setting of CHF, impaired insulin signaling function (i.e., insulin resistance) was reported more than a decade ago.<sup>104</sup> Overt diabetes mellitus is a common co-morbidity in CHF, and the Euro Heart Failure Survey reported an incidence as high as 27%.<sup>105</sup> As insulin resistance occurs years if not decades before the clinical criteria of diabetes mellitus are met, the incidence may be much higher. Indeed, subclinical impairment of glucose metabolism has been reported for 43% of patients with CHF.<sup>106</sup> It is also well established that diabetes mellitus is an important risk factor for the development of CHF.<sup>107</sup>

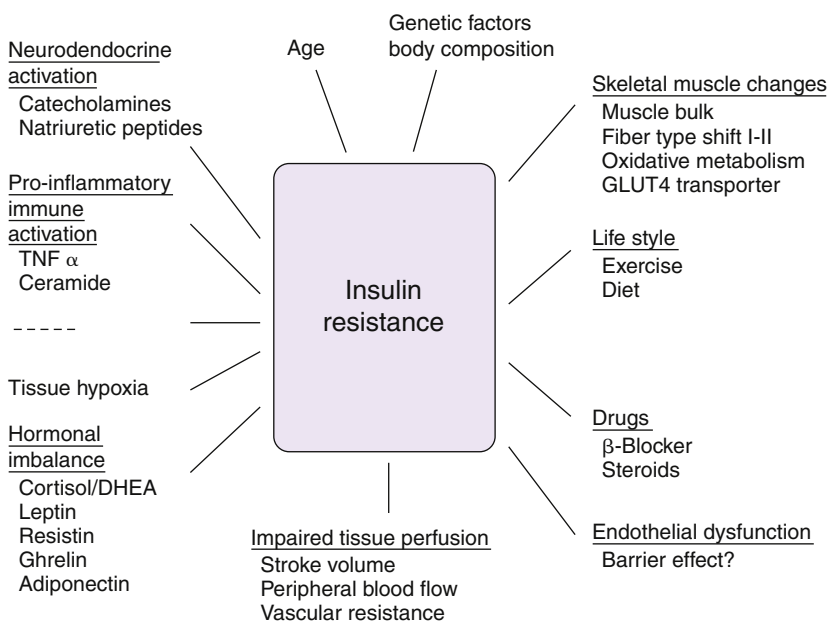

Importantly, insulin resistance occurs as a consequence of CHF and independently and on top of the metabolic syndrome, a clear risk factor for ischemic-type heart failure. Insulin resistance in CHF correlates directly with the severity of the symptomatic status.<sup>108</sup> In a study of 41 patients and 21 healthy control subjects, insulin sensitivity (assessed by intravenous glucose tolerance testing) was reduced by 31% in patients with CHF compared with controls ( $P < .01$ ), and fasting insulin levels were higher in patients than in controls ( $P < .01$ ).<sup>38</sup> Serum leptin levels remained the only independent predictor of insulin resistance. Moreover, a recent study identified insulin resistance as a prognosticator in patients with CHF independent of previously established prognostic factors.<sup>109</sup> It has been shown that skeletal muscle GLUT 4 transport protein—the rate-limiting step of glucose

uptake and subsequent use as energy substrate—is reduced in CHF well in parallel to CHF severity (Figure 21-4).<sup>110</sup> Mechanisms that cause insulin resistance in patients with CHF are not entirely understood but are likely a complex cluster of mechanisms including hormonal interaction, immune activation, oxidative stress, hemodynamic impairment, and tissue hypoperfusion, skeletal muscle adaptation to disabled life-style, and others (Figure 21-5).<sup>111</sup>

Pathophysiological mechanisms and clinical and prognostic implications suggest insulin resistance as a potential treatment target, in particular when body wasting and cachexia are involved. The novel class of insulin sensitizers or glitazones would be a plausible option. The use of TZD in CHF is, however, limited by their characteristic to increase fluid retention and edema, suggesting progression of heart failure<sup>112</sup> disease and increased hospitalization.<sup>113</sup> There are recent studies reporting promising data in favor of this concept with regard to prognostic benefit<sup>114,115</sup> and myocardial functional assessment.<sup>116</sup> However, given the ongoing controversy on increased cardiovascular risk following TZD therapy, their use in CHF patients is currently not recommended.<sup>117</sup>

**FIGURE 21-4** Reduced GLUT 4 transport protein in skeletal muscle in patients with CHF according to CHF severity (NYHA I/II  $n = 18$ , NYHA III/IV  $n = 11$ ).  $+P < .05$ ,  $++P < .01$  vs. controls ( $n = 7$ ). (Adapted from Doehner W, Gathercole D, Ciccoira M, et al. Reduced glucose transporter GLUT4 in skeletal muscle predicts insulin resistance in nondiabetic chronic heart failure patients independently of body composition. *Int J Cardiol* 2010; 138:19-24.)

MECHANISMS OF WASTING IN DIFFERENT BODY COMPARTMENTS

CH 21

Investigations of specific tissue compartments reveal detailed characteristics of body wasting, beyond the clinically overt loss of total body weight. Lean body mass depletion is a dominant feature of cardiac cachexia. Muscle atrophy is observed in up to 68% of patients with CHF.<sup>118</sup> Reduction in muscle tissue is of utmost importance in association to progressing symptomatic status of the patients. It has been shown, however, that bone and fat mass also are decreasing later in the course of the disease, all adding to the observed net weight loss of the patients.

Muscle (see also Chapter 19)

The major site of protein loss has been observed in skeletal muscle. Time course studies revealed that the process of tissue degradation in skeletal muscle starts early in the course of the disease, before overt weight loss even becomes apparent. In a study of noncachectic and cachectic patients with stable CHF and, healthy controls of similar age were assessed using dual energy absorption (DEXA) technology.<sup>119</sup> Noncachectic CHF patients displayed reduced lean tissue in the legs as compared with healthy subjects (−9%,  $P < .01$ ). Interestingly, no weight difference was observed, suggesting replacement of muscle with nonfunctional tissue. Cachectic patients had further reduced lean (−20% vs. noncachectic CHF, −21% vs. control), fat (−37% vs. noncachectic CHF, −33% vs. control), and bone tissue (−16% vs. noncachectic CHF, −18% vs. control) (all  $P < .0001$ ; Figure 21-6). The ubiquitin-proteasome pathway has been identified as the pathway for accelerated proteolysis in various catabolic conditions. IGF-1 and insulin have been shown to suppress the expression of atrogin-1, a muscle-specific ubiquitin ligase that induces atrophy.<sup>120</sup> This ability of IGF-1 and insulin constitute important new actions of these hormones that must contribute in a major way to their capacity to stimulate muscle growth.

A number of metabolic derangements have been described in the skeletal muscle of CHF patients (Table 21-3). Biopsy studies have shown defects in oxidative and lipolytic enzymes, succinate dehydrogenase, citrate synthetase, and  $\beta$ -hydroxyacyl dehydrogenase.<sup>121</sup> The reduced exercise capacity in CHF patients results largely from muscle wasting.<sup>122</sup> In fact, skeletal muscle quantitative and qualitative changes might explain some of the major symptoms, such as early fatigue, exercise limitation, and exertional dyspnea, better than abnormalities of central hemodynamic parameters.<sup>123,124</sup>

These peripheral abnormalities may even account for the progression of the disease by maintaining a vicious cycle of deterioration of CHF, coined the “muscle hypothesis” (Figure 21-7).<sup>125</sup>

However, after onset of tissue wasting and the observation of cachexia, peripheral blood flow becomes a stronger predictor of exercise capacity than muscle mass.<sup>126</sup> This suggests impaired nutritional flow to the skeletal muscle as a major reason for reduced maximal exercise capacity of CHF patients. Impaired skeletal muscle metabolism, seen in the lower and upper limbs during exercise in patients with CHF, was related to systemic exercise tolerance.<sup>127</sup> In MRI studies, it has been shown that also myocardium tissue is lost in patients who develop cachexia, although the amount may not significantly contribute to the weight change observed.<sup>21,22</sup>

Fat Tissue (see also Chapter 20)

Lipolysis is controlled mainly by the enzyme *hormone-sensitive lipase*. It is chiefly activated by catecholamines via  $\beta$ -adrenoceptors. The natriuretic peptides (atrial, B-type, and

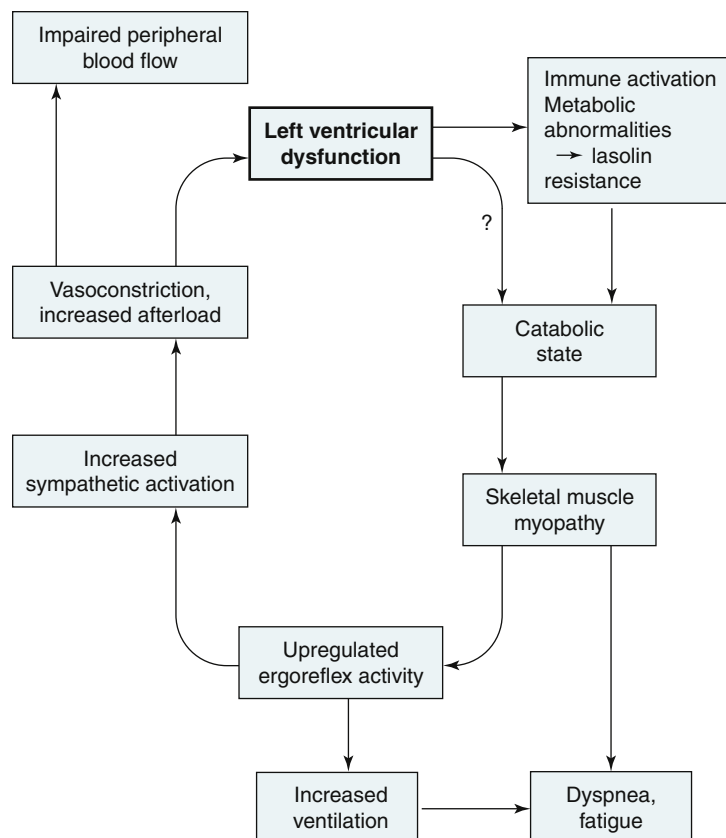

C-type natriuretic peptides) were recently identified to be involved in fat-cell metabolism.<sup>128</sup> The natriuretic peptides control lipid mobilization and lipid oxidation by increasing intracellular cGMP and lipolysis.<sup>129</sup> They also reduce leptin production, increase circulating free fatty acids, and increase insulin resistance.<sup>130</sup>

Insulin is the main antilipolytic substance. Loss of adipose tissue in patients with cachexia could be mediated by increased lipolysis or reduced lipogenesis.<sup>131</sup> Study data from patients with cancer cachexia point to the fact that the predominant mechanism is increased lipolysis. Indeed, fasting plasma glycerol levels, which reflect triglyceride breakdown, are higher in cancer patients with weight loss than in those without.<sup>132,133</sup> This has not been demonstrated in patients with cardiac cachexia or patients with CHF; however, it is tempting to speculate that increased levels in catecholamines and possibly natriuretic peptides may be responsible for the loss of adipose tissue that has been observed in such patients.<sup>119</sup>

**FIGURE 21-7** The muscle hypothesis of chronic heart failure. An initial reduction in left ventricular function activates a self-enhancing cycle of skeletal muscle abnormalities and central feedback signaling. This contributes to exercise intolerance and further sympathetic activation that in turn worsens the left ventricular function, maintaining a vicious cycle of deterioration. (Adapted from Coats AJ, Clark AL, Piepoli M, et al. Symptoms and quality of life in heart failure: the muscle hypothesis. *Br Heart J* 1994;72(suppl 2):S36-S39.)

TNF- $\alpha$ , which is also overexpressed in both CHF<sup>134</sup> and cardiac cachexia,<sup>90</sup> plays a major role in fat cell lipolysis and inhibiting insulin signaling. The latter is an important aspect in the development of insulin resistance.

## Bone

Bone undergoes constant remodeling (i.e., a process of coordinated resorption and formation of skeletal tissue). Few studies have investigated alterations in bone mass in patients with CHF. Genuine osteoporosis has also been observed in advanced stages of the disease.<sup>135</sup> In their study of 31 adult male cardiac transplant recipients and 14 adult men with CHF awaiting cardiac transplantation, Lee et al found that bone mineral density in the proximal femur was below normal in both groups compared with age-matched control subjects. CHF patients had a trend toward elevations of parathyroid hormone, 1,25-dihydroxyvitamin D, and urinary calcium excretion compared with transplant patients. Eight of 31 transplant patients and 2 of 14 CHF patients presented with vertebral compression fractures ( $P < .001$ ). In fact, reduced 1,25(OH)(2)D levels (Vit D39) in inverse relation to increased osteoporosis and frailty score were reported in CHF patients.<sup>136</sup>

Lower serum levels of calcium in CHF patients have been observed compared with controls with bone mineral content and bone mineral density being lower in cachectic, but not noncachectic patients than controls ( $P < .01$ ).<sup>137</sup> An earlier study investigated markers of bone turnover in 101 patients with advanced CHF (NYHA class III-IV).<sup>138</sup> For this purpose, patients had parathyroid hormone, 1,25-dihydroxyvitamin D, serum osteocalcin, urinary hydroxyproline, and pyridinium analyzed. Osteoporosis was present in 7% to 19% (depending on the site of assessment), osteopenia in 42% to 47% of patients with a gender difference toward higher numbers in women ( $P = .007$ ). Notable, low serum vitamin D metabolites

were associated with biochemical evidence of increased bone turnover.<sup>138</sup> Many of the details of the underlying mechanisms of bone wasting in cardiac cachexia still need to be elucidated in future studies.

## THERAPEUTIC APPROACHES TO METABOLIC IMBALANCE, WEIGHT LOSS, AND CACHEXIA IN CHF

The significant contribution of metabolic abnormality to CHF pathophysiology with implications for both morbidity and mortality is increasingly recognized. Despite the emerging evidence there is currently no approved therapeutic option to specifically target metabolic failure, weight loss, or cachexia in CHF.

In the following section an overview is provided on three different aspects of metabolically targeted therapeutic approaches: impact of current state of the art medical therapy in CHF, specific nutritional considerations in CHF, and potential novel medical treatment strategies. For some of these, benefit has been shown from retrospective analyses; some have even shown their efficacy in clinical pilot studies. Others have yet to prove their therapeutic benefit based on intriguing theoretical concepts.

### Impact of Current CHF Therapy on Body Composition and Metabolic Balance

#### Angiotensin-converting Enzyme Inhibitors and Angiotensin Receptor Antagonists (see also Chapter 45)

A substantial body of evidence has been accumulated to demonstrate the benefit of inhibition of the renin-angiotensin system for morbidity and mortality in CHF. Besides neurohormonal inhibition as the main effect of angiotensin-converting

enzyme (ACE) inhibitors and angiotensin receptor blockers (ARB), a range of additional effects of these compounds have been identified that add to the favorable properties.

Retrospective analyses have shown that ACE inhibitors may prevent or delay the risk of weight loss in patients with CHF. A substudy from the SOLVD database showed that 817 of 1929 patients had a weight loss of 5% during follow-up.<sup>18</sup> Enalapril at a dose of  $\geq 20$  mg once daily significantly reduced the risk of weight loss 6% body weight by 19% as compared with placebo ( $P = .0054$ ). Data from the Cardiovascular Health Study (CHS), a community-based prospective cohort study of 5888 older adults, showed that ACE inhibitor use was associated with less annual weight loss when used as an antihypertensive treatment and in CHF treatment.<sup>139</sup>

Additionally, ACE inhibitors have been implicated in the improvement of insulin resistance.<sup>140</sup> A substudy of the HOPE trial (Heart Outcomes Prevention Evaluation) demonstrated a delay of new onset of diabetes among high-risk patients with established vascular disease following ramipril therapy.<sup>141</sup> Indeed, among those who received the placebo ( $n = 2883$ ), a total of 155 patients (5.4%) developed new-onset diabetes during 4.5 years of follow-up as compared with 102 patients (3.6%,  $P < .001$ ) who received ramipril ( $n = 2837$ ). In a meta-analysis from 22 clinical trials, including 143,153 patients who did not have diabetes at randomization, a significant risk reduction for development of diabetes with ARB (OR 0.57, 95% CI 0.46 to 0.72) or ACE inhibitor (OR 0.67, 95% CI 0.56 to 0.80, both  $P < .0001$ ).<sup>142</sup>

#### ***β-Blockers (see also Chapter 46)***

A range of  $\beta$ -blockers, such as metoprolol, bisoprolol, carvedilol, and nebivolol, have proven their beneficial effect in CHF therapy. In addition to their effect on survival,  $\beta$ -blockers may exert beneficial effects on weight development. This effect might be explained by the inhibition of catecholamine-induced lipolysis<sup>143</sup> and decreased resting energy expenditure.<sup>144</sup>

A subanalysis of the COPENICUS (Carvedilol Prospective Randomized Cumulative Survival) database showed that carvedilol-treated patients showed a significant increase in weight compared with placebo-treated patients.<sup>145</sup> At 12 months of follow-up, mean changes in weight in the carvedilol versus the placebo group were +1.1 kg versus +0.2 kg ( $P < .001$ ). A similar finding has been reported from the CIBIS II-study (Cardiac Insufficiency Bisoprolol Study). Bisoprolol at a target dose of 10 mg once daily prevented or delayed the risk of weight loss in patients with CHF<sup>146</sup> with a 0.84-kg weight gain at 12 months and 1.2 kg at 24 months compared with a placebo.

This effect appears to be mainly due to an increase in body fat mass as data from a small prospective study found increases in body fat content with  $\beta$ -blocker therapy.<sup>147</sup> Hryniewicz et al studied patients with CHF before and after 6 months of  $\beta$ -blocker therapy.<sup>148</sup> Interestingly, 6 months of  $\beta$ -blocker therapy yielded a significantly greater weight gain in patients classified as cachectic than in the noncachectic patients ( $+5.2 \pm 9.6$  vs.  $+0.8 \pm 5.0$  kg,  $P = .027$ ).

Metabolic effects in CHF patients may also be translated from findings in patients with severe burns in whom  $\beta$ -blockers have been shown to reverse excess protein catabolism.<sup>149</sup> In this study by Herndon et al with severely burned children, propranolol treatment yielded a decrease in resting energy expenditure and increased muscle-protein balance by 82% over baseline. The fat-free mass did not change substantially. In addition to these effects, it has been observed in an animal model that  $\beta$ -blockers may mediate an increase in skeletal muscle mass.<sup>150</sup>

With regard to insulin sensitivity, the heterogeneity between  $\beta$ -blockers may not allow a common conclusion as the

### **BOX 21-1 Pleiotropic Effects of Statins**

Effects on endothelial function  
Induction of eNOS  
Increased NO release  
Reduced oxidative stress  
Mobilization of endothelial progenitor cells  
Antiinflammatory properties  
Reduced proteasome activity  
Antitumor activities  
Induction of apoptosis

negative and positive impact of  $\beta$ -blockers has been reported. In contrast to nonselective  $\beta$ -blockers,  $\beta_1$ -selective blockers appear to be without significant negative influences on glucose metabolism.<sup>151,152</sup> It has been shown that  $\beta_1$ -selective blockers have no important adverse effect on glucose metabolism and do not prolong hypoglycemia or mask hypoglycemic symptoms.<sup>153</sup> In fact, beneficial effects of metoprolol and atenolol on insulin sensitivity in subjects with hypertension and impaired glucose tolerance have been reported,<sup>154</sup> but the controversy continues and conflicting results have also been reported.<sup>155</sup> Further analyses are needed to show if there is a specific effect of  $\beta$ -blockers on glucose metabolism in CHF patients.

#### ***Statins (see also Chapter 24)***

Statins are well established to significantly reduce plasma cholesterol and hence cardiovascular risk.<sup>156,157</sup> However, a reduction in recurrent coronary events can be observed as early as 16 weeks after therapy initiation,<sup>158</sup> by far too short to ascribe the risk reduction to cholesterol reduction alone.<sup>159</sup> Moreover, statins seem to be able to ameliorate morbidity and mortality in patients with coronary artery disease irrespective of plasma cholesterol values. Thus effects beyond mere cholesterol reduction, so-called pleiotropic effects of statins, are intensely discussed and have been subject to vigorous research over the past several years (Box 21-1). Some of them might be particularly helpful in the treatment of CHF and possibly cardiac or other forms of cachexia.

Statins have been found to improve endothelial function by a number of different mechanisms, including induction of endothelial nitric oxide synthase (eNOS),<sup>160</sup> increase in nitric oxide release,<sup>161</sup> and reduced oxidative stress.<sup>162</sup> Statins are also able to mobilize endothelial progenitor cells from the bone marrow,<sup>163,164</sup> and possess antiinflammatory properties.<sup>165,166,167</sup> The antiinflammatory properties of statins may be particularly useful in cachectic patients. Additionally, it has been shown that lovastatin can inhibit proteasome activity in cell lysates of a human breast cancer cell line.<sup>168</sup> Statins have also been shown to possess antitumor activities. Indeed, lovastatin was demonstrated to inhibit the cell cycle of a murine fibroblast cell line<sup>169</sup> and a human bladder carcinoma cell line<sup>170</sup> in the G1 phase. In addition to this effect, the induction of apoptosis might be another important antitumor activity.<sup>171</sup>

The use of statins in CHF has recently suffered a significant setback. Based on favorable findings in retrospective observations and meta-analyses, the prospective CORONA (Controlled Rosuvastatin Multinational Trial in Heart Failure) study enrolled 5011 patients with ischemic CHF and an impaired LVEF to test the effect of rosuvastatin 10 mg daily versus placebo in a double-blind fashion.<sup>172</sup> After a median follow-up of 32.8 months, no significant difference between the two groups could be detected for the primary outcome (composite of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke). The primary endpoint was observed in 692 patients in the rosuvastatin and

732 patients in the placebo group (hazard ratio 0.92, 95% CI 0.83 to 1.02,  $P = .12$ ). The only beneficial effect that was noted in the rosuvastatin group was a reduction in the total number of hospitalizations for worsening heart failure ( $P = .01$ ). It has been discussed that the pleiotropic effect is not a class effect of statins, and that rosuvastatin may not possess effects that are beneficial in CHF. Interestingly, rosuvastatin did reduce levels of C-reactive protein during follow-up ( $P < .0001$ ), which, however, failed to translate into beneficial effects.

A second large-scale randomized controlled study, the GISSI-HF trial (Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza Cardiaca) tested the impact of n-3 polyunsaturated fatty acids (PUFA) and rosuvastatin in patients with CHF.<sup>173</sup> Patients with CHF (NYHA class II-IV), irrespective of cause, and left ventricular ejection fraction were included and randomly assigned to rosuvastatin 10 mg daily ( $n = 2285$ ) or placebo ( $n = 2289$ ). Median follow-up was 3.9 years (IQR 3.0 to 4.4). Death from any cause occurred in 657 (29%) versus 644 (28%) patients in the rosuvastatin versus the placebo group (adjusted HR 1.00; 95.5% CI 0.898 to 1.122,  $P = .943$ ). Also the other primary endpoint, death or admission to hospital for cardiovascular reasons, was stunningly similar between groups (adjusted HR 1.01; 99% CI 0.908 to 1.112,  $P = .903$ ). These findings were despite a 27% decreased LDL cholesterol in the rosuvastatin group at 3 years. Based on these two large trials, treatment of CHF patients in general with statins seems unlikely to translate into clinical benefit. Whether particular patients with cachexia may benefit from statin therapy needs to be clarified.

## Nutrition

Energy and substrate input are naturally major determinants of the body's metabolic balance. Accordingly, nutritional supply contributes significantly to the development of prevention of tissue wasting. Patients with CHF are prone to reduced appetite and reduced food intake.<sup>174</sup> Besides changes in the fine-tuned balance in the regulation of hunger and satiety (see previous discussion), dietary advice on salt and calorie intake, social isolation, derangements in bowel perfusion, and an altered intestinal barrier<sup>175</sup> may all contribute to reduced food intake in CHF patients. These alterations are likely to cause both deficiencies in micronutrients and macronutrients that may fuel the wasting process.

Large-scale studies on appetite and food intake in CHF are not available. Since both the intake of micronutrients and macronutrients may be affected in patients with CHF and those with cardiac cachexia, it may be necessary to optimize food intake of all components that are affected. This, however, is not always possible, and clinical guidelines on this issue for patients with CHF are missing. Some general rules, however, appear to apply for patients with CHF as for those with cardiac cachexia.

A diet high in sodium is generally viewed as potentially harmful in CHF because it may cause fluid overload and consequently acute hemodynamic decompensation. Rare cases of micronutrient deficiency as a cause of CHF have been reported for selenium and thiamine (vitamin B<sub>1</sub>).<sup>176</sup> One study suggests that thiamine supplementation per se may improve cardiac function.<sup>177</sup> Low levels of selenium have been reported in patients with CHF. In a study in 21 patients with CHF (NYHA class II-III, mean LVEF  $29 \pm 6\%$ ), baseline selenium levels were approximately 20% lower than those in healthy control subjects ( $P = .0004$ ).<sup>178</sup> Lower levels of copper and zinc were also reported in this study (both  $P < .05$ ).<sup>178</sup>

Patients with CHF are usually receiving loop diuretics, which increase urinary excretion of micronutrients. This affects, for example, magnesium and calcium.<sup>176</sup> Witte et al performed a placebo-controlled, randomized, double-blind

study of multiple micronutrient supplementation in 30 patients with CHF.<sup>179</sup> Patients received capsules containing thiamine (daily dose: 200 mg), vitamin C (500 μg) and E (400 mg), magnesium (150 mg), selenium (50 μg), zinc (15 mg), coenzyme Q10 (150 mg), and various other substances. Interestingly, 9 months of treatment yielded an improvement in LVEF by  $5.3 \pm 1.4\%$  in the micronutrient group ( $P < .05$  vs. placebo). It is not clear how this effect had been mediated but it may be that a reduction in oxidative stress took place. Indeed, many micronutrients can scavenge free radicals.<sup>180</sup> This may ensue through direct action as with vitamins C and E or through indirect action. In agreement with this, vitamin C has also been shown to improve endothelial dysfunction.

As discussed previously, wasting takes place not only in muscle tissue but also in fat and bone tissue. The constituent amino acids are capable of being transformed into all three macronutrients (i.e., protein, carbohydrate, and fat<sup>181</sup>). Therefore, amino acid supplementation has been studied in some clinical settings, and some models indicate that patients with CHF require a greater amount of protein than healthy adults of the same age.<sup>181</sup> Thus the current dietary reference of 0.8 g protein per kg of body weight may be too low for patients with CHF and those with cardiac cachexia.<sup>181</sup>

Low plasma levels of glutamine were found in critically ill patients and patients with chronic illness associated with muscle wasting.<sup>182,183</sup> After 4 weeks of treatment with glutamine, a nonessential amino acid that is involved in cellular integrity and immune function, patients with cancer cachexia gained  $0.95 \pm 0.66$  kg compared with control subjects who lost  $0.26 \pm 0.78$  kg.<sup>184</sup> This change was due to a significant increase in fat-free mass in the active treatment group ( $+1.12 \pm 0.68$  kg vs.  $-1.34 \pm 0.78$  kg,  $P = .02$ ). Patients in the active treatment group received not only glutamine, but a mixture of β-hydroxy-β-methylbutyrate (3 g/day), L-arginine (14 g/day), and L-glutamine (14 g/day). Patients in the control group received a mixture of nonessential amino acids in double-blind fashion.

Branched-chain amino acids, namely, leucine, isoleucine, and valine, have been suggested as a useful supplementation in the treatment of cachexia<sup>185</sup> because they may exert anabolic effects by promoting protein synthesis and by inhibiting proteolysis. This effect appears to be most potentially exerted by leucine.<sup>186</sup> Supplementation of any amino acid is certainly not beneficial. Homocysteine, for example, is known to possess negative inotropic properties.<sup>187</sup> In patients with CHF, high levels of homocysteine were found in association with low levels of vitamins B<sub>6</sub>, B<sub>9</sub> (folate), B<sub>12</sub>, and magnesium. Indeed, a correlation has been shown between circulating homocysteine levels and certain vitamins because homocysteine degradation is dependent on the presence of vitamins B<sub>6</sub>, B<sub>9</sub>, and B<sub>12</sub>.<sup>188</sup> Gorelik et al have shown that the intake of vitamin B<sub>9</sub> did not reach the recommended daily amount (400 μg) in 57 patients with CHF who were hospitalized and 40 healthy controls.<sup>189</sup>

The use of n-3 polyunsaturated fatty acids derived from fish oil has been studied in a canine model of heart failure.<sup>190</sup> A total of 28 dogs, 15 of which were cachectic, were fed fish oil supplement or placebo for 8 weeks. Interestingly, active treatment decreased plasma levels of IL-1 ( $P = .02$ ) and improved cachexia ( $P = .01$ ) compared with the placebo group.

As an alternative to the supplementation of single substances, Rozentryt et al studied the effects of high caloric enteral support in a small, randomized, placebo-controlled study in 29 patients with cardiac cachexia.<sup>191</sup> Patients were randomized in a 3:1 fashion to either high caloric enteral support (600 kcal daily in addition to their normal diet) or a placebo for 6 weeks. Weight increased by 2.6 kg after 12 weeks' follow-up. Moreover, 6-minute walking distance improved from  $366 \pm 108$  m to  $433 \pm 106$  m;  $P = .02$ .

It is important to understand, however, that increased food intake and high caloric or specific substrate supplementation alone may not be sufficient to prevent or reverse the overall catabolic process underlying the development of weight loss and cachexia. As noted earlier, the complex pathophysiology of tissue wasting includes impairment of resorption, assimilation, storage, and metabolic use of substrates. Increased nutritional supply to the system needs to be accompanied by improved energy and substrate metabolic efficiency of the body's tissues and increased anabolic drive and attenuated catabolic stimulation to prevent or reverse a continued catabolic spiral toward cachexia.

### Nutritional Considerations

The daily sodium intake should be restricted to 2 g in all patients with advanced CHF or cardiac cachexia.<sup>174</sup> Thus all food rich in salt should be avoided. This is particularly true for cheese, sausages, crisps, canned soup and vegetables, ham, bacon, canned meat, and canned or smoked fish.<sup>174</sup> Prolonged periods of fasting are potentially harmful, and cachectic patients should be advised to eat small, frequent meals.<sup>192</sup> Fluid intake should be restricted to 1.5 to 2.0 liters per day, especially in patients with severe symptoms or those requiring high doses of diuretics.<sup>174</sup> At least one study suggests that multiple micronutrient supplementation is potentially beneficial.<sup>179</sup> Such supplements should contain antioxidant supplements and B-group vitamins. Statin therapy should be initiated with caution, because retrospective data indicate that low levels of total cholesterol, LDL, and triglycerides are associated with poor outcomes in CHF patients.<sup>193,194</sup> However, statin therapy is still associated with survival benefits in patients with CHF. Thus statins may be beneficial in CHF patients not because but despite of their cholesterol lowering effects (see later discussion).<sup>195</sup>

It is also recommended to avoid food and lifestyle factors that trigger the acute phase response such as an excess of carbohydrates or saturated fats, alcohol, and smoking.<sup>196</sup> Food that counteracts inflammatory responses, on the other hand, can be recommended. This includes fish oil supplements, olives, walnuts, flaxseed oil, any fruits or vegetables, garlic, ginger, turmeric, sunflower seeds, eggs, herring, or nuts.<sup>196</sup> Enteral nutrition should always be given preference over parenteral nutrition; however, if the latter cannot be avoided, the general guidelines can be followed: 35 kcal per kg of body weight per day, 1.2 g of protein per kg per day, and a 70:30 glucose:lipid ratio for the nonprotein energy.<sup>8</sup>

## Pharmacotherapy of Cardiac Cachexia

Despite the emerging data of weight loss and cachexia as a significant impact on morbidity and mortality on CHF, there is currently no approved therapy available to prevent, reduce, or reverse the tissue wasting in these patients. A range of compounds are available and in use for other conditions. Their value for the setting in CHF, however, is unclear if not controversial. The following section provides an overview on therapeutic strategies currently under evaluation or in use in other settings of wasting and cachexia, such as, above others, in cancer and HIV (Box 21-2).

### Appetite Stimulants

Appetite stimulating compounds are naturally of great interest in the context of anticachectic therapy. Synthetic derivatives from the steroid hormone progesterone, such as medroxyprogesterone acetate and megestrol acetate, have shown their efficacy in stimulating appetite in cachectic patients in a number of randomized controlled trials.<sup>197,198</sup> The precise mechanism by which the resulting weight gain is mediated is presently unknown but a range of effects, including stimulation of neuropeptide Y,<sup>199</sup> inhibition of proinflammatory

## BOX 21-2 Potential Therapeutic Options to Improve Metabolic Status

### Appetite Stimulants

Megestrol acetate  
Medroxyprogesterone acetate  
Cyproheptadine  
Dronabinol

### Anabolic Steroids (Selection)

Danazol  
Fluoxymesterone  
Methandrostenolone  
Methyltestosterone  
Nandrolone decanoate  
Nandrolone phenpropionate  
Oxandrolone  
Oxymetholone  
Stanozolol

### Antiinflammatory Substances

TNF- $\alpha$  inhibitory potential  
Adenosine  
Amiodarone  
Etanercept  
IC14 (LPS receptor blocker, not approved)  
Infliximab  
Pentoxifylline  
Thalidomide

### Proteasome Inhibitors

cytokines,<sup>200</sup> and modulation of calcium channels in the ventromedial hypothalamus,<sup>201</sup> are discussed. Clinical studies focused on cancer- and AIDS-associated wasting and no studies in patients with cardiac cachexia are available.

### Cannabinoids

Cannabinoids are known to stimulate appetite. Two indications are currently approved for delta-9-tetrahydrocannabinol: chemotherapy-associated nausea and vomiting and AIDS-associated anorexia and wasting. The active ingredient of cannabis is delta-9-tetrahydrocannabinol. Dronabinol, nabilone, and levonantradol are synthetic cannabinoids for oral application. Patients in AIDS-<sup>202</sup> and cancer-related<sup>203,204</sup> weight loss studies, however, have not shown a significant weight gain.

Cardiac side effects of cannabinoids such as tachycardia, hypotension, and decreased cardiac function<sup>205</sup> seem to contraindicate the use in patients with cardiac cachexia.

### Anabolic Steroids

Anabolic steroids are chemically related to testosterone, yielding an increase in protein synthesis and hence an increase in muscle mass. Due to an extensive first-pass metabolism in the liver, the oral bioavailability of testosterone is poor. Intramuscular injections, implantable pellets, buccal, and transdermal systems are available for delivery. Other anabolic steroids such as methyltestosterone, danazol, oxandrolone, and others are available for oral administration.

While testosterone replacement was shown to improve functional capacity and symptoms in general heart failure patients,<sup>206,207</sup> no study has been performed in patients with cardiac cachexia. Observations in patients with cachexia due to COPD and in HIV patients<sup>208</sup> showed significant increase in body weight, particularly in lean tissue.<sup>209</sup>

### Antiinflammatory Substances (see also Chapter 11)

A vast array of substances from different drug classes has been shown to suppress inflammation, especially the production or the action of proinflammatory cytokines.<sup>210</sup> Despite the intriguing pathophysiological concept, however (see previous discussion), results so far were disappointing.

One approach used etanercept, which is a TNF- $\alpha$  receptor 2 fusion protein that binds and thus inactivates the cytokine. A large trial program using etanercept included the RENAISSANCE trial (Randomized Etanercept North American Strategy to Study ANtagonism of CytokineEs) and the RECOVER trial (Research into Etanercept: CytOkine Antagonism in VEntricular Dysfunction) plus the combined analysis (RENEWAL). The program was terminated early following a recommendation of its Independent Data Safety Monitoring Board (DSMB)<sup>211</sup> when interim analyses revealed a lack of efficacy of the treatment.

Infliximab is a chimeric (mouse/human) IgG<sub>1</sub> monoclonal antibody that binds both soluble and membrane-bound TNF- $\alpha$ . It is clinically used with good effect in the treatment of Crohn disease. The ATTACH (Anti-TNF- $\alpha$  Therapy Against Chronic Heart failure) trial, a multicenter, randomized, double-blind, placebo-controlled study in CHF, was stopped prematurely because of an increased risk of death (RR 2.84, 95% CI 1.01 to 7.97,  $P < .05$ ) with the higher dose of infliximab (i.e., 10 mg/kg body weight).<sup>212</sup> Like with etanercept, it is not easy to explain the disappointing results. Infliximab was shown to be directly cytotoxic to cells expressing TNF- $\alpha$  on their membranes. This effect is beneficial in eliminating activated T cells in Crohn's disease, but it is deleterious in CHF, in which failing myocytes express TNF- $\alpha$  on their surfaces.<sup>213</sup>

### Inhibition of Lipopolysaccharide Bioactivity

Since LPS is discussed as a trigger of inflammatory activation in CHF (see previous discussion), this pathway, including the Toll-like receptor 4, may serve as a therapeutic target.<sup>214</sup> IC14, an antibody that blocks CD14-mediated LPS binding to Toll-like receptor 4, has been shown to downregulate LPS-induced TNF- $\alpha$  production in whole blood samples from patients with CHF.<sup>215</sup>

A rather unexpected finding was that patients with CHF and higher plasma cholesterol levels have better (not worse) survival rates than those with lower levels.<sup>193,194</sup> Additional in vitro data showed a linear relationship between plasma cholesterol levels and LPS-stimulated TNF- $\alpha$  production.<sup>216</sup> This suggests that LPS is inactivated by cholesterol, which lends support to the endotoxin-lipoprotein hypothesis.<sup>217</sup> This hypothesis suggests that micelle formation by cholesterol around LPS could be beneficial in CHF.

### Immune Modulation by Thalidomide (see also Chapter 11)

Thalidomide was part of one of the largest drug tragedies in the history of medicine because of the initially unrecognized induction of congenital abnormalities, most frequently phocomelia.<sup>218</sup> The drug was later found to inhibit angiogenesis,<sup>219</sup> resulting in limb malformation, after only a single dose taken within a specific period during pregnancy.

The potent TNF- $\alpha$  selective antiinflammatory capacity of thalidomide<sup>220</sup> and amino-substituted analogues may yield positive immune modulatory effects.<sup>221</sup> This led to the suggestion of using thalidomide in the treatment of CHF<sup>222</sup> and cachexia.<sup>223</sup> Results from early small studies suggest increased LVEF<sup>223</sup> and improved the 6-minute walking distance.<sup>224,225</sup> Others, however, were unable to find effects on LVEF or any other echocardiographic parameters after treatment with thalidomide.<sup>226</sup> The potential role in cardiac cachexia warrants further investigation.

### Proteasome Inhibitors

To date, four different classes of proteasome inhibitors have been described that are either reversible or irreversible

inhibitors of specific activities of the proteasome.<sup>227</sup> Bortezomib was given approval by the U.S. Food and Drug Administration for the treatment of multiple myeloma and mantle cell lymphoma in patients who had received at least one prior therapy. No studies are available that have specifically evaluated whether bortezomib or possibly other proteasome inhibitors are able to reverse weight loss in cachectic patients.

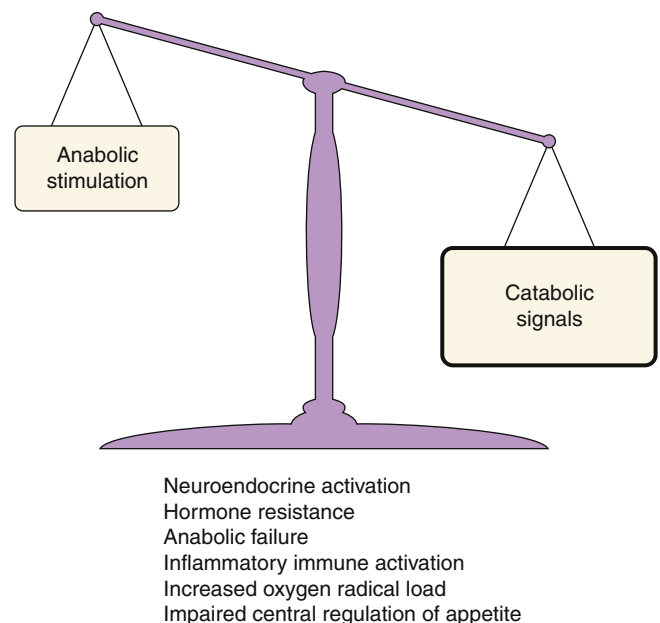

### Pentoxifylline (see also Chapter 11)

It was initially characterized as a hemorrheologic agent; however, recent studies suggested that pentoxifylline may inhibit TNF- $\alpha$  formation.<sup>228</sup> A number of clinical studies have been performed in patients with CHF. Increased LVEF in parallel to reduced TNF- $\alpha$  plasma levels were observed.<sup>229,230</sup> In other randomized, double-blind, placebo-controlled studies, a significant increase in NYHA class and improved LVEF<sup>231</sup> were observed. Other studies were, however, unable to confirm the former findings in CHF.<sup>232</sup> Beneficial effects in the treatment of cancer cachexia have been reported to prevent muscle atrophy and suppress protein breakdown by inhibition of the ubiquitin-proteasome pathway.<sup>233,234</sup> Future studies need to define the role of pentoxifylline in the setting of cachexia.

## CONCLUSION AND OUTLOOK

The pathophysiology of cardiac cachexia is exceedingly complex, and we still do not understand when and how CHF progresses into this syndrome. Metabolic imbalance, hormonal dysregulation, and proinflammatory cytokines play important parts in the interrelated system (Figure 21-8). Despite convincing concepts on pathophysiological grounds, a range of approaches failed when tested in clinical studies. We are currently not able to interfere with appetite regulation in a promising way, although initial steps have been undertaken and may prove beneficial in future studies.

No studies are currently available that have specifically targeted cardiac cachexia using a pharmacological approach. Nutritional recommendations to prevent or reverse cardiac cachexia remain speculative, and no large-scale, randomized, controlled trials have been performed.

**FIGURE 21-8** Pathophysiology of cachexia in chronic illness: An overall catabolic dominance results from a combined effect of impaired regulatory systems, such as neuroendocrine activation, metabolic hormonal signaling failure, inflammatory activation, impaired central regulation of appetite, and others.

With better understanding of the complex interaction of metabolic abnormalities within the pathophysiology of CHF we may advance the pharmacological therapeutic options in CHF beyond the neuroendocrine activation. Targeting immune activation, feeding, and metabolic balance are promising areas for future therapeutic concepts. Novel compounds constantly coming along the pharmaceutical development pipelines and future research will show whether those may translate into clinical improvement of patients with CHF.

**Conclusion, 353**

Heart failure (HF) is a syndrome associated with high morbidity and mortality and considerable economic burden.<sup>1</sup> It is the third most prevalent cardiovascular disease and the third leading cause of cardiovascular death in the United States.<sup>2</sup> Once diagnosed, HF continues to portend a grim prognosis despite advances in treatment. Recognizing the importance of the preclinical phases of HF and the possibility of prevention, the American Heart Association and American College of Cardiology classify HF into four stages (Figure 22-1): presence of risk factors, but with normal cardiac structure and function (Stage A), subclinical changes in left ventricular structure and/or function (Stage B), clinical HF (Stage C), and advanced HF (Stage D).<sup>3</sup> Understanding the epidemiology of the preclinical and clinical stages of HF may facilitate preventative strategies. In this chapter, we provide (1) an overview of HF stages A and B, and (2) detail the epidemiology of clinical HF.

## EPIDEMIOLOGY OF HF RISK FACTORS

Several etiological factors have been described for HF (Table 22-1).<sup>4</sup> Of these, coronary heart disease (CHD) and hypertension account for approximately three fourths of all HF, although their relative importance differs according to age, sex, and race.<sup>5</sup> Also, the relative contribution of

observations highlight the importance of CHD as a determinant of HF occurrence both from individual risk and population burden perspectives.

A separate issue of concern is the trend in the incidence of HF after myocardial infarction (MI). Data from Framingham demonstrate a rise in post-MI HF between 1971 and 2000, mostly due to an increase in HF incidence in the very early post-MI period.<sup>12</sup> This is likely due to improved survival of people with MI<sup>13</sup> leading to an increase in population “at risk” for HF and thereby contributing to an increase in HF prevalence.

## EPIDEMIOLOGY OF HYPERTENSION IN RELATION TO HF RISK

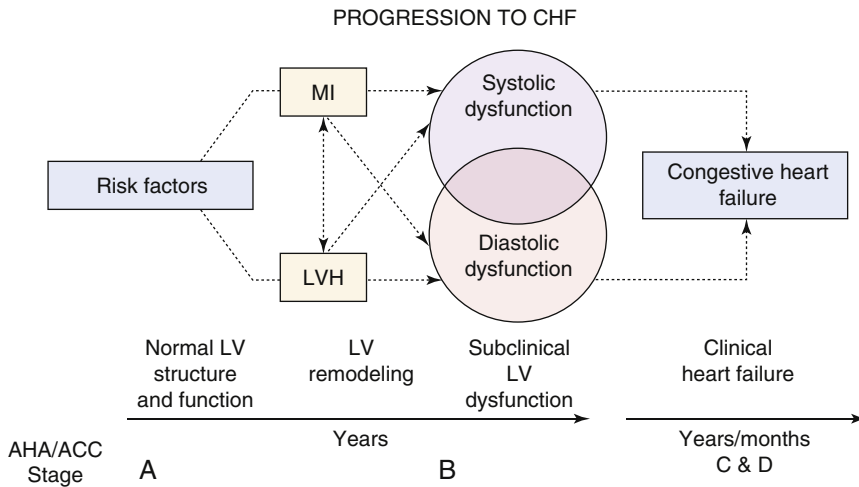

In the United States, approximately 74 million people have hypertension (see also Chapter 28), with millions more having blood pressures in the “high normal” range.<sup>3</sup> Data from the Framingham study show that hypertension is an antecedent of the vast majority of individuals with HF in the community.<sup>11</sup> The relative risk of HF in people with hypertension is twofold and threefold higher in men and women, respectively, compared with those without hypertension.<sup>11</sup> Both systolic blood pressure and pulse pressure independently carry a 55% increased risk of HF per standard deviation increment after accounting for standard risk factors<sup>14</sup> and a 30% increased risk of HF per standard deviation increment after additionally accounting for prevalent and incident MI.<sup>15</sup> The effect of increased blood pressure on HF risk persists for many years, as evidenced by the independent contributions of recent and remote blood pressure elevations to HF risk, after adjustment for current measurements.<sup>15,16</sup>

The population burden of hypertension-associated HF is substantial, as evidenced by a PAR of 39% in men and 59% in women in a Framingham study investigation.<sup>11</sup> Although the prevalence of hypertension is high and may be increasing over time,<sup>17</sup> the PAR for hypertension (for HF risk) is decreasing, likely due to improving blood pressure control in the community, and attendant attenuation of blood pressure-CVD risk relations.<sup>18,19</sup> Despite these improvements, a substantial number

the various risk factors to HF occurrence in the community may be changing over time. Data from the Framingham Heart Study demonstrate that from the 1950s onward there has been a steady decline in the contribution of valvular disease to HF burden, whereas that of CHD has increased substantially.<sup>6</sup> When not initially apparent, the diagnosis of the specific cause of HF is often difficult; in one study of 1230 individuals with initially unexplained cardiomyopathy, 50% were ultimately classified as idiopathic after a comprehensive workup, including endomyocardial biopsy.<sup>7</sup>

## EPIDEMIOLOGY OF CHD IN RELATION TO HF RISK

Angiographic coronary artery disease is present in approximately half of all patients with new-onset HF.<sup>8</sup> In various investigations, CHD has been reported to account for 23% to 73% of HF in the patients evaluated. In the HF series that focused on patients with a reduced LV ejection fraction, CHD is usually the most common cause.<sup>9</sup> Data from the National Health and Nutrition Examination Survey (NHANES-I) show that presence of CHD confers an eightfold higher HF risk.<sup>10</sup> Framingham data indicate a differential contribution of CHD to HF burden in men versus women; the population attributable risk (PAR) for HF associated with CHD was 39% in men and 18% in women.<sup>11</sup> These

**FIGURE 22-1** Progression to HF. HF develops over several years starting with the onset of risk factors, progressing to alterations in LV structure and function, and culminating in clinical HF. "Minor" risk factors—less consistently related to HF risk.

of people have poorly controlled or refractory hypertension,<sup>20</sup> offering the possibility of further reductions in hypertension-associated HF by targeting these individuals.

## EPIDEMIOLOGY OF OBESITY IN RELATION TO HF RISK (see Chapter 20)

Approximately a third of U.S. adults are obese<sup>21</sup> (defined as body mass index [BMI] of 30 kg/m<sup>2</sup>), and an additional third are overweight (BMI between 25.0 and 29.9 kg/m<sup>2</sup>). Observations from the Framingham Heart Study show that the risk for incident HF increases by 5% and 7% in men and women,

respectively, per unit increase in BMI.<sup>22</sup> There is a graded increase in HF risk across categories of BMI in both men and women (Figure 22-2), and compared with people with normal BMI, those with obesity carry approximately twice the HF risk after accounting for established HF risk factors.<sup>22</sup> The HF risk portended by obesity seems to be partially ameliorated by concomitant physical activity; participants of the Physicians Health Study who were overweight or obese but had regular physical activity had HF risk that was intermediate to those who were lean and active and those who were obese but not active.<sup>23</sup> Potential explanations for the association between overweight/obesity and HF occurrence include greater prevalence of other HF risk factors and higher prevalence and incidence of MI in this group, and obesity-associated LV remodeling.<sup>24</sup> A recent investigation from Framingham also reported the increased risk for incident HF portended by elevated resistin (an adipokine) levels, providing clues to a potential direct mechanistic link between increased adiposity and HF risk.<sup>25</sup>

There has been a substantial increase in both the prevalence and incidence of overweight and obesity over the past few decades,<sup>26,27</sup> including an increased prevalence of extreme obesity (BMI  $\geq 40$  kg/m<sup>2</sup>).<sup>28</sup> However, there has been a parallel decline in prevalence of other HF risk factors (notably hypertension, smoking, and hyperlipidemia) among those overweight and obese in the same timespan,<sup>29</sup> suggesting that people with these conditions are being increasingly targeted for cardiovascular risk factor modification, and raising the possibility that the obesity epidemic may not translate into an HF epidemic.

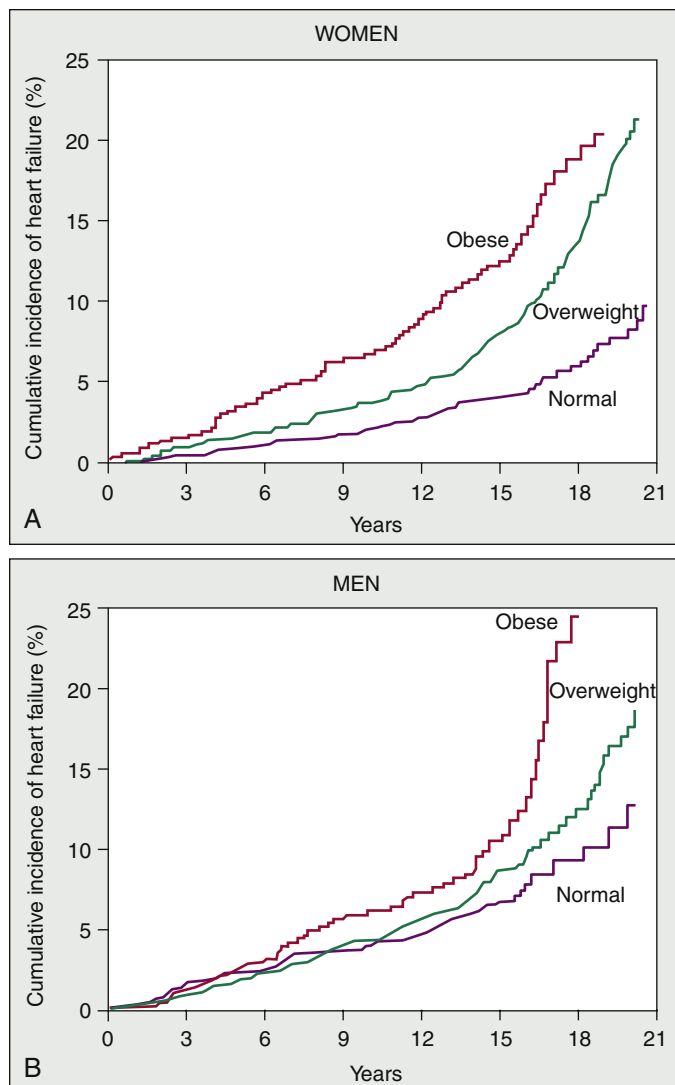

## STRUCTURAL AND/OR FUNCTIONAL ALTERATIONS THAT PREDISPOSE TO HEART FAILURE

A variety of cardiac structural and functional abnormalities detected either indirectly (e.g., with electrocardiography or chest roentgenography) or directly (e.g., with echocardiography or cardiac magnetic resonance imaging [CMR]) have been shown to antedate clinical HF. Electrocardiographic LV hypertrophy, QRS prolongation, QT prolongation, and evidence of a prior MI predict incident HF.<sup>30,31</sup> Similarly, a cardiothoracic ratio greater than 0.5 on a chest x-ray is associated with twofold higher odds of HF.<sup>32</sup>

## LV Structural Alterations (see Chapter 15)

The advent of echocardiography and CMR has enhanced our ability to directly visualize changes in cardiac structure and in global and regional cardiac function. Left ventricular mass

**FIGURE 22-2** Cumulative incidence of heart failure according to category of body-mass index at the baseline examination. The body-mass index was 18.5 to 24.9 in normal subjects, 25.0 to 29.9 in overweight subjects, and 30.0 or more in obese subjects. (Modified from Kenchaiah S, Evans JC, Levy D, et al. Obesity and the risk of heart failure. *N Engl J Med* 2002;347:305-313; and Mann DL. Management of heart failure with a depressed ejection fraction. In Libby PL, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, ed 8, Philadelphia, 2004, Elsevier.)

(calculated using validated formulas from measurements of LV dimensions) has been consistently identified as a predictor of HF risk.<sup>33-35</sup> LV mass also predicts future occurrence of depressed LV systolic function in participants with an initial normal ejection fraction.<sup>36</sup> Estimates of the magnitude of increment in HF risk with an increase in LV mass vary according to the quantitative denominator (i.e., per standard deviation or gram increment, etc.), method of indexation, modality of assessment (echocardiography or CMR, etc.), and the covariates adjusted for.

Increased LV end-systolic and end-diastolic internal dimensions are powerful risk factors for HF. Observations from the Framingham Heart Study show that in people without a prior MI, each standard deviation increment in height-indexed LV end-systolic and end-diastolic dimensions is associated with a 43% and 47% increased risk of HF, respectively.<sup>37</sup> LV dilation in the immediate postinfarction period and dilation 6 months post-MI also predict incident HF.<sup>38,39</sup>

## Asymptomatic LV Dysfunction

Asymptomatic LV dysfunction (comprising either systolic dysfunction, diastolic dysfunction, or both) has been conventionally accepted as an antecedent of HF. However, the proportion of HF preceded by either systolic or diastolic dysfunction is unclear. Estimates of prevalence of asymptomatic LV systolic dysfunction vary depending on the criteria used (Table 22-2).<sup>40</sup> The prevalence of mild and moderate to severe asymptomatic LV diastolic dysfunction is approximately 20% and 7%, respectively, in the general adult population, and 48% and 17%, respectively, in those at high risk for HF (Table 22-3).<sup>41</sup> Prospectively, the rates of HF incidence among HF-free people with ejection fraction (EF)  $\leq 50\%$  and those with EF greater than 50% have been estimated to be 5.8 and 0.7, respectively, per 100 person-years.<sup>42</sup> Individuals with EF  $\leq 50\%$  carry an HF risk that is approximately five times greater than those with EF greater than 50%, after adjusting for standard cardiovascular risk factors.<sup>42</sup> Several other measures of systolic and diastolic function, notably endocardial fractional shortening, transmitral Doppler peak E, and Doppler E/A ratio, also predict incident HF.<sup>43</sup>

The natural history of asymptomatic LV diastolic dysfunction has not been well described. Of note, the prevalence of diastolic dysfunction in the community is either the same or higher in men compared with women, in contrast to the relative prevalences of diastolic HF (that has a female preponderance).<sup>44,45</sup> The reason for this paradox is unclear.

## Screening for Ventricular Remodeling

There has been considerable interest in screening for LV remodeling as a way of identifying people at high risk for developing HF.<sup>46</sup> However, although people with the aforementioned structural and functional alterations are at higher risk for HF compared with those without, the prevalence of HF in groups identified by using these traits individually is low, suggesting that widespread echocardiographic screening may not be cost-effective.<sup>40</sup> The performance of natriuretic peptides for the detection of LV systolic dysfunction or elevated LV mass in the community is suboptimal, implying limited usefulness for identifying those who could potentially benefit from cardiac imaging.<sup>47</sup> An alternate approach may be to use clinical factors as an initial screen to identify a subset of individuals who would be most likely to benefit from additional imaging tests. A recent report identified clinical measures that predict LV dilation and/or dysfunction; such “clinical rules” may help identify people who may benefit from screening with imaging.<sup>48</sup> In addition, combining several imaging indices in the form of a composite score may further help identify those at very high risk for HF. One investigation used a score based on five echocardiographic measures that demonstrated good stratification; the incidence of HF ranged from 4% to 48% across strata of risk index.<sup>49</sup> Such “staged” screening strategies (a serial testing strategy using a clinical score to identify candidates for imaging; an imaging score to identify those at high risk for HF, who could then be targeted for preventive intervention) may offer greater utility at a lower cost. However, the cost-effectiveness of these approaches has not been evaluated.

## EPIDEMIOLOGY OF CHRONIC HF

### Prevalence

There are approximately 5 million people with HF in the United States.<sup>2</sup> There has been a doubling of HF prevalence in the past 25 years,<sup>50</sup> and by the year 2040, it is estimated to further increase to 10 million. The prevalence of heart failure

**TABLE 22-2 Prevalence of Asymptomatic LV Systolic Dysfunction**

Study	Country	Participants	Mean Age/ Age Range	% Men	LSVD Criteria	Prevalence of Asymptomatic LVSD
<b>EF &gt;40 or Equivalent</b>						
Strong Heart Study	United States	3184	58	37	EF ≤0.54	12.5

increases with age: from less than 1% in the 20-to-39-year age group to more than 20% in people age 80 years or older.<sup>51</sup> There is an increasing trend in HF prevalence; in the decade 1989-1999, HF prevalence increased by 1 per 1000 and 0.9 per 1000 in women and men, respectively.<sup>52</sup> The aging of the U.S. population, and an improved survival and “salvage” of patients with MI (with subsequent progression to pump failure) will likely contribute to increasing prevalence over the next few decades.

The relative prevalence of HF with normal EF versus reduced EF varies with characteristics of the study sample and of the threshold used to define a “normal” EF (Figure 22-3 displays the relative prevalence of HF with normal EF and reduced EF reported in various epidemiological studies; Table 22-4 lists the sample age and HF definition characteristics of studies from which Figure 22-3 data are drawn).<sup>41</sup> Overall each group (reduced and preserved EF) accounts for approximately one half of HF cases.<sup>53,54</sup> The prevalence of HF with normal EF increases substantially with age.<sup>55</sup> There has been an increasing trend in the incidence of HF with a normal EF,<sup>56</sup> likely reflecting increasing awareness of the condition and willingness of clinicians to make the diagnosis. HF with normal EF is more commonly associated with female gender, hypertension, and atrial fibrillation, and less commonly with MI and electrocardiographic left bundle branch block.<sup>57</sup>

## Incidence

More than half a million new cases of heart failure are diagnosed each year in the United States, and this incidence is expected to rise to 772,000 new cases per year by 2040 (Figure 22-4).<sup>41</sup> This increase in incidence is mainly due to the aging of the population, as HF incidence doubles with each successive decade above age 45 for both men and women.<sup>58</sup> An analysis from Framingham showed that when adjusted for

**TABLE 22-3 Prevalence of Asymptomatic LV Diastolic Dysfunction**

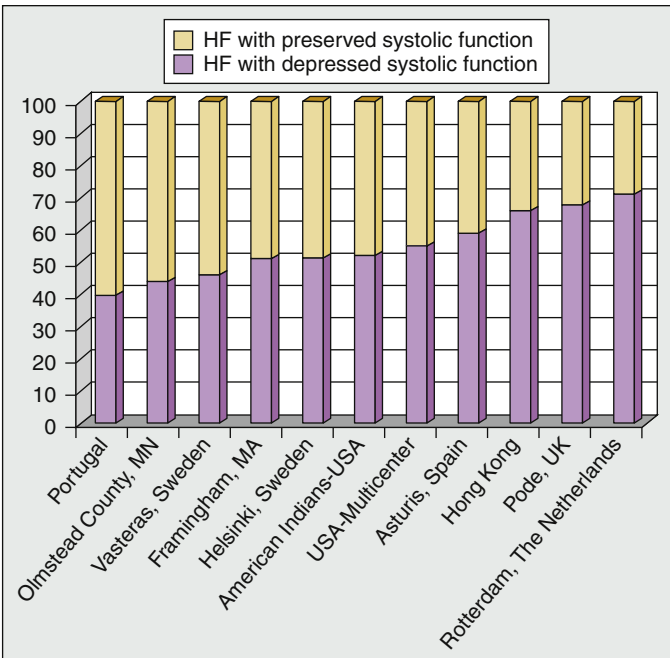

Diastolic Dysfunction			
Variables	No. of Participants	Mild	Moderate to Severe
<b>General Adult Population</b>			
All	1991	20.6 (18.7-22.6)	6.8 (5.6-8.0)
Men	952	22.3 (19.5-25.3)	6.2 (4.7-8.1)
Women	1039	19.1 (16.7-21.8)	7.3 (5.7-9.1)
<b>High-risk Population (Aged &gt;65 yr and with Hypertension or Coronary Artery Disease)</b>			
All	396	47.6 (42.1-53.1)	16.5 (12.6-20.9)
Men	196	48.7 (40.7-56.8)	14.6 (9.5-21.0)
Women	200	46.5 (38.8-54.3)	18.2 (12.7-24.9)

Prevalence of asymptomatic diastolic dysfunction as assessed by Doppler echocardiographic analysis of 2042 men and women greater than 45 years of age.

age, there has been no increasing trend in HF incidence for men, and may be slightly decreasing in women,<sup>59</sup> whereas data from Olmsted County show no change in HF incidence for either gender.<sup>60</sup>

## Lifetime Risk

The lifetime risk of developing heart failure is estimated at 20% in both men and women (Figure 22-5).<sup>61</sup> An age-related increase in HF risk is counterbalanced by a decreasing life

**FIGURE 22-3** Prevalence of HF with normal systolic function in community based studies. Prevalence of HF with preserved systolic function varied across studies, ranging from 40% (in Portugal) to 71% (in Rotterdam). (Adapted from Owan TE, Redfield MM. Epidemiology of diastolic heart failure. *Prog Cardiovasc Dis* 2005;47:320-332 and Parikh N, Vasan RS. Epidemiology of heart failure. In Colucci WS, editor. *Atlas of heart failure*, ed 5, Philadelphia 2008, Springer.)

**FIGURE 22-4** Projected increase in HF incidence. Projections are based on current HF incidence rates. (Adapted from Owan TE, Redfield MM. Epidemiology of diastolic heart failure. *Prog Cardiovasc Dis* 2005;47:320-332; and Parikh N, Vasan RS. Epidemiology of heart failure. In Colucci WS, editor. *Atlas of heart failure*, ed 5, Philadelphia, 2008, Springer.)

report, those with four or more of six healthy lifestyle habits (consumption of breakfast cereals, fruits and vegetables, maintenance of normal body weight, regular exercise, refraining from smoking, and moderate alcohol intake) had half the lifetime risk for HF compared with those who adhered to none.<sup>62</sup>

### Morbidity and Mortality

HF accounts for 12 to 15 million office visits and 6.5 million days of hospital stay each year in the United States.<sup>63</sup> The number of HF hospitalizations has risen to more than a million per year over the past decade,<sup>2</sup> and they now account for at least 20% of all admissions for persons older than 65 years.<sup>64</sup> The estimated annual cost of caring for HF patients is \$37 billion.<sup>2</sup> In one prospective study, the 1-year costs for prevalent (at the time of study entry) and incident (during study period) HF with normal EF were \$32,000 and \$45,000, respectively, and corresponding estimated costs for HF with reduced EF were approximately \$33,000 and \$49,000, respectively.<sup>65</sup> In addition, HF patients usually have multiple comorbid conditions,<sup>66</sup> which influence the risk for both hospitalization and death,<sup>67</sup> especially in those with HF with normal EF.<sup>68</sup>

There are approximately 50,000 HF deaths in the United States annually. An earlier report from the Framingham Heart Study revealed 1-year and 5-year survival rates of 57% and 24% in men, and 64% and 38% in women, respectively.<sup>69</sup> Mortality increased with increasing age at 27% per decade.<sup>69</sup> Median survival after the onset of HF was 1.7 years and 3.2 years in men and women, respectively.<sup>70</sup> An examination of the temporal trends in survival after HF onset demonstrated a modest improving trend between the years 1950 and 1999 (Figure 22-6). However, in a more recent Framingham evaluation, the median survival was 2.1 years and a 5-year mortality rate 74%, with equally dismal prognosis in both men and women, and in both those with HF with preserved EF and normal EF.<sup>57</sup>

Of note is a striking geographic heterogeneity in HF mortality rates (Figure 22-7).<sup>71</sup> The highlighted areas indicate an “HF belt” across the United States that consists of states with the highest HF death rates. Higher prevalence of hypertension and CHD, varying access to early diagnosis compounded by regional differences in HF management, and differences in death certificate coding practices may explain this occurrence.

Study Location	Population	Age	Definition of Preserved Systolic Function
Portugal	5434	>25	EF ≥0.45
Olmstead County, MN	2042	≥45	EF ≥0.50
Framingham, MA	73	Mean = 73	EF ≥0.50

expectancy with advancing age, so that the lifetime risk of HF remains relatively stable at 20% at all ages above 40 years. Even without antecedent CHD, the lifetime risk of developing heart failure at age 40 years is estimated at 11.4% for men, and 15.4% for women.<sup>61</sup> A significant proportion of lifetime risk of HF is accounted for by lifestyle factors; in a recent

**FIGURE 22-5** Lifetime HF incidence. Lifetime risk of developing HF was estimated at various ages (between 40 years and 80 years of age) among 3757 men and 4472 women in the Framingham Heart Study from 1971 to 1996. (Adapted from Lloyd-Jones DM, Larson MG, Leip EP, et al. Lifetime risk for developing congestive heart failure: the Framingham Heart Study. *Circulation* 2002;106:3068-3072; and Parikh N, Vasan RS. Epidemiology of heart failure. In Colucci WS, editor. *Atlas of heart failure*, ed 5, Philadelphia, 2008, Springer.)

## EPIDEMIOLOGY OF STAGE D HF

Few investigations have addressed the epidemiology of Stage D HF. In a study of a population-based cross-sectional random sample of people aged 45 years from Olmsted County, 0.2% had Stage D HF, and the prevalence increased with advancing age. Stage D HF accounted for 0.4% of all stages of HF, and 2% of clinical HF.<sup>72</sup> Stage D was associated with markedly reduced survival (20% in 5 years).<sup>72</sup> An analysis of the Acute Decompensated Heart Failure Registry (ADHERE) compared those with Stage D HF to people with acute decompensated HF (ADHF) and noted that people with Stage D were younger, more likely male, had a higher prevalence of dyslipidemia and CHD, and were more likely to receive intravenous vasoactive therapy compared with those with ADHF.<sup>73</sup> The 1-year survival rate free of death or hospitalization was only 33%.<sup>73</sup> The pathophysiological significance or clinical implications of these differences between Stage D HF and ADHF are unclear.

## EPIDEMIOLOGY OF ACUTE HF (see Chapter 43)

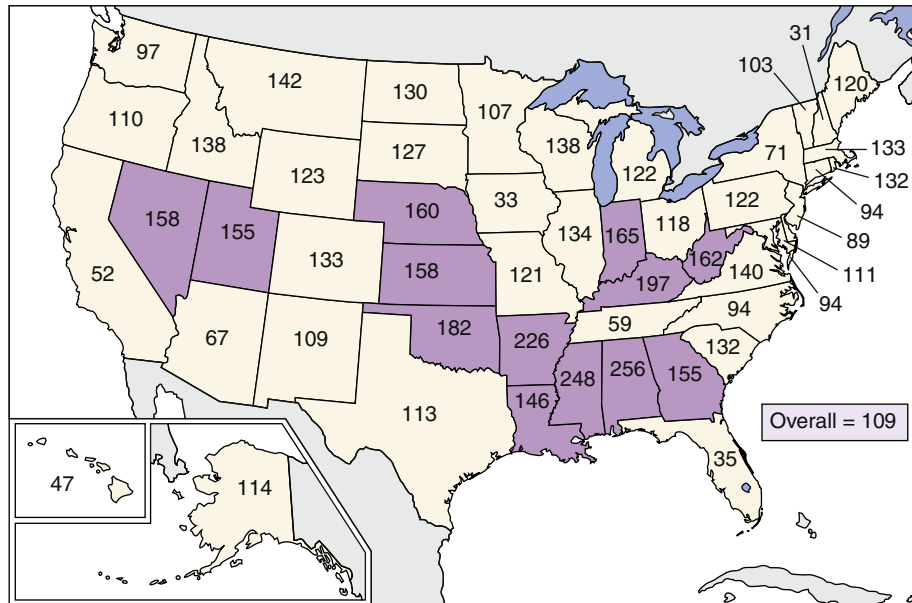

Acute HF (also referred to as ADHF or “acute HF syndromes”) is the rapid occurrence of symptoms and signs of HF, or the deterioration of stable chronic HF, leading to the requirement of hospitalization and/or intensive therapy (see also Chapters 43 and 44).<sup>74</sup> It may occur in the presence or absence of pre-existing cardiac disease, and may be new-onset HF or worsening of previously stable HF.<sup>75</sup> Thus acute HF has a broad spectrum of clinical presentations and an evolving clinical definition.<sup>76</sup>

Approximately 65% to 87% of acute HF episodes are worsening of chronic HF.<sup>77</sup> Factors precipitating hospitalizations include pneumonia or other respiratory infections, myocardial ischemia, arrhythmias, or worsening renal function.<sup>78</sup> The in-hospital mortality rates are 3% to 4%; older age, lower systolic blood pressure, lower serum sodium, and elevated serum creatinine are independently associated with a greater mortality risk.<sup>79</sup> The 60- to 90-day postdischarge mortality rate and readmission rate are 8.6% and 29.6%, respectively; the most important predictors for these complications include older age, lower weight and systolic blood pressure, lower serum sodium, elevated serum creatinine, and associated pulmonary disease.<sup>80</sup> The relative prevalence of normal and reduced EF in people with acute HF is similar to those with chronic HF.<sup>81</sup> The 60- to 90-day postdischarge mortality

**FIGURE 22-6** Age-adjusted survival after the onset of heart failure (ages 65-74 years) **A**, Temporal trends in age-adjusted survival after the onset of heart failure in men. **B**, Temporal trends in age-adjusted survival after the onset of heart failure in women. (Adapted from Levy D, Kenchaiah S, Larson MG, et al. Long-term trends in the incidence of and survival with heart failure. *N Engl J Med* 2002;347:1397-1402; and Parikh N, Vasan RS. Epidemiology of heart failure. In Colucci WS, editor. *Atlas of heart failure*, ed 5, Philadelphia, 2008, Springer.)

risk and rehospitalization rates are similar in the two types of HF.<sup>81</sup> A heartening recent trend is the improvement in conformity to quality of care measures in people hospitalized with acute HF, with attendant improvement in in-hospital mortality and morbidity.<sup>82</sup>

**FIGURE 22-7** Geographic variation in U.S. HF death rates. Displayed numbers indicate state-specific, age-adjusted death rates per 100,000 persons in the time period 1990-1996, for men and women 65 years of age. (From Changes in mortality from heart failure—United States, 1980-1995. *MMWR Morb Mortal Wkly Rep* 1998;47:633-637; and Parikh N, Vasan RS. Epidemiology of heart failure. In Colucci WS, editor. *Atlas of heart failure*, ed 5, Philadelphia, 2008, Springer.)

## DIFFICULTIES IN INTERPRETING EVALUATIONS ADDRESSING HF EPIDEMIOLOGY

HF diagnosis is typically based on the presence of a constellation of symptoms, signs, radiographic and/or laboratory abnormalities, and objective measures of LV function. As such, there is no universally accepted diagnostic schema, and several sets of criteria (with varying performance characteristics) have been used in epidemiological studies.<sup>83,84</sup> Published differences in the epidemiological characteristics of HF between different geographical regions, different populations, and across time periods may therefore be influenced by varying diagnostic methodologies as opposed to true differences; the magnitude of epidemiological differences attributable to differences in criteria used to diagnose HF is unknown. The major issues in evaluating the epidemiology of HF are:

1. Differences between studies in criteria used for HF diagnosis<sup>84</sup>
2. Nonuniform case ascertainment methods<sup>85</sup>
3. Changing clinical diagnosis patterns over time: increasing use of imaging<sup>86</sup> and laboratory testing (e.g., natriuretic peptide measurements) over time
4. Difficulties in reconciling findings between studies addressing overall trends versus cause-specific trends (e.g., post-MI HF vs. hypertensive HF) or type-specific trends (HF with normal vs. reduced EF)
5. Differences in morbidity statistics due to clinical practice patterns related to hospitalizations, changes in reimbursement, and differences in coding of diagnosis-related groups
6. Differences due to sources of information regarding the epidemiology of HF: longitudinal studies versus registries versus clinic databases

Data regarding the trends and epidemiological pattern of HF should therefore be interpreted with caution in light of these caveats.

## FUTURE DIRECTIONS

HF is the only cardiovascular disease increasing in prevalence, and as noted previously, it continues to be associated with a very high morbidity and mortality burden. Improved characterization of (1) those at risk for HF, (2) determinants of poor prognosis in people with established HF, and (3) elucidation of factors associated with varying responses to therapy may aid in the prevention of and reduction in mortality associated with HF.

## BIOMARKERS FOR HF RISK PREDICTION

There has been considerable interest recently in the use of circulating biomarkers for prediction and stratification of HF risk.<sup>87,88</sup> Circulating biomarkers of inflammation, renin-angiotensin-aldosterone axis, neurohormonal activation, fibrinolytic potential, and oxidative stress have all been reported as associated with cardiovascular remodeling and/or HF risk.<sup>89-94</sup> Similarly, cardiac troponins T and I, BNP, and interleukin receptors have been shown to predict outcomes in patients with HF.<sup>95-97</sup> However, the incremental utility of these markers in improving risk prediction is unclear at present. Experiences from coronary event risk prediction efforts suggest that contribution of biomarkers to overall risk prediction may be more modest than anticipated.<sup>98</sup> However, biomarkers may be useful in improving the stratification of individuals deemed to be at “intermediate risk” of developing HF based on clinical factors alone.<sup>99</sup>

## INVESTIGATION OF HF GENOMICS

The sequencing of the human genome<sup>100</sup> and publication of the HapMap template<sup>101</sup> allow us to elucidate genetic attributes that may help in predicting both HF risk and its prognosis. The most common type of genetic variation is the single nucleotide polymorphism (SNP) and the recently developed

technique of genomewide association study (GWAS) may allow us to identify genetic predictors in the near future. GWAS may also help identify molecular targets for therapy and predictors of pharmacological response, thus offering the possibility of “personalized medicine.” However, no GWAS targeting HF has been published to date.

## OTHER MOLECULAR APPROACHES TO HF EVALUATION

Another avenue for improving the clinical and epidemiological description of HF is the use of transcriptomics.<sup>102</sup> The “transcriptome” is a complete qualitative and quantitative description of the messenger RNA in a cell. By elucidating the specific gene programs expressed under a given set of conditions, transcriptomic analyses allow us to identify the determinants of disease manifestations and the interplay between genetic and environmental factors. As an example, one recent investigation identified a profile of 46 overexpressed genes that delineated HF patients into those with good versus poor prognosis with 74% sensitivity and 90% specificity.<sup>103</sup>

## CONCLUSION

HF is a complex syndrome with numerous risk factors and determinants of outcome. Significant progress has been made in identifying the major risk factors and the population patterns of HF and associated trends. Newer technologies offer further promise of clarifying the clinical and epidemiological course of this condition.<sup>104</sup> The development of universally accepted definitions for diagnosis and classification of HF will simplify and aid epidemiological research, and help in instituting initiatives for prevention.

## Heart Failure as a Consequence of Ischemic Heart Disease

James D. Flaherty, Robert O. Bonow, and Mihai Gheorghiade

Despite significant progress in the prevention and treatment of cardiovascular disease over the past 30 years, national statistics indicate that the incidence and prevalence of heart failure (HF) continue to rise.<sup>1</sup> This has occurred during a time period in which death rates from coronary artery disease (CAD) and stroke have declined. HF and CAD are age-related conditions (the prevalence of HF is 1% between the ages of 50 and 59 years, but 10% above the age of 75 years).<sup>2</sup> The increased survival after myocardial infarction (MI) and advances in medical and device therapies (e.g.,  $\beta$ -blockers and implantable cardioverter-defibrillators [ICDs]) for the prevention of sudden cardiac death (SCD) have increased the pool of patients with the potential to develop chronic HF.<sup>3-5</sup>

### PREVALENCE OF CORONARY ARTERY DISEASE IN HEART FAILURE

CAD has emerged as the dominant causal factor in HF (see Chapter 22). Survivors of acute MI, even when not complicated by

In this study alone, two thirds of all patients who underwent angiography had obstructive CAD (defined as >50% luminal stenosis), although CAD was not considered the primary causal factor in all cases. In a recent analysis of a large U.S. acute HF registry, myocardial ischemia was found to be a leading precipitating factor for hospitalization.<sup>35</sup>

### PROGNOSTIC SIGNIFICANCE OF CORONARY ARTERY DISEASE IN HEART FAILURE

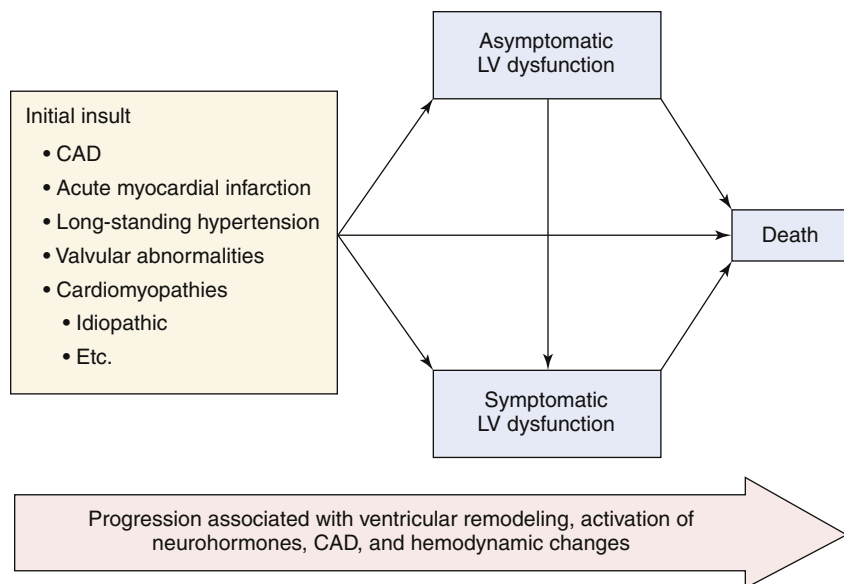

The presence of CAD in patients with HF has been shown to be independently associated with a worsened long-term outcome in numerous studies.<sup>36</sup> Atherosclerosis is an important contributing cause of death in HF patients through a variety of mechanisms, including SCD, progressive ventricular failure, MI, renal failure, and stroke. In patients with HF, the long-term prognosis is directly related to the angiographic extent and severity of CAD.<sup>37,38</sup> This has been demonstrated both in HF patients with LV systolic dysfunction (LVSD) and in those with preserved systolic function.<sup>39</sup>

Recent data suggest that the mechanism of SCD may differ between ischemic and nonischemic HF, with acute coronary events representing the major cause of SCD in patients with CAD.<sup>40,41</sup> In the Assessment of Treatment with Lisinopril and Survival (ATLAS) study, 54% of patients with chronic HF and CAD who died suddenly had autopsy evidence of acute MI.<sup>40</sup> In another autopsy study of 180 patients with known ischemic cardiomyopathy, acute MI was responsible for 57% of the deaths.<sup>41</sup> This study revealed that, before autopsy data were available, many deaths due to acute MI in patients with HF were misclassified as due to progressive HF or arrhythmias. In another study of patients with HF and LVSD, 25% of repeat hospitalizations were attributed to ACS.<sup>42</sup> However, approximately 10% of patients with a history of HF who were subsequently hospitalized for ACS were originally classified as having a nonischemic cause. These findings further emphasize the importance of accurately assessing for the presence of CAD in patients with HF.

HF, have a relatively high incidence of subsequent HF hospitalization.<sup>6</sup> This is due not only to the initial ventricular insult caused by the MI, but also the progressive nature of CAD (Figure 23-1). The Framingham Heart Study suggests that the factors contributing to HF are changing, as evidenced by a decrease in valvular heart disease and left ventricular (LV) hypertrophy, but an increase in MI as a risk factor from 1950 to 1998.<sup>3</sup> In this analysis, the odds of a prior MI as a cause of HF increased by 26% per decade in men and 48% per decade in women. In contrast, hypertension as a cause of HF decreased by 13% per decade in men and 25% in women, and valvular heart disease as a cause of HF decreased by 24% per decade in men and 17% in women.

In the Studies of Left Ventricular Dysfunction (SOLVD) registry, which enrolled 6273 patients, CAD was determined as the underlying cause of chronic HF in approximately 70% of patients, whereas hypertension was invoked as the primary cause in only 7% of cases.<sup>7</sup> Of note, there was a history of hypertension in 43% of patients. There were striking racial differences observed in this registry. HF was considered due to CAD in 73% of Caucasian patients, but only 36% of African American patients.

Pooling data from 26 multicenter trials of chronic HF since 1986 with greater than 43,000 patients revealed that 62% carried a diagnosis of CAD<sup>8-33</sup> (Table 23-1). This number may actually underestimate the true prevalence of CAD in this population as in clinical practice and in most studies there is no systemic assessment of coronary artery anatomy. In addition, most of these trials excluded patients with a recent MI, angina, or objective evidence of active ischemia. In a study of 136 patients (<75 years old) hospitalized with de novo HF, a review of the clinical, angiographic, and myocardial perfusion imaging data was used to determine that CAD was the primary cause in greater than 50% of cases.<sup>34</sup>

**FIGURE 23-1** Coronary artery disease (CAD) contributes to left ventricular (LV) dysfunction not only during an initial insult (e.g., myocardial infarction) but throughout its progression. In addition, progression of chronic heart failure is associated with ventricular remodeling, activation of neurohormones, and hemodynamic changes.

## PATHOPHYSIOLOGY OF ACUTE HEART FAILURE IN PATIENTS WITH CAD

### Underlying Coronary Artery Disease

Patients hospitalized with acute HF differ from patients with chronic ambulatory HF with respect to prognosis and early management.<sup>43</sup> Patients with CAD who develop acute HF do so with either an ACS or a non-ACS presentation. Although the majority of such patients do not have ACS, there is considerable overlap in these two presentations with respect to clinical characteristics (Table 23-2, A) and potential therapies (Table 23-2, B). However, the approach to the patient with ACS has become more standardized in clinical practice guidelines compared with the acute HF patient with a non-ACS presentation. Myocardial injury is common in both, but in ACS patients it is usually the principal cause of HF, whereas in non-ACS patients myocardial injury may be the result of worsening HF. In these latter patients, cardiac troponin levels are frequently elevated in patients with acute HF, representing myocardial injury. These values typically do not reach the established threshold values for ACS, but are still associated with worse outcomes.<sup>44-49</sup>

Low-level myocardial injury in patients with acute HF and underlying CAD may be the result of the marked hemodynamic and neurohormonal abnormalities that are frequently present in acute HF, but less likely to be present in chronic ambulatory HF. In acute HF, a high LV diastolic pressure can result in subendocardial ischemia. The excessive neurohormonal activation can exacerbate ischemia via increased cardiac contractility and reduced coronary perfusion because of endothelial dysfunction. In addition, patients with acute HF and CAD often have hibernating or stunned myocardium.<sup>50</sup> Together, all of these factors may result in myocardial injury.<sup>52</sup>

Patients with acute HF and a low blood pressure have a much higher mortality compared to patients who are normotensive or hypertensive at the time of admission.<sup>51 and 52</sup> Low systemic blood pressure combined with elevated LV diastolic pressure reduces coronary perfusion, and in this setting, the autoregulation between coronary artery perfusion pressure and coronary vasoactive tone may be lost or impaired in patients with obstructive epicardial CAD. This may contribute to myocardial injury (as reflected by cardiac enzyme elevation) and worse outcomes. This may help to explain why patients with acute HF and underlying CAD have a worse outcome than

those without CAD and have improved outcomes if they have a history of myocardial revascularization.<sup>48,53</sup>

### Acute Coronary Syndromes

Approximately 10% to 20% of patients with ACS have concomitant acute HF and roughly 10% of ACS patients develop HF in-hospital.<sup>54-59</sup> In the EuroHeart Survey II on HF, 42% of all de novo HF cases were due to ACS.<sup>60</sup> Patients with ACS and ST-segment elevation typically have a high degree of myocardial injury. ACS patients with HF but without ST-segment elevation also have significant cardiac enzyme elevation, but a smaller degree of injury.<sup>47</sup> The short-term risk of adverse outcomes in ACS patients with HF is directly proportional to the level of troponin elevation.<sup>61</sup> Most of these patients do not have a history of HF or LVSD.<sup>54,56</sup>

Patients with ACS complicated by HF have markedly increased short- and long-term mortality rates compared with ACS patients without HF.<sup>54-56,61-69</sup> ACS patients who develop HF after the initial presentation have even higher mortality rates.<sup>55,59</sup> The prognosis of ACS complicated by HF is directly related to the Killip class.<sup>55,57,59</sup> Compared with Killip class I patients, patients with an ACS in Killip class II or III HF are four times more likely to die in-hospital.<sup>56,59</sup> The risk goes up to tenfold for patients with cardiogenic shock (Killip class IV). Among ACS patients who recover from transient HF, the majority develop recurrent HF.<sup>6</sup>

## PATHOPHYSIOLOGY OF CHRONIC HEART FAILURE IN PATIENTS WITH CAD AND REDUCED EJECTION FRACTION

HF in the setting of CAD is a heterogeneous condition with several possible factors contributing to clinical manifestations of HF and LVSD and/or diastolic dysfunction. First and foremost, the sequelae of MI, with loss of functioning myocytes, development of myocardial fibrosis, and subsequent LV remodeling, result in chamber dilation and neurohormonal activation that lead to progressive deterioration of the remaining viable myocardium.<sup>70</sup> This is a well-recognized clinical process that can be ameliorated after acute MI by the use of angiotensin-converting enzyme (ACE) inhibitor therapy,  $\beta$ -blocking agents, and myocardial revascularization.<sup>71-74</sup> Second, the majority of patients surviving MI have significant

Coronary artery disease was documented to be present in nearly 65% of patients.

atherosclerotic disease in coronary arteries other than the infarct-related artery.<sup>75</sup> Thus superimposed on the left ventricle with irreversibly damaged myocardium, there is often a considerable degree of jeopardized myocardium served by a stenotic coronary artery either within the infarct zone or remote from the infarcted tissue. This may result in myocardial ischemia/hibernation, contributing to LV dysfunction and the risk of recurrent MI producing further deterioration in LV function or SCD. Finally, endothelial dysfunction, a characteristic feature of atherosclerotic CAD, may also contribute importantly and independently to the progression of LV dysfunction (Figure 23-2).<sup>76</sup>

### Left Ventricular Remodeling (see also Chapter 15)

According to St. John Sutton and Sharpe, LV remodeling is the process by which the left ventricle's size, shape, and function are altered in response to acute and chronic injury or overload, a process that is regulated by mechanical, neurohormonal, and genetic factors (Figure 23-3).<sup>70</sup> The severe

loss of myocardial cells after acute MI results in an abrupt increase in loading conditions that induces a unique pattern of remodeling involving the infarct zone, the infarct border zone, and the remote noninfarcted myocardium.<sup>70</sup> Myocyte necrosis initiates a process of reparative changes, which

**FIGURE 23-2** Progression of coronary artery disease (CAD) leads to decreased contractility, which stimulates neurohormonal activation of chamber remodeling, hypertrophy, and myocyte damage. CAD, Coronary artery disease; MI, myocardial ischemia. (Adapted from Gheorghiade M, Bonow RO. Chronic heart failure in the United States: a manifestation of coronary artery disease. *Circulation* 1998;97:282-289.)

**FIGURE 23-3** Remodeling of left ventricle after ST-elevation myocardial infarction (STEMI). *Left*, Apical STEMI (white zone of left ventricle). Over time, the infarct zone elongates and thins. Progressive remodeling of the left ventricle occurs (*center and right*), ultimately converting the left ventricle from an oval shape to a spherical shape. Pharmacological and catheter-based reperfusion strategies for STEMI have a favorable impact on this process by minimizing the extent of myocardial necrosis (*left*) through prompt restoration of flow in the epicardial infarct vessel. (Modified from McMurray JJV, Pfeffer MA, editors. *Heart failure updates*, London, 2003, Martin Dunitz.)

consist of dilation, hypertrophy, and the formation of collagen scar. This process usually continues into the chronic phase until the heart, strengthened by collagen scarring, offsets the dilating forces. Other factors may influence this process, including the location and transmural extent of the infarct, the extent of myocardial stunning beyond the initial infarction, infarct-related artery patency, and local trophic factors.<sup>70</sup> Three components participate in this process: the myocytes, the extracellular matrix, and the microcirculation. Postinfarction remodeling has been arbitrarily divided into an early phase (within 72 hours) and a late phase (beyond 72 hours). In patients with transmural MI, the early phase involves expansion of the infarct, with thinning and bulging that may result in ventricular rupture, aneurysm, mitral insufficiency, and ventricular tachyarrhythmias. Late remodeling involves the left ventricle globally and is associated morphologically with dilation, hypertrophy, and myocyte hypertrophy (see Figure 23-3).<sup>70</sup> These processes all may contribute to deterioration in contractile function. In summary, LV remodeling consists of ventricular thinning and dilation in the infarct zone, myocyte hypertrophy in the noninfarct zones, fibrosis, and activation of neurohormones. These processes impact the biology of the cardiac myocyte and nonmyocyte components of the myocardium and contribute independently to the progression of HF.<sup>77</sup>

## Myocardial Ischemia

Under basal conditions, episodes of reversible myocardial ischemia caused by a severe coronary artery stenosis superimposed on the left ventricle with depressed systolic function may produce transient worsening of LV function. This exacerbates dyspnea on exertion and fatigue. In many patients, these HF symptoms, stimulated by exercise, represent an anginal equivalent that may occur in the absence of chest pain.

Transient LV dysfunction can aggravate symptoms during stress or spontaneous ischemia in patients with CAD and HF. Ischemia can also produce a rapid and massive increase in the concentration of all three endogenous catecholamines (norepinephrine, epinephrine, dopamine) in the myocardial interstitial fluid, which is mediated by inhibition of neuronal reuptake mechanisms.<sup>78</sup> High myocardial catecholamine concentration may have a deleterious effect on cardiac myocytes.<sup>79-81</sup>

Ischemia may also lead to myocyte apoptosis, which may result in progression of LV dysfunction without a clear ischemic event.<sup>82</sup> This situation also indicates that ischemia from a chronic stenosis can produce substantial myocyte loss in the absence of significant necrosis or fibrosis. Ischemia may also cause an increase in endothelin production that may have a negative effect on LV function.<sup>83</sup> Aggressive medical and surgical interventions designed to ameliorate ischemia appear to have a substantial impact on limiting apoptosis.

## Hibernation/Stunning (see also Chapter 36)

Episodes of transient myocardial ischemia may cause prolonged LVSD that persists after the ischemic insult itself has resolved. This process is termed *stunning*, which is similar to more severe and protracted myocardial stunning that results from coronary occlusion and reperfusion (Figure 23-4, A).<sup>84</sup> Recurrent episodes of myocardial ischemia that produce repetitive myocardial stunning may contribute to overall LV dysfunction and HF symptoms.

Another important mechanism for systolic dysfunction with additive effects on LV performance is myocardial hibernation. Once considered a process in which myocardial contraction is downregulated in response to chronic reduction in myocardial blood supply,<sup>85-87</sup> the current evidence supports the hypothesis that persistent contractile dysfunction in patients with chronic CAD represents a process of programmed disassembly of contractile elements following repeated episodes of reversible ischemia (Figure 23-4, B).<sup>88-92</sup> Thus rather than a “protective” mechanism, hibernation represents a disadvantageous process that, left uncorrected, may lead to apoptosis and myocyte loss, replacement fibrosis, graded and reciprocal changes in  $\alpha$ - and  $\beta$ -adrenergic receptor density, progressive LVSD, and the risk of ventricular arrhythmias (Figure 23-5). This process may affect a substantial number of HF patients. Among patients with HF, CAD, and LVSD, approximately 50% have evidence of viable but dysfunctional myocardium.<sup>93-95</sup>

## Diagnosis

Hibernating myocardium should be suspected in all patients with CAD and chronic LV dysfunction of any degree, regional and global.<sup>95</sup> Up to 50% of patients with CAD and chronic LV dysfunction have significant areas of dysfunctional but viable myocardium.<sup>96</sup> Hibernating myocardium can be determined with the use of imaging techniques that detect myocardial contractile reserve, preserved metabolic activity, or cell membrane integrity within the region of dysfunctional myocardium.<sup>74,97-100</sup> Intact perfusion, cell membrane integrity, and intact mitochondria can be evaluated with single photon emission tomography using thallium-201 and/or technetium-99m labeled tracers. Preserved glucose metabolism can be

## CONSEQUENCES OF ACUTE ISCHEMIA

A

## CONSEQUENCES OF CHRONIC REPETITIVE ISCHEMIA

B

**FIGURE 23-4** Effects of ischemia on left ventricular (LV) function and irreversible injury. The ventriculograms illustrate contractile dysfunction (dashed lines and arrows). **A**, Consequences of acute ischemia. A brief total occlusion (right) or a prolonged partial occlusion (caused by an acute high-grade stenosis, left) leads to acute contractile dysfunction proportional to the reduction in blood flow. Irreversible injury begins after 20 minutes following a total occlusion but is delayed for up to 5 hours following a partial occlusion (or with significant collaterals) caused by short-term hibernation. When reperfusion is established before the onset of irreversible injury, stunned myocardium develops and the time required for recovery of function is proportional to the duration and severity of ischemia. With prolonged ischemia, stunning in viable myocardium coexists with subendocardial infarction and accounts for reversible dysfunction. Brief episodes of ischemia preceding prolonged ischemia elicits protection against infarction (acute preconditioning). **B**, Effects of chronic repetitive ischemia on function distal to a stenosis. As stenosis severity increased, coronary flow reserve decreases and the frequency of reversible ischemia increases. Reversible repetitive ischemia initially leads to chronic preconditioning against infarction and stunning (not shown). Subsequently, there is a gradual progression from contractile dysfunction with normal resting flow (chronically stunned myocardium) to contractile dysfunction with depressed resting flow (hibernating myocardium). This transition is related to the physiological significance of a coronary stenosis and can occur in a time period as short as 1 week or develop chronically in the absence of severe angina. The cellular response during the progression to chronic hibernating myocardium is variable, with some patients exhibiting successful adaptation with little cell death and fibrosis and others developing degenerative changes difficult to distinguish from subendocardial infarction. (From Canty JM. Coronary blood flow and myocardial ischemia. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier.)

assessed by positron emission tomography using F18-fluorodeoxyglucose. Contractile reserve can be unmasked by infusion of low-dose dobutamine during echocardiography. The use of these techniques has been associated with improved survival in patients with chronic HF and significant viability who underwent myocardial revascularization.<sup>97-101</sup>

Cardiac magnetic resonance imaging is also an established technique to assess myocardial viability and the potential for

recovery of LV function.<sup>102-104</sup> Resting cine MRI can be used to assess LV end-diastolic wall thickness. An end-diastolic wall thickness less than 5 to 6 mm is a marker of transmural MI and virtually excludes the presence of viable myocardium. In dysfunctional myocardium with preserved end-diastolic wall thickness (6 mm), detection of contractile reserve during low-dose dobutamine infusion confirms the presence of viable myocardium. Gadolinium-based contrast agents have been

**FIGURE 23-5** Myocyte cellular changes in hibernating myocardium. The increased myocyte loss results in compensatory myocyte cellular hypertrophy in hibernating myocardium. Whereas reticular collagen is regionally increased (about 2%), there is no evidence of infarction. The electron microscopic characteristics of hibernating myocardium demonstrate myofibrillar loss, an increased number of small mitochondria, and increased glycogen content. Although these are markedly different from normal myocardium (sham), biopsies of normal remote, nonischemic segments show similar morphological changes, indicating that these structural abnormalities are not directly related to ischemia nor are they the cause of regional contractile dysfunction. LAD, left anterior descending artery. (From Canty JM, Fallavollita JA. Hibernating myocardium. *J Nucl Cardiol* 2005;12:104.)

used to detect nonviable myocardium because these agents accumulate selectively in areas of scar tissue.<sup>102,103</sup> It should be noted that this technique is extremely sensitive to detect scar tissue (with very high spatial resolution), but the absence of scar tissue does not permit discrimination between normal tissue and hibernating or stunned myocardium.

#### Clinical Implications

The presence of viable but dysfunctional myocardium can be used to predict a favorable response to myocardial revascularization and pharmacological therapy.<sup>101,105,106</sup> The restoration of blood flow with revascularization or treatment with agents that improve endothelial function and blood flow, such as statins and  $\beta$ -blockers, may improve contractility in a hibernating area.<sup>105-108</sup> In contrast, agents like dobutamine and milrinone, especially at high doses, may precipitate myocardial necrosis and are associated with worse long-term outcomes in patients with CAD and HF.<sup>109-112</sup> Hibernating myocardium is associated with global alterations in LV volume and shape, not just impairment of underperfused segments.<sup>99</sup> This explains why myocardial revascularization of hibernating territories can promote reverse remodeling globally.<sup>113</sup>

### Endothelial Dysfunction (see Chapter 17)

Available data suggest that the coronary endothelium plays an important role not only in the control of blood flow and vascular patency but also in the physiological modulation of myocardial structure and function.<sup>114</sup> Thus endothelial dysfunction, an inherent component of the pathophysiology of atherosclerotic CAD, may directly affect ventricular function.<sup>115</sup>

According to Bell and associates,<sup>116</sup> the coronary endothelium has numerous physiological roles including:

- Regulation of vascular tone through the release of mediators such as nitric oxide (NO), prostacyclin, and endothelin
- Maintenance of a permeable barrier to provide for exchange and active transport of substances into the artery wall
- Synthesis and secretion of cytokines and growth factors
- Alterations of lipoproteins in the arterial wall
- Provision of a nonthrombogenic surface and a nonadherence surface for leukocytes
- Maintenance of basement membrane collagen proteoglycans<sup>117</sup>

### Endothelial Vasodilators

The endothelial release of NO relaxes vascular smooth muscle cells in association with activation of guanyl cyclase and increased levels of cyclic glucose monophosphate. NO is the most potent endogenous vasodilator and is responsible for the maintenance of vasovascular tone. NO also inhibits smooth muscle cell proliferation and migration, leukocyte adhesion, and platelet aggregation.<sup>118,119</sup>

### Endothelial Vasoconstrictors

The major endothelin-derived vasoconstrictive substances include angiotensin-II and endothelin. Angiotensin-II is a potent vasoconstrictor that also exerts a variety of effects on vascular structure and function.<sup>120</sup> Studies of angiotensin II indicate the involvement of the renin-angiotensin system in

many aspects of vascular homeostasis. Angiotensin II increases the production of plasminogen activator inhibitor type 1, the primary endogenous inhibitor of tissue plasminogen activator, and promotes vascular growth in addition to stimulating the production of other growth factors.<sup>121</sup> Angiotensin II also enhances platelet aggregation, sensitizes the platelets to the effects of direct platelet agonists, and stimulates the production of endothelin.<sup>122</sup> Endothelin is the most potent endogenous vasoconstrictor yet identified and promotes proliferation of smooth muscle cells and secretion of extracellular matrix, which contribute to the formation of atherosclerotic plaque.<sup>123</sup>

Disordered endothelial function in patients with CAD stimulates vasoconstriction, smooth muscle migration and proliferation, increased lipid deposition in the vessel wall, and possibly coronary thrombosis. This promotes myocardial ischemia, which may further contribute directly or indirectly to progression of LV dysfunction.<sup>115,124-126</sup> The release of endothelin is also increased in failing myocardium.<sup>127</sup> Angiotensin II contributes to the release of endothelin and the excessive degradation of nitric oxide.<sup>125</sup> Taken together, these observations make a case for an interplay between the failing myocardium and the coronary endothelium that potentiates the progression of both CAD and LV dysfunction.

Properties of the normal endothelium serve to relax vascular tone, and inhibit smooth muscle growth, platelet aggregation, and leukocyte adhesion. Many drugs that reduce mortality and reinfarction in patients with CAD have the potential to improve endothelial function, including lipid lowering agents, ACE inhibitors, nonselective  $\beta$ -blockers, and aspirin.<sup>128-131</sup> For example, marked reduction of serum cholesterol is associated with a rapid recovery of endothelial function, improvement of myocardial perfusion, and reduction of myocardial ischemia.<sup>132-138</sup> An improvement in tissue perfusion is an important goal in patients with HF in terms of both the peripheral and the coronary circulation.

In summary, endothelial dysfunction may further reduce blood flow, promote progression of coronary atherosclerosis, and have direct negative effects on the myocardial cells and the interstitium.<sup>139,140</sup>

### Clinical Manifestations

**Reinfarction.** Patients with HF and CAD are at increased risk for reinfarction. An analysis of the SOLVD trial found that patients who experienced MI had an approximately two-fold higher rate of hospitalization for HF and about a four-fold increase in death compared with patients who did not experience MI.<sup>141</sup> Similarly, an analysis of the Survival and Ventricular Enlargement (SAVE) trial found that patients with evidence of a previous MI before enrollment were at significantly greater risk for cardiovascular death, LV enlargement, or both.<sup>142</sup> In clinical trials, the rate of infarction or reinfarction is relatively low, with a fatal MI rate of 3%.<sup>143</sup> However, in one study, more than half of patients with HF and CAD who died suddenly had autopsy evidence of an acute ischemic event (e.g., coronary clot, recent infarct),<sup>40</sup> suggesting that the number of patients with plaque rupture is not accounted for in clinical trials.

**Sudden Cardiac Death.** The risk of SCD after MI has significantly declined in recent years.<sup>144</sup> However, the occurrence of HF post-MI is associated with a markedly increased risk of SCD.<sup>144</sup> In several clinical HF trials, SCD accounted for 20% to 60% of deaths, depending on the severity of HF.<sup>145</sup> In the Metoprolol CR/XL Randomised Intervention Trial in Congestive Heart Failure (MERIT-HF), 64% of patients in NYHA class II who subsequently died had SCD compared with 59% of patients in class III and 33% of patients in class IV.<sup>146</sup> Several factors have been implicated in the high rate of SCD in patients with HF. These include subendocardial ischemia, ventricular hypertrophy, stretching of myocytes, a high sympathetic tone, abnormal baroreceptor responsiveness

**FIGURE 23-6** Relation of acute coronary findings to mode of death and presence of coronary artery disease in the ATLAS trial. Patients with SCD had the highest prevalence of acute coronary findings. (Key: + Indicates presence of CAD; -, absence of). (From Uretsky BF, Thygesen K, Armstrong PW, et al. Acute coronary findings at autopsy in heart failure patients with sudden death: results from the assessment of treatment with lisinopril and survival (ATLAS) trial. *Circulation* 2000;102:611-616.)

lowering the threshold for a malignant arrhythmia, potassium and magnesium depletion, and coronary artery emboli from atrial or LV thrombi.<sup>145</sup> However, CAD probably contributes directly to SCD.<sup>145</sup> Patients with CAD and systolic HF have dilated hearts, large regions of myocardial scar, and obstructive epicardial coronary stenoses. CAD and its major structural consequences (i.e., plaque rupture, thrombosis, and infarction) constitute the most common structural basis of SCD.<sup>147,148</sup>

Uretsky et al reported the relative importance of an acute coronary event as a trigger for SCD in patients with HF who were studied in the Assessment of Treatment with Lisinopril and Survival (ATLAS) trial, which included 3164 patients with moderate to severe systolic HF.<sup>40</sup> There were 1383 deaths (43.7%) during the follow-up period of 3 to 5 years. An autopsy was performed in only 188 patients, and the post-mortem data were available in only 171 patients (12.4% of the total patients who died). Patients who died in this study were older and had both more symptoms and a higher prevalence of CAD than the surviving patients. The patients who died and did not undergo autopsy were similar to those who died and were subjected to autopsy. Acute coronary findings were observed in 54% of the patients with significant CAD who died suddenly (Figure 23-6). The ATLAS study was the first to demonstrate that recent coronary events are frequently unrecognized in patients with moderate to advanced HF symptoms who die suddenly, especially in patients with CAD.

Other studies have documented a high frequency of plaque rupture or coronary thrombosis in patients with CAD who suffered SCD.<sup>147,149</sup> However, it should be noted that these studies reported a much higher incidence of ruptured plaque, ranging from 57% to 81%, than the ATLAS autopsy study.<sup>40,147,149</sup> However, the prevalence of clinical acute coronary findings in the same series ranged from 21% to 41%, which was similar to the ATLAS study.<sup>40</sup> Because the autopsy findings reported in ATLAS were based on routine clinical examinations, it is unlikely that the examinations involved the degree of detail necessary to observe ruptured plaque and small thrombi. Therefore, it is possible that the rate of acute coronary events may have been even higher than reported. This study underlines the importance of strategies to prevent and treat acute coronary events to successfully prevent SCD in patients with HF. For example, in the ATLAS trial, two thirds of patients had CAD but only 40% of this group was taking aspirin.<sup>40</sup>

Among patients with HF who receive an ICD for the primary prevention of SCD, those who receive shocks have a markedly increased short-term risk of death compared with those who do not receive shocks. This risk may be much higher in patients with CAD.<sup>150,151</sup> A recent analysis of the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) revealed that patients with HF due to CAD who received an appropriate ICD shock had a threefold increased risk of mortality compared with patients with HF and a nonischemic cause who received an appropriate ICD shock. This suggests that among patients with HF, those with CAD can develop fundamental alterations in the underlying arrhythmic substrate that predisposes them to SCD.

## CORONARY ARTERY DISEASE AND DIASTOLIC HEART FAILURE

The vast majority of HF trials conducted over the past 30 years have studied patients with LVSD. However, HF with relatively preserved systolic function is present in approximately half of all patients hospitalized with HF.<sup>152-159</sup> Among patients with HF and preserved systolic function, approximately 60% have documented CAD.<sup>156</sup> Over the past two decades, the relative proportion of patients with HF and preserved systolic function has risen steadily relative to those with LVSD.<sup>153</sup> Patients with HF and preserved systolic function tend to be older than those with HF and LVSD. Thus the relative rise in this category of HF is reflective of an aging population. This rise has also corresponded to increased rates of CAD, hypertension, diabetes, and atrial fibrillation in this population. Among patients hospitalized with HF, the early and long-term risk of death is similar for patients with preserved systolic function and LVSD.<sup>154,157-159</sup> However, patients with HF and preserved systolic function are more likely to die from other cardiac comorbidities, including CAD, rather than progressive HF when compared with patients with HF and LVSD.<sup>160,161</sup>

When systolic function is preserved, it is assumed that the majority of these patients have HF signs and symptoms on the basis of abnormal LV diastolic function.<sup>162</sup> A variety of factors predispose to abnormalities in diastolic functional behavior of the left ventricle and lead to elevating filling pressures, impaired forward output, or both, despite normal systolic function.<sup>163</sup> Myocardial ischemia is one of the leading factors. Pulmonary congestion can be caused by reversible episodes of ischemia, which impair LV relaxation and impair LV filling pressure.<sup>164</sup>

The prognosis in patients with HF and preserved systolic function in the presence of CAD may be directly related to the angiographic burden of CAD. O'Connor et al demonstrated that patients with HF and preserved systolic function have a worse 5-year survival if they have left main or 3-vessel CAD versus those with 1- to 2-vessel CAD.<sup>42</sup> Similarly, according to the Coronary Artery Surgery Study (CASS) registry, the 6-year survival rate of patients with normal ejection fraction and HF symptoms was 92% in patients with no CAD, 83% in patients with 1- or 2-vessel CAD, and 68% in patients with 3-vessel disease.<sup>165</sup>

There is a need for reappraisal on whether systolic function is truly normal at the time when HF symptoms are present in patients diagnosed with HF and “normal” systolic function. The majority of studies of this syndrome did not report the timing of the evaluation demonstrating normal systolic function relative to the episodes of HF itself.<sup>166</sup> In other studies, the evaluation was performed days to weeks after the episode.<sup>167</sup> Transient ischemia may cause regional systolic dysfunction, which in many patients was severe and extensive enough to cause a brief but profound reduction in global LV function.<sup>167</sup> The pathophysiological changes in regional and global systolic function form the basis for exercise radionuclide ventriculography and exercise echocardiography as diagnostic

tests for myocardial ischemia due to CAD. It may be that many patients with apparently normal systolic function and HF caused by CAD do not have isolated diastolic dysfunction but instead have transient systolic and diastolic dysfunction at the time when myocardial ischemia induces HF symptoms.

## DIABETES, HEART FAILURE, AND CAD (see also Chapter 24)

In terms of cardiovascular risk, a diagnosis of diabetes is comparable to a diagnosis of CAD.<sup>168,169</sup> The prevalence of documented CAD in diabetic patients has been shown to be as high as 55%, compared with 2% to 4% for the general population.<sup>170</sup> Diabetic patients with a history of MI have a markedly worse prognosis than individuals with only one of these conditions.<sup>168,169</sup> A significant number of patients with HF have diabetes: 23% in the CONSENSUS trial, 25% in SOLVD, 20% in V-HeFT, 20% in ATLAS, 27% in RESOLVD, 42% in the OPTIMIZE-HF registry, and 44% in the ADHERE registry.<sup>9,11,40,171,172-174</sup> Diabetes is an independent risk factor for the development of HF.<sup>175-177</sup> In the Framingham Heart Study, the relative risk for developing HF in diabetic patients was 3.8 for men and 5.5 for women, respectively, compared with nondiabetic patients.<sup>177</sup> The risk of developing HF in diabetic patients has been directly related to glycemic control.<sup>178,179</sup> In the United Kingdom Prospective Diabetic Study (UKPDS), for each 1% increase in glycosylated hemoglobin level, the risk of HF rose by 12%.<sup>179</sup>

The presence of diabetes in patients with HF is associated with substantially higher mortality rates.<sup>180-189</sup> Several studies suggest that the increased risk in diabetic patients with HF compared with nondiabetic patients with HF is limited to individuals with concomitant CAD.<sup>186-189</sup> Diabetic patients with CAD also have worse outcomes following myocardial revascularization.<sup>190</sup> Derangements associated with diabetes, including hyperglycemia, insulin resistance, dyslipidemia, inflammation, and thrombosis, contribute to the development of hypertension, endothelial cell dysfunction, accelerated atherogenesis, and coronary thrombosis.<sup>190,191</sup> In addition, diabetic patients exhibit more complex and diffuse anatomical patterns of CAD, including more lipid-rich plaques and intracoronary thrombi but less compensatory vascular remodeling.<sup>190,192-194</sup>

Diabetes directly contributes to HF in patients with LVSD, diastolic dysfunction, or both.<sup>195,196</sup> The increased mortality in patients with HF in the presence of diabetes has been observed in patients with either LVSD or preserved systolic function.<sup>182</sup> Ventricular dysfunction in patients with HF and diabetes has been termed “diabetic cardiomyopathy” and is the result of the complex interplay between the sympathetic nervous system and the renin-angiotensin-aldosterone system (RAAS), increased levels of circulation cytokines, alterations in heart rate variability, and increased oxidative stress.<sup>197</sup> Chronic hyperglycemia leads to the glycation of collagen and elevated serum levels of advanced glycation end products, which results in increased myocardial stiffness.<sup>198</sup> Pathologically this cardiomyopathy is characterized by myocyte atrophy, interstitial fibrosis, increased periodic acid-Schiff (PAS) positive material, intramyocardial microangiopathy, and depletion of myocardial catecholamines.<sup>199</sup> In diabetic patients with HF and LVSD, myocardial fibrosis and the deposition advanced glycation end products predominate, while in those with HF and preserved systolic function, increased cardiomyocyte resting tension is a more important mechanism.<sup>196</sup>

## Therapeutic Options

Recognition that progression of CAD may contribute importantly to progression of HF, in at least a subset of patients, shifts the focus from medical management designed solely

to reduce neurohormonal activation and alleviate congestive symptoms to a strategy designed to employ aggressive secondary prevention measures. Those efforts to slow the progression of CAD include attention to reducing the risk of acute coronary events by plaque stabilization, reducing ischemia, and enhancing endothelial function. It is noteworthy that the classes of drugs that have shown conclusively to improve survival in HF—ACE inhibitors, angiotensin receptor blockers (ARBs),  $\beta$ -blockers, and aldosterone antagonists, address those factors. The beneficial effects of these drugs may relate as much to their vascular protective effects as to their neurohormonal blocking effects. Patients hospitalized with HF are frequently undertreated for CAD. For example, ACS patients with acute HF are less likely to receive antiplatelet agents,  $\beta$ -blockers, ACE inhibitors, or statins than ACS patients without HF.<sup>42,45,46,51,158</sup> In addition to pharmacological therapy, myocardial revascularization, surgical therapy, and cardiac device therapy may play an important role in the treatment of patients with HF in the setting of CAD.

### Immediate Management of the Hospitalized Patient

The immediate management of acute HF usually occurs in the emergency department.<sup>200</sup> There is considerable overlap in the presentation and management of acute HF patients with CAD and ACS versus CAD and non-ACS (Tables 23-2, A, and 23-2, B). In patients with underlying CAD who are not hypotensive, nitrates may provide a rapid reduction of myocardial ischemia and improve coronary perfusion. In patients with severe pulmonary edema, the combination of high-dose nitrates and low-dose diuretics (vs. low-dose nitrates and high-dose diuretics) led to significantly decreased rates of mechanical ventilation and MI.<sup>201</sup> A regimen for acute HF consisting of lower doses of diuretics has been proposed as a method of preserving renal function. In a large acute HF registry, the use of intravenous nitroglycerin or nesiritide was associated with lower in-hospital mortality compared with treatment with dobutamine or milrinone.<sup>202</sup> However, compared with intravenous nesiritide in acute HF patients, of whom greater than 60% had documented CAD, intravenous nitroglycerin has been associated with less deterioration of renal function and a trend toward less mortality at 30 days.<sup>203-204</sup>

Inotropes may be particularly harmful when used in HF patients with CAD. Experimentally, the use of dobutamine in a model of HF with hibernating myocardium led to increased myocardial necrosis.<sup>205</sup> Hospitalized HF patients with troponin elevation have significantly higher in-hospital mortality when inotropes are used.<sup>49</sup> In the Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure (OPTIME-CHF) trial, use of the phosphodiesterase inhibitor milrinone in patients with CAD was associated with increased postdischarge mortality compared with a placebo.<sup>111</sup> In general, a decrease in coronary perfusion as a result of a decrease in blood pressure and/or an increase in heart rate resulting from inotropes with vasodilator properties, or inotropes used in conjunction with vasodilators, may be particularly deleterious in HF patients with CAD.<sup>112,206</sup>

### Long-term Therapies for the Heart Failure Patient with CAD

**Renin-Angiotensin-Aldosterone System Modulators.** The RAAS regulates sodium balance, fluid volume, and blood pressure, which has a profound impact on HF and CAD (see also Chapter 45).<sup>207</sup> The use of ACE inhibitors or ARBs is strongly indicated in HF patients with LVSD and is also indicated for the secondary prevention of cardiovascular events in all patients with CAD.<sup>208-210</sup>

Endothelial dysfunction plays a fundamental role in many forms of cardiovascular disease and is the final common pathway through which most cardiovascular risk factors

contribute to inflammation and atherosclerosis. Angiotensin II is a powerful vasoconstrictor, and also stimulates smooth muscle cells (hyperplasia), fibroblast proliferation, collagen deposition, inflammation, and thrombosis. All these maladaptations can be mitigated by the use of ACE inhibitors or ARBs.<sup>129,207,211</sup> In the SOLVD and the SAVE trials, the ACE inhibitors enalapril and captopril not only reduced overall mortality in patients with CAD, but also reduced the rate of nonfatal MI and unstable angina.<sup>141,212</sup> In the SAVE trial, a 25% decrease in MI with captopril occurred despite the selection criteria, which excluded patients with residual ischemia who were considered at great risk of reinfarction.<sup>212</sup> The reduction of acute ischemic events would not have been anticipated only on the basis of the hemodynamic or neurohormonal effects of ACE inhibitors. Moreover, in the SOLVD trial, the reduction of unstable angina and MI with enalapril was not evident until more than 6 months after randomization.<sup>141</sup> This suggests that the beneficial effects of enalapril on ischemic events was not due to an immediate effect related to a primary or secondary reduction in LV afterload.

The addition of eplerenone, an aldosterone antagonist, to optimal medical therapy in ACS patients with acute HF and LVSD significantly reduced death and rehospitalization in the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) trial (Figure 23-7).<sup>104</sup> The reduction in death corresponded with a decrease in SCD, which may be due to the inhibition of myocardial fibrosis.<sup>213</sup> Recently, direct renin inhibitors have been added to the armamentarium of RAAS inhibition. These agents effectively suppress angiotensin II and aldosterone levels without the rebound increase in plasma renin activity seen with ACE inhibitors and ARB therapy.<sup>214</sup> Aliskiren, the first commercially available direct renin inhibitor for the treatment of hypertension, is being investigated for use in patients with HF and LVSD in the Aliskiren Trial on Acute Heart Failure Outcomes (ASTRONAUT).

**$\beta$ -Blockers.**  $\beta$ -blockers are effective for the reduction of death and rehospitalization in patients with HF and CAD.<sup>98</sup> The continuation or predischARGE initiation of  $\beta$ -blockers in patients hospitalized with HF is associated with improved medication adherence and an early survival advantage (see also Chapter 46).<sup>215-217</sup> Patients with viable but dysfunctional myocardium derive greater improvement in LV function and remodeling from  $\beta$ -blocker therapy than those without viability.<sup>96,113</sup>

The improvement in survival with  $\beta$ -blockers in the MERIT-HF and CIBIS II trials was more pronounced in patients with HF and documented CAD than in patients with a presumed nonischemic cause.<sup>145,218</sup> However, improvement in survival was slightly more pronounced in patients with presumed nonischemic HF and mild to moderate HF studied in the U.S. Carvedilol Trials and in patients with severe HF patients studied in the Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) Trial.<sup>18,19</sup> These differential effects were minor since the reduction in mortality in each of these four trials was less than 30% and there was a nonsignificant difference in mortality benefit between ischemic and nonischemic patients.<sup>219</sup> In MERIT-HF, mortality was slightly higher in diabetic patients with HF who were treated with metoprolol succinate than in nondiabetic patients with HF, while carvedilol showed similar reductions for diabetic and nondiabetic patients in both the U.S. Carvedilol Trials and COPERNICUS. The benefit of carvedilol in CAD patients was later confirmed in post-MI patients in the CAPRICORN study (Carvedilol Post-Infarct Survival Control in LV Dysfunction).<sup>220</sup> In 1959 patients with a LV ejection fraction of 40% or less (with or without HF symptoms) carvedilol, in addition to ACE inhibition and antiplatelet therapy, reduced the mortality and reinfarction rate by 29%; the risk reduction was similar for diabetic patients (Figure 23-8).<sup>220</sup> The differences observed with  $\beta$ -blockers in outcomes based on the presence

**FIGURE 23-7** Trial using aldosterone antagonists. EPHEUS, Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study; RALES, Randomized Aldactone Evaluation Study; RR, relative risk. (Modified from Pitt B, Zannad F, Remme WJ, et al. The effect of spironolactone on morbidity and mortality in patients with severe heart failure. Randomized aldactone evaluation study investigators. *N Engl J Med* 1999;341:709; and Pitt B, Remme W, Zannad F, et al. Eplerenone, a selective aldosterone blocker, in patients with left ventricular dysfunction after myocardial infarction. *N Engl J Med* 2003;348:1309.)

of CAD in HF patients may be due to cause-related differences in pathophysiological derangements on the  $\beta$ -adrenergic signal transduction pathway.<sup>221</sup> This may also relate to the more severe symptoms of patients enrolled in COPERNICUS, differences in  $\beta_1$ -selectivity versus  $\beta_1$ -nonselectivity, or other pharmacological differences between  $\beta$ -blocking agents, such as  $\alpha$ -blockade, antioxidant effect, and lipophilicity.<sup>222</sup>

**Lipid-lowering Agents.** Statin therapy is strongly recommended in patients with CAD.<sup>223</sup> The benefits of statins may be due to plaque stabilization and improvements in endothelial function. The Cholesterol and Recurrent Events (CARE) trial, which demonstrated beneficial effects of pravastatin in patients with mild elevation of serum cholesterol after MI, prospectively randomized a subset of patients with an ejection fraction between 25% and 40%<sup>224</sup>; these patients had similar characteristics to those entered into post-MI ACE inhibitor trials, such as SAVE.<sup>142</sup> Pravastatin significantly

**FIGURE 23-8** Effect of carvedilol on morbidity and mortality in patient with left ventricular dysfunction after acute myocardial infarction in the CAPRICORN study. (From Dargie HJ. Effect of carvedilol on outcome after myocardial infarction in patients with left-ventricular dysfunction: the CAPRICORN randomised trial. *Lancet* 2001;357:1385-1390).

decreased cardiac events in this subgroup. Similarly, in the Scandinavian Simvastatin Survival Study (4S), simvastatin decreased the development of HF symptoms after MI; among patients who experienced HF, simvastatin decreased mortality from 32% to 25%.<sup>225</sup> Furthermore, in patients with either stable CAD or ACS, the use of high-dose statin therapy is associated with a decreased risk for HF hospitalization compared with low-dose statin therapy.<sup>226, 227</sup>

In unselected HF patients, the use of statins is associated with lower mortality, including the elderly and patients with preserved systolic function.<sup>228-230</sup> However, the Controlled Rosuvastatin Multinational Trial in Heart Failure (CORONA) showed that rosuvastatin therapy in older patients (60 years or older of age) with chronic HF and LVSD did not lead to a decrease in all-cause death (Figure 23-9, A), although there was a reduction in HF hospitalizations.<sup>231</sup> There was also a trend toward fewer coronary events in the patients treated with rosuvastatin. In the Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza Cardiaca Heart Failure (GISSI-HF) trial, the use of rosuvastatin in patients with chronic HF (mean age 68 years, 90% with LVSD, 40% ischemic cause) did not decrease mortality or cardiovascular hospitalization at 4 years (Figure 23-9, B).<sup>232</sup> These data suggest that statin therapy may be important for the prevention of HF and ischemic events in patients with CAD, but may be unable to impact mortality in patients with chronic HF and LVSD.

Fish consumption and dietary supplementation with n-3 polyunsaturated fatty acids (PUFA), in individuals with and without established CAD, is associated with reduced cardiovascular mortality.<sup>176, 233, 234</sup> In a separate GISSI-HF trial, the use of n-3 PUFA in patients with chronic HF (mean age 67 years, 90% with LVSD, 50% ischemic cause) led to a 2% absolute risk reduction in mortality (27% vs. 29% at 4 years,  $P = .041$ ) and a similar reduction in cardiovascular hospitalization.<sup>235</sup> It is suspected that n-3 PUFA may exert their beneficial effect via the reduction of arrhythmic events and not ischemic events. As the use of ICD therapy in this trial was low (7%), the impact of this therapy on patients with chronic HF and LVSD with appropriate indications for ICD therapy is unclear.

**Antiplatelet and Anticoagulation Therapy.** The use of antiplatelet therapy (i.e., aspirin or clopidogrel) is strongly indicated in the presence of CAD for the secondary prevention of cardiovascular events.<sup>236</sup> Dual antiplatelet therapy, clopidogrel added to aspirin, has been shown to be beneficial

**FIGURE 23-9** Effect of rosuvastatin on patients with HF. **A**, Effects of rosuvastatin on all-cause death in older patients (60 years of age) with chronic HF and LVSD in the CORONA study. **B**, Effects of rosuvastatin on all-cause death in patients with chronic HF with depressed and preserved systolic function in the GISSI-HF trial. (Modified from Kjekshus J, Apetrei E, Barrios V, et al. Rosuvastatin in older patients with systolic heart failure. *N Engl J Med* 2007;357:2248-2261; and GISSI-HF Investigators. Effect of rosuvastatin in patients with chronic heart failure. *Lancet* 2008;372:1231-1239.)

in ACS patients for the prevention of recurrent ischemic events and was associated with an 18% reduction in subsequent HF.<sup>237</sup> There is experimental evidence that aspirin inhibits the acute arterial and venous vasodilator response to ACE inhibitors in patients with chronic HF.<sup>238</sup> However, there is no prospective evidence that this potential interaction is clinically relevant. Nevertheless, it may be prudent to limit the combination of aspirin and ACE inhibitor therapy in HF patients to those with established CAD.

LVSD is independently associated with an increased risk of ischemic stroke.<sup>239</sup> The use of oral anticoagulation is strongly indicated in HF patients with atrial fibrillation and patients with confirmed or suspected LV thrombus. However, to date, there is a lack of evidence that the use oral anticoagulation in HF patients without atrial fibrillation has a beneficial effect on cardiovascular events, including embolic stroke.<sup>240, 241</sup>

**Myocardial Revascularization.** The role of surgical management of HF patients with stable coronary artery disease is not certain (see also Chapter 55). To date no randomized clinical trials have evaluated the outcomes of revascularization in patients with advanced ischemic cardiomyopathy. The three major randomized clinical trials that have compared coronary artery bypass graft surgery with medical management, the Veterans Administration Cooperative Study, the European Coronary Surgery Study, and the Coronary Artery Surgery Study, all excluded patients with heart failure or severe LVSD. In the absence of clinical trial data, registries and databases have been used to guide decision making for patients with ischemic cardiomyopathy. For example, a recent report from the Duke database compared coronary artery bypass graft (CABG) surgery versus medical therapy over a 25-year period. Medical therapy was used in 1052 patients and CABG in 339.<sup>72</sup> Unadjusted and adjusted survival (Cox proportional hazards model) strongly favored CABG after 30 days and at 10 years. This analysis included all groups by extent of coronary artery disease, and by different subgroups (Figure 23-10). Adjusted overall survival at 1 year, 5 years, and 10 years was 83% versus 74%; 61% versus 37%; 42% versus 13% for CABG versus medical therapy (all  $P < .0001$ ).

Because the results of registries and databases have generally favored myocardial revascularization over medical therapy, no formal prospective randomized clinical trials

of this therapy were initiated until 2002 when the National Institutes of Health initiated funding for the STICH (Surgical Treatment for Ischemic Heart Failure) trial. Patients who have suffered a large anterior MI often develop HF that may not improve with revascularization alone if this territory has a large transmural scar with LV aneurysm formation. In these patients, surgical LV restoration (with or without concomitant CABG) has been shown to improve LV systolic function and NYHA functional class. The STICH trial is a prospective randomized study that includes 2800 patients randomized from 100 centers. Patients with CAD and LVSD amenable to CABG were randomized to combinations of three different treatment strategies: CABG, surgical ventricular reconstruction (SVR), and intensive medical therapy. The trial is powered to address two primary hypotheses: (1) CABG combined with medical therapy improves long-term survival when compared with medical therapy alone; and (2) SVR provides an additional long-term survival benefit when combined with CABG and medical therapy. The results of the second arm of the study have been reported recently. SVR reduced the end-systolic volume index by 19%, as compared with a reduction of 6% with CABG alone. Cardiac symptoms and exercise tolerance improved from baseline to a similar degree in the two study groups. However, there was no significant difference in a composite of death from any cause and hospitalization for cardiac causes, which was the primary outcome of the trial (Figure 23-11). The results of the STICH trial may indicate that a stricter definition of what constitutes an LV aneurysm may need to be applied in future studies of SVR.<sup>242</sup>

Revascularization may improve outcomes in patients with HF and dysfunctional but viable myocardium. In a meta-analysis of greater than 3000 patients with LVSD, revascularization was associated with markedly decreased yearly mortality (3.2% vs. 16.0%,  $P < .0001$ ) if viability was present.<sup>101</sup> In patients without hibernating myocardium, revascularization did not improve survival. A different retrospective observational study examined the role of myocardial revascularization in approximately 4000 patients with chronic HF.<sup>243</sup> At 1 year, patients who underwent revascularization had substantially reduced mortality (11.8% vs. 21.6%; HR 0.52; 95% CI, 0.47 to 0.58). The survival curves continued to diverge through 7 years of follow-up. Moreover, studies have

**FIGURE 23-10** Subgroup analysis of coronary artery revascularization versus medical therapy in patients with heart failure. Hazard ratios (95% confidence interval) for mortality for a number of baseline characteristics all favored CABG. shown that outcomes in patients with HF in the setting of an ACS are improved by a strategy of early myocardial revascularization.<sup>244</sup> This includes patients with and without ST-segment elevation and those in cardiogenic shock.<sup>245</sup> Despite this, patients with ACS complicated by HF are less likely to undergo revascularization than ACS patients without HF.<sup>6,244</sup> Non-ACS patients hospitalized with acute HF have improved early survival if they have a history of myocardial revascularization, although this a retrospective finding.<sup>47,53</sup> This relationship has been observed in acute HF patients with LVSD or preserved systolic function (see Figure 23-11). These data generate the hypothesis that early revascularization will be beneficial in acute HF patients with ischemia due to CAD. A management strategy for the acute HF failure based on the presence, extent, and severity of CAD could help

identify appropriate candidates for optimal medical therapy for CAD and, when indicated, myocardial revascularization (Figure 23-12). The performance of in-hospital angiography in patients with acute HF and CAD is associated with an increased use of aspirin, statins,  $\beta$ -blockers, ACE inhibitors, and myocardial revascularization and improved postdischarge outcomes.<sup>246</sup>

### Cardiac Device and Mitral Valve Therapy

Patients with HF and an LV ejection fraction of  $\leq 35\%$  should be strongly considered for ICD implantation.<sup>247</sup> In addition, the presence of electrical dyssynchrony (QRS complex  $> 120$  ms) and/or mechanical LV dyssynchrony (as assessed by echocardiographic techniques) is another important therapeutic target in a select group of HF patients with LVSD. The use of cardiac resynchronization therapy in these patients can improve symptoms and prolong survival.<sup>248</sup>

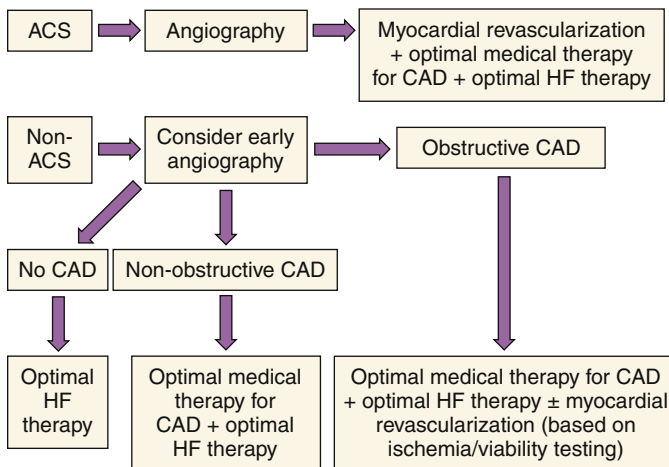

HF accompanied by mitral regurgitation is associated with worse outcomes, particularly among patients with moderate to severe regurgitation.<sup>249</sup> Advancements in surgical mitral valve repair techniques and the emergence of percutaneous mitral valve procedures to reduce mitral regurgitation are promising to play a role in the future management of HF patients.<sup>250-255</sup>

### CONCLUSIONS

The progression of LV dysfunction, worsening of HF, and death in many patients with CAD may be related to the progressive nature of CAD, in addition to the neurohormonal mechanisms that exacerbates myocardial dysfunction. This progression does not require a discrete coronary event such as an acute MI. Myocardial ischemia or hibernation (or both) may contribute to symptoms of HF. In addition, myocardial hibernation appears to be an unstable process that may progress with time to myocyte loss, apoptosis, and replacement fibrosis, leading to more LV dysfunction. As previously noted, endothelial dysfunction may also lead to progression of myocardial dysfunction. Measures specifically targeting reduction in the risk of subacute ischemic events and improvement in

endothelial function may be important in blunting the progression of HF and in improving prognosis. If mortality from HF is to be reduced, CAD must be recognized as a leading cause of HF in the United States. Although some patients may be candidates for myocardial revascularization or surgical and device therapy to improve LV function, all patients are candidates for aggressive secondary prevention strategies designed to reduce progression of CAD.

# Heart Failure as a Consequence of Dilated Cardiomyopathy

Biykem Bozkurt

## DEFINITION

The term “dilated cardiomyopathy” (DCM) refers to a spectrum of heterogeneous myocardial disorders (Table 24-1) that are characterized by ventricular dilation and depressed myocardial contractility in the absence of abnormal loading conditions (such as hypertension or valvular disease) or ischemic heart disease sufficient to cause global systolic impairment.<sup>1</sup> The dilated cardiomyopathies constitute the largest group of myopathic

disorders that are responsible for systolic heart failure. Indeed, more than 75 specific diseases can produce a dilated cardiomyopathic phenotype. Thus DCM can be envisioned as the final common pathway for a myriad of cardiac disorders that either damage the heart muscle or, alternatively, disrupt the ability of the myocardium to generate force and subsequently cause chamber dilation.

In clinical practice and recent multicenter trials in heart failure, the cause of heart failure has often been categorized into two categories: ischemic and nonischemic cardiomyopathy and the term “DCM” has been interchangeably used with “nonischemic cardiomyopathy.” Though this approach may be practical, it has certain drawbacks. It fails to recognize that the term “nonischemic cardiomyopathy” may include cardiomyopathies due to volume or pressure overload—such as hypertension or valvular heart disease—which are not conventionally accepted under the definition of DCM.<sup>1</sup>

## EPIDEMIOLOGY OF DILATED CARDIOMYOPATHY

The reported incidence of DCM varies annually about 5 to 8 cases per 100,000 of the population. The true incidence may be underestimated due to underreporting or underdetection of asymptomatic cases of DCM, which may occur in as many as 50% to 60% of heart failure patients. In most multicenter, randomized trials in heart failure, approximately 30% to 40% of the enrolled patients have nonischemic dilated cardiomyopathy.<sup>2,3</sup> According to the Acute Decompensated Heart Failure National Registry (ADHERE), one of the largest databases on acute heart failure, 47% of the patients admitted to the hospital with heart failure have nonischemic cardiomyopathy.<sup>4</sup> The age-adjusted prevalence of DCM in the United States averages 36 cases per 100,000 population and DCM accounts for 10,000 deaths annually.<sup>5</sup>

Compared with whites, African Americans have almost a threefold increase in risk for developing DCM. This increased risk for developing DCM in African Americans is not explained by differences in hypertension, cigarette smoking, alcohol use, or socioeconomic factors.<sup>6</sup> Moreover, African Americans have approximately a 1.5- to 2.0-fold higher risk of dying from DCM when compared with age-matched whites with DCM. While the reason(s) for these differences are not known, there are several potential explanations, including differences in the genetic predisposition, the cause of heart failure, the number of risk factors for development of heart failure, the rate of progression of heart failure, access to medical care and/or differences in response to therapy. Recent data from the second Vasodilator-Heart Failure Trial (V-HeFT II),<sup>7</sup> Beta-Blocker Evaluation of Survival Trial,<sup>8</sup> and Studies of Left Ventricular Dysfunction (SOLVD)<sup>9</sup> suggest that African American patients with heart failure may not benefit from commonly used doses of currently recommended therapies to the same extent

as White patients, although unanimity of opinion does not exist with regard to this issue.<sup>10</sup>

In general, heart failure is more common in men than women (see also Chapters 22 and 49). Epidemiological data suggesting sex-related differences in the occurrence and prognosis of heart failure are conflicting and may be confounded by differing causes of heart failure. The overall effect of female gender on the prognosis of heart failure is not clear at this time, in large measure because many of the early clinical trials in heart failure have been comprised predominantly of male subjects. Women with heart failure in the Framingham Heart Study (even after controlling for age and cause of heart failure)<sup>11</sup> and women in the National Health and Nutrition Examination Survey-I (NHANES-I)<sup>12</sup> had improved survival compared with men. Studies of Left Ventricular Dysfunction (SOLVD), in which only 15% of the patients were women, reported no difference in gender-related survival.<sup>13</sup> However, the SOLVD registry, which included approximately 20% female patients, suggested that women had significantly higher annual risk of heart failure–related mortality and higher rates of hospitalization than age-matched male subjects.<sup>14</sup> Analyses from MERIT-HF<sup>15</sup> and CIBIS-II<sup>16</sup>  $\beta$ -blocker treatment trials in heart failure suggest that female sex may be a significant independent predictor of survival in patients with heart failure, independent of ischemic or nonischemic cause. One of the challenges in defining gender-specific causes and prognostic factors in dilated cardiomyopathy is that hypertension, which represents the major and strongest risk factor for development of heart failure in women, has been categorized under “nonischemic cardiomyopathy” in most large-scale clinical trials. In the Framingham Heart Study, hypertension was the cause of heart failure in 59% of women.<sup>17</sup> There aren’t many trials reporting specific causes of nonischemic cardiomyopathy in women; therefore, the “true” incidence of dilated cardiomyopathy in women, independent of hypertension is not well known. One of these few studies was the EuroHeart Failure Survey II (EHFS), in which women had less incidence of dilated cardiomyopathy compared with men.<sup>18</sup>

<b>Physiological Agents</b>
Tachycardia Heat stroke Hypothermia Radiation
<b>Autoimmune Disorders</b>

Further studies will be helpful to define the role of gender on the development and prognosis of DCM.

Advancing age is a risk factor for mortality in heart failure. As reported in the SOLVD registry, the risk of death at 1 year for a person over the age of 64 years with heart failure was 1.5 times greater than for subjects who were less than 64 years

of age.<sup>14</sup> Advancing age has been reported as an independent risk factor for mortality in DCM in several studies.<sup>19</sup> Indeed, Sugrue et al reported the relative risk of dying from DCM increases by 0.59 with every 10 years of increase in age.<sup>20</sup> Interestingly, though the number of hospitalizations for heart failure continues to increase among the elderly, with advances in the pharmacological and device treatment, the prognosis of heart failure and DCM has significantly improved over the past 20 years.<sup>21</sup>

The prevalence, cause, and prognosis of dilated cardiomyopathy can differ according to the geographical location and sociodemographics of the affected populations. For example, in Western developed countries, dilated nonischemic cardiomyopathy accounts for approximately 30% to 40% of the heart failure population, of which idiopathic cardiomyopathy is the most frequent cause. The prevalence of DCM in Japan appears to be about half, and in Africa and Latin America approximately double that of the Western populations.<sup>22</sup> As populations go through epidemiological, socioeconomic transitions, and health care modifications, the features of DCM will continue to change. Failure of treatment and eradication of AIDS globally and especially in Africa, rising prevalence of ethanol or substance abuse in Western countries, the development of obesity, new metabolic and dietary trends in North America, and the success in treatment of protozoal diseases in Latin America will continue to play a dynamic role in the epidemiology of DCM.

## NATURAL HISTORY OF DILATED CARDIOMYOPATHY

The natural history of DCM is not well established for two reasons: first, as noted at the outset, DCM represents a heterogeneous spectrum of myocardial disorders that may each progress at different rates,<sup>23</sup> and second, the onset of the disease may be insidious, particularly in the case of familial and/or idiopathic dilated cardiomyopathies. Indeed, approximately 4% to 13% of the patients with DCM will have asymptomatic left ventricular (LV) dysfunction and LV dilation. For these patients the overall prognosis is unclear. However, once DCM patients become symptomatic, the available evidence suggests that the prognosis is relatively poor, with 25% mortality at 1 year and 50% mortality at 5 years (Figure 24-1).<sup>19</sup> The cause of death appears to be primarily pump failure in approximately 70% of patients with DCM, whereas sudden cardiac death accounts for approximately 30% of all deaths in patients with DCM. However, it should be recognized that many of the natural history studies of DCM were performed before angiotensin-converting enzyme (ACE) inhibitors and  $\beta$ -blockers were routinely used. More recent studies suggest that the prognosis for patients with DCM and mild LV dilation may be more favorable, perhaps reflecting earlier diagnosis and better treatment.<sup>20</sup> Furthermore, it should be recognized that approximately 25% of DCM patients with the recent onset of symptoms of heart failure will improve spontaneously, including patients who have been referred for cardiac transplantation.<sup>24</sup> This statement notwithstanding, patients with symptoms lasting more than 3 months who have severe clinical decompensation generally have less chance of recovery.<sup>24</sup>

As shown in Box 24-1, there are a number of other parameters that predict a poor prognosis in patients with DCM, including left and right ventricular enlargement, left and right ventricular ejection fraction, persistent S<sub>3</sub> gallop, right-sided heart failure, elevated LV filling pressures, moderate to severe mitral regurgitation, pulmonary hypertension, ECG findings of first- or second-degree atrioventricular block, left bundle branch block or marked intraventricular conduction delay, recurrent ventricular tachycardia, reduced heart rate variability, late potentials of QRS in signal average EKG, myocytolysis

**FIGURE 24-1** Survival of patients with idiopathic dilated cardiomyopathy in seven published series (A to G). n = number of patients enrolled. To identify each specific series, please refer to the article by Dec and Fuster.<sup>26</sup> (Dec GW, Fuster V. Idiopathic dilated cardiomyopathy. *N Engl J Med* 1994;331:1564-1575, reproduced with permission from the *New England Journal of Medicine*.)

### BOX 24-1 Factors Predicting a Poor Prognosis in Patients with Dilated Cardiomyopathy

- Left ventricular enlargement
- Right ventricular enlargement
- Left and right ventricular ejection fraction
- Elevated LV filling pressures
- Persistent S<sub>3</sub> gallop
- Right-sided heart failure
- Pulmonary hypertension
- Moderate to severe mitral regurgitation
- ECG findings: first- or second-degree atrioventricular block or LBBB
- Recurrent ventricular tachycardia
- Reduced heart rate variability
- Late potentials of QRS in signal average EKG
- Myocytolysis on endomyocardial biopsy
- Elevated levels of neurohormones (BNP, NE, PRA, and ET-1)
- Elevated levels of cytokines (TNF- $\alpha$  and IL-6)
- Elevation of serum CK/MB, troponin T, troponin I levels
- Peak oxygen consumption <10-12 mL/kg/min
- Reduced contractile response with dobutamine
- Serum sodium <137 mmol/L
- Advanced New York Heart Association class
- Advanced age (>64 years)

on endomyocardial biopsy, elevated levels of neurohormones (norepinephrine, plasma renin activity, atrial natriuretic peptide, brain natriuretic peptide, and endothelin-1), elevated levels of cytokines (tumor necrosis factor  $\alpha$  and interleukin-6), persistently elevated markers of myocardial cell death (elevation of serum troponin T levels, an increased ratio of creatine kinase MB<sub>2</sub>/MB<sub>1</sub> peak oxygen consumption less than 10 to 12 mL/kg/min, serum sodium less than 137 mmol/L, New York Heart Association class rating, age older than 64 years, and reduced contractile response with dobutamine. Concomitant renal or hepatic dysfunction may limit the use of optimal diuretics or ACE inhibitors and therefore may have an impact on prognosis that is not easily appreciated. Finally, it should be emphasized that comorbid conditions, such as

diabetes and hypertension, increase the risk of developing heart failure approximately fivefold.

## Ischemic Versus Dilated Cardiomyopathy

In general practice and clinical research trials, the term “ischemic cardiomyopathy” is defined as cardiomyopathy due to ischemic heart disease. The classification of cardiomyopathies proposed by the WHO/ISFC Task Force in 1995,<sup>1</sup> however, defines ischemic cardiomyopathy as “a dilated cardiomyopathy with impaired contractile performance not explained by the extent of coronary disease or ischemic damage” reserved for the remodeling process of the noninfarcted myocardium. In this chapter, we will use the term “ischemic cardiomyopathy” defined as cardiomyopathy due to ischemic heart disease rather than the WHO/ISFC Task Force definition.

The existing clinical studies suggest that patients with idiopathic dilated cardiomyopathy have a lower total mortality.<sup>25</sup> The risk of sudden cardiac death, however, appears to be relatively higher in patients with DCM in some studies.<sup>25</sup> The differential treatment benefit seen in DCM patients compared with patients with ischemic cardiomyopathy that has been observed in several randomized clinical trials such as with digoxin<sup>26</sup> or amiodarone<sup>27</sup> suggest that there may be therapeutic differences between ischemic and nonischemic heart failure. Similar earlier reports of survival difference with  $\beta$ -blockers<sup>28</sup> or amlodipine<sup>29</sup> in patients with dilated but not ischemic cardiomyopathy, have not been reproduced in subsequent large-scale randomized trials,<sup>2,28</sup> in which the benefit was similar in both the ischemic and nonischemic heart failure patients. This has raised the question whether there truly is a difference in response to treatment according to the cause of heart failure. On the other hand, the absence of a rigorous definition of “nonischemic heart failure” in many studies may account for this discrepancy and make interpretation of the results difficult. Further studies to clarify the effects of the cause of heart failure could be particularly important to achieve further treatment benefit over and above the conventional treatment strategies that target heart failure as a single disease entity.

## PATHOPHYSIOLOGY

Dilated cardiomyopathy may be viewed as a progressive disorder initiated after an “index event” that either damages the heart muscle, with a resultant loss of functioning cardiac myocytes, or alternatively disrupts the ability of the myocardium to generate force, thereby preventing the heart from contracting normally. This index event may have an abrupt onset, as in the case of acute exposure to toxins, or it may have a gradual or insidious onset, as in the case hemodynamic pressure or volume overloading, or it may be hereditary, as in the case of many of the familial cardiomyopathies. Regardless of the nature of the inciting event, the feature that is common to each of these index events is that they all, in some manner, produce a decline in pumping capacity of the heart. The anatomic and pathophysiological abnormalities that occur in LV remodeling are discussed in Chapter 15. Patients with dilated cardiomyopathy generally have dilation of all four chambers of the heart (Figure 24-2). Despite the fact that there is thinning of the LV wall in patients with DCM, there is massive hypertrophy at the level of the intact heart, and at the level of the cardiac myocyte, which has a characteristic elongated appearance that is observed in myocytes obtained from hearts subjected to chronic volume overload (Figure 24-3). The coronary arteries are usually normal in DCM, although it should be emphasized the end-stage “ischemic cardiomyopathies” may also have a dilated phenotype. The cardiac valves are anatomically normal; however, there is usually tricuspid and mitral annular dilation due to cavity enlargement,

**FIGURE 24-2** Pathology of normal heart (*left*) and a dilated cardiomyopathic ventricle (*right*). The dilated cardiomyopathic ventricle is characterized by enlargement of all four cardiac chambers, and a more spherical shape, in comparison to the normal ventricle. (From Kasper EK, Hruban RH, Baughman KL. Idiopathic dilated cardiomyopathy. In Abelman WH, editor. *Atlas of heart diseases: cardiomyopathies, myocarditis and pericardial disease*, Philadelphia, 1995, Current Medicine, reproduced with permission from Current Medicine.)

**FIGURE 24-3** Cardiac myocyte structure (*top*) in normal myocardium and in dilated cardiomyopathy (*bottom*). Cardiac myocytes isolated from myocardium from patients with DCM have an elongated shape as the result of the sarcomeres being formed in series. (From Gerdes AM, Kellerman SE, Moore JA, et al. Structural remodeling of cardiac myocytes in patients with ischemic cardiomyopathy. *Circulation* 1992;86:426-430, reproduced with permission from Lippincott Williams & Wilkins.)

distortion of subvalvular apparatus, and stretching of the papillary muscles giving rise to valvular regurgitation. Intracavitary thrombi are common usually in the ventricular apex.

## Myocardial Diseases Presenting as Dilated Cardiomyopathy

As shown in **Figure 24-4**, the most common causes of DCM are idiopathic, alcoholic/toxic, inflammatory, familial, and miscellaneous other (inflammatory noninfectious, acquired, metabolic, and nutritional causes). However, it should be recognized that the exact prevalence of the various forms of dilated cardiomyopathy will vary based on the demographics of the patient population. In the section that follows, we will review the various specific causes that lead to the development of DCM.

### Idiopathic Dilated Cardiomyopathy

Although the term “idiopathic dilated cardiomyopathy” has become synonymous with that of dilated cardiomyopathy in some heart failure parlance, the term “idiopathic” was

**FIGURE 24-4** Causes of dilated cardiomyopathy. As shown, the most frequent causes of DCM are: idiopathic dilated cardiomyopathy; familial cardiomyopathy; alcoholic/toxic cardiomyopathy; viral cardiomyopathy; and miscellaneous other (inflammatory noninfections, acquired, metabolic, and nutritional causes).

originally intended to characterize the subset of DCM patients in whom no known etiological cause for ventricular dilation and depressed myocardial contractility was apparent. However, with increasing sophistication in diagnostic testing, clinicians have become aware that many cases of so-called idiopathic dilated cardiomyopathy may occur as the result of inherited and/or spontaneous mutations of genes that regulate cardiac structure and/or function, such as the genes for cytoskeletal proteins, or as a consequence of undiagnosed hypertension, autoimmune diseases, viral illness, or toxin exposure. Nonetheless, in the context of the present chapter we use the terminology of idiopathic dilated cardiomyopathy to refer to those patients with DCM whose etiological cause remains unknown. As shown in **Figure 24-4**, idiopathic dilated cardiomyopathy represents the largest subset of patients with DCM; however, as alluded to previously, it is likely that the proportion of patients with idiopathic dilated cardiomyopathy will diminish with increased sophistication in diagnostic testing.

### Familial Cardiomyopathy

There is growing evidence that many cases of previously diagnosed “idiopathic” dilated cardiomyopathies have a genetic basis. It is estimated that at least 20% to 30% of dilated cardiomyopathy cases are familial. This topic is discussed in detail in Chapter 27.

### Alcoholic/Toxic Cardiomyopathy

**Alcoholic Cardiomyopathy.** Chronic alcoholism is one of the most important causes of dilated cardiomyopathy in the Western world.<sup>30</sup> It is estimated that two thirds of the adult population use alcohol to some extent and more than 10% are heavy users. In the United States, in both sexes and all races, long-term heavy alcohol consumption (of any beverage type) has been quoted as the leading cause of a nonischemic, dilated cardiomyopathy by some investigators.<sup>30</sup> A large proportion of chronic alcoholics demonstrate impairment of cardiac function. The clinical diagnosis of alcoholic cardiomyopathy can be made when biventricular dysfunction and dilation are persistently observed in a heavy drinker, in the absence of other known causes for myocardial disease. Thus the diagnosis of alcoholic cardiomyopathy remains a diagnosis of exclusion. The prevalence of alcoholic cardiomyopathy is variable and ranges from 23% to 40%. Alcoholic cardiomyopathy most commonly occurs in men 30 to 55 years of age who have been heavy consumers of alcohol for more than 10 years. Women represent approximately 14% of the alcoholic cardiomyopathy cases but women may be more vulnerable to the development of alcohol-related cardiomyopathy, since it has been reported that alcoholic cardiomyopathy develops in women with a less total lifetime exposure to alcohol compared with men.<sup>30</sup> In all races, death rates due to alcoholic heart muscle disease are greater in men compared with women, and are greater in

African American men and women compared with white men and women with alcoholic cardiomyopathy.<sup>30</sup> Even before the clinically overt heart failure, LV contractile dysfunction can be demonstrated in alcoholics. Although chronic alcoholic liver disease and heart failure usually are not observed clinically in the same patient, cirrhotic patients may have asymptomatic LV dysfunction, in which case atrial fibrillation is usually the initial presenting manifestation of cardiac dysfunction. The point at which these abnormalities appear during the course of an individual's lifetime of drinking, such that the abnormalities can be called a dilated cardiomyopathy, is not well established and is highly individualized.

The risk of developing alcoholic cardiomyopathy appears to be related to both the mean daily alcohol intake and the duration of drinking. In general, alcoholic patients consuming greater than 90 g of alcohol a day (approximately seven to eight standard drinks per day) for more than 5 years are at risk for the development of asymptomatic alcoholic cardiomyopathy. On the other hand, mild to moderate alcohol consumption has recently been reported to be protective against development of heart failure in the general population. According to the Framingham Heart Study, moderate alcohol consumption is not associated with increased risk for congestive heart failure, and in fact appears to be protective against development of congestive heart failure.<sup>31</sup> Similarly, in a prospective cohort study of elderly persons, moderate alcohol consumption was associated with a decreasing risk of heart failure.<sup>32</sup> These paradoxical findings (i.e., alcohol may be protective against development of heart failure in certain populations when used in moderation, but detrimental in others, especially when used in excess over longer periods of time) suggest that duration of exposure and individual genetic susceptibility play an important role in pathogenesis. Persistent DCM develops in only 1% to 2% of chronic drinkers, and the role of genetic predisposition, or the presence of synergistic cardiovascular factors such as hypertension or arrhythmias in the development of alcohol-related cardiomyopathy are not clear at the present time.

Studies in experimental animals have demonstrated that both acute and chronic ethanol administration impairs cardiac contractility. Alcohol results in acute and chronic depression of myocardial contractility even when ingested by normal individuals in quantities consumed during social drinking.<sup>33</sup> Compensatory mechanisms such as vasodilation or sympathetic stimulation may mask the direct acute myocardial depressant effects of alcohol. Despite the known deleterious effects of alcohol, it has been difficult to produce heart failure in animal models in which ethanol has been administered. Thus the direct causal relationship between alcohol consumption and the development of cardiomyopathy has not been rigorously demonstrated in experimental models, despite the long-recognized clinical relationship between alcohol consumption and the development of DCM. The pathophysiology and progression of alcoholic cardiomyopathy are complex and involve changes in many aspects of myocyte function. The potential mechanisms that have been invoked to explain the depressed myocardial function include the direct toxic effects of alcohol on striated muscle, since most alcoholics have manifestations of skeletal myopathy and cardiomyopathy. Shifts in the relative expression of the contractile proteins  $\alpha$ -myosin heavy chain to  $\beta$ -MHC have been reported in animal models after exposure to ethanol.<sup>30</sup> Alcohol and its metabolite acetaldehyde can also cause alterations in cellular calcium, magnesium, or phosphate homeostasis. The toxic effects of acetaldehyde or the formation of fatty acid ethyl esters may also impair mitochondrial oxidative phosphorylation. In acute ethanol toxicity free radical damage and/or ischemia may occur, possibly due to increased xanthine oxidase activity or  $\beta$ -adrenergic stimulation, respectively. In addition, ethanol and its metabolites interfere with numerous membrane and cellular functions such as transport

**FIGURE 24-5** Electron microscopy of cardiomyocytes of patients with alcoholic cardiomyopathy revealing the presence of nuclei with mitochondria accumulated in their core, associated with chromatin displacement to periphery of the nucleus. (From Bakeeva LE, Skulachev VP, Sudarikova YV, et al. Mitochondria enter the nucleus [one further problem in chronic alcoholism]. *Biochemistry (Mosc)* 2001;66(12):1335-1341, reproduced with permission from *Biochemistry*.)

and binding of calcium, mitochondrial respiration, lipid metabolism, myocardial protein synthesis, signal transduction, and excitation contraction coupling.<sup>34</sup> Both autopsy and endomyocardial biopsy specimens from alcoholic cardiomyopathy patients reveal marked mitochondrial swelling, with fragmentation of cristae, swelling of endoplasmic reticulum, entrance of mitochondria into the nucleus potentially promoting attack of mitochondria by nuclear proteins and the attack of nuclear DNA by proteins of the mitochondrial intermembrane space,<sup>35</sup> cytoskeletal disorganization, and destruction of myofibrils (Figure 24-5). Several studies suggest that heavy drinking alters both lymphocyte and granulocyte production and function, raising the possibility that myocardial damage secondary to prolonged alcohol consumption might initiate autoreactive mechanisms comparable to those observed in viral or idiopathic myocarditis. The point at which the changes in mitochondrial, sarcoplasmic reticulum, contractile protein, and calcium homeostasis culminate in intrinsic cell dysfunction is incompletely understood. There are several early reports that support the role for myocyte loss as a final mechanism underlying alcohol-induced cardiac dysfunction. Application of insulin-like growth factor (IGF)-1 has been reported to attenuate the apoptotic effects of ethanol in primary neonatal myocyte cell cultures.<sup>30</sup>

Recent reports suggest that certain genetic traits influence the occurrence, pathogenesis, and progression of alcoholic cardiomyopathy, which may explain interindividual variations in the sensitivity of the myocardium to alcohol-induced myocardial damage. In addition, nutritional deficiencies, commonly thiamine deficiency, may play an additive role to the direct myocardial damage of ethanol. Thus the cardiomyopathy that develops following chronic alcohol consumption may be multifactorial in origin.

The management of patients with alcohol cardiomyopathy begins with total abstinence from alcohol, in addition to the conventional management of heart failure, as described later. There are currently no studies of specific pharmacotherapies in patients with alcoholic cardiomyopathy other than the standard therapy of heart failure; however, there are numerous reports that detail the reversibility of depressed LV dysfunction after the cessation of drinking.<sup>36</sup> Many heart failure programs limit alcoholic beverage consumption to no more than alcoholic beverage serving daily for all patients with LV dysfunction, regardless of the cause being alcohol related or not.<sup>37</sup> Even if the depressed LV function does not normalize completely, the symptoms and signs of congestive heart failure improve after abstinence.<sup>36</sup> However, the overall prognosis remains poor, with a mortality of 40% to 50% within 3 to 6 years, if the patient is not abstinent.<sup>30</sup> Survival is significantly lower for patients who continue to drink compared with patients with idiopathic DCM or alcoholic cardiomyopathy patients who abstain.<sup>30</sup>

**Cocaine Cardiomyopathy.** Long-term abuse of cocaine, a drug which causes postsynaptic nervous system norepinephrine reuptake blockade and possible presynaptic release of dopamine and norepinephrine, may eventuate in dilated cardiomyopathy even without presence of coronary artery disease, vasculitis, or regional myocardial injury. This has been termed as “cocaine-related cardiomyopathy” and perhaps reflects the direct toxicity of the cocaine on the myocardium. Depressed LV function has been reported in 4% to 9% of asymptomatic cocaine abusers.<sup>38</sup> Similarly, Om et al reported 18% of cocaine abusers who underwent cardiac catheterization had normal coronary arteries with low ejection fraction and global hypokinesia.<sup>39</sup>

The cardiovascular evaluation of a patient with cocaine abuse usually reflect the following: The electrocardiogram may reveal increased QRS voltage, early repolarization, ischemic or nonspecific ST-T changes, or pathological Q waves. Episodes of ST elevation may be seen during Holter monitoring. An echocardiogram usually reveals LV hypertrophy. Segmental wall motion abnormalities usually suggest myocardial injury; however, as mentioned previously, approximately 18% of patients with cocaine abuse manifest global hypokinesia and depressed myocardial function. Cardiac catheterization in these patients may reveal normal coronaries or mild coronary artery disease not significant enough to explain the extent of myocardial dysfunction. However, accelerated coronary atherosclerosis, coronary vasculitis, coronary spasm, or coronary thrombosis are perhaps more common findings in cocaine-related heart disease.

Cocaine may produce LV dysfunction through its direct toxic effects on the myocardium by provoking coronary arterial spasm (and hence myocardial ischemia), and by causing increased release of catecholamines, which may be directly toxic to cardiac myocytes. These effects will decrease myocardial oxygen supply and may increase demand if heart rate and blood pressure rise. The vasoactive effects of cocaine are further complicated with enhanced platelet aggregation, anticardiolipin antibody formation, and endothelial release of potent vasoconstrictors such as endothelin-1. Upregulation of tissue plasminogen activator inhibitors, increased platelet aggregation, and decreased fibrinolysis by cocaine predispose to coronary thrombosis and/or microvascular disease.<sup>38</sup> Myocarditis with inflammatory lymphocytes and eosinophils has also been reported in 20% of patients dying of natural or homicidal causes in whom cocaine was detected, raising the possibility of hypersensitivity myocarditis due to cocaine or associated contaminants.<sup>40</sup> Alternatively, the myocarditis may occur directly in response to the necrosis that is caused by cocaine. Scattered foci of myocyte necrosis, contraction band necrosis, and foci of myocyte fibrosis have been reported in patients with cocaine abuse. Additionally, experimental

studies and clinical case reports suggest that cocaine may also cause lethal arrhythmias. Cocaine prolongs repolarization by a depressant effect on potassium current and may generate early after depolarizations.<sup>38</sup>

Other than abstinence, very little is known about the treatment of cocaine-induced cardiac dysfunction. Indeed, there are case reports of reversibility of cardiac function after cessation of drug use. In patients who develop cardiomyopathy, the traditional therapy for LV dysfunction is appropriate. Given that some of the toxicity of cocaine is caused by catecholamine excess and/or myocardial ischemia, the use of  $\beta$ -adrenergic blocking agents appeared to be a logical treatment, both in terms of preventing further disease progression, and for treating the ventricular arrhythmias that are prone to develop in this setting. Two decades ago, the treatment of cocaine-induced cardiovascular effects favored the use of  $\beta$ -blockers, especially propranolol. As the clinical use of propranolol increased, reports of accentuation of cocaine-induced hypertension and myocardial ischemia began to surface, blaming the unopposed  $\alpha$  effects of the  $\beta$ -blockers. Although these reports were isolated, the routine use of propranolol and subsequently all  $\beta$ -adrenergic blockers decreased to the point that  $\beta$ -blockers were considered relatively contraindicated in treating cocaine-induced cardiovascular emergencies. The end result is that an entire generation of potent and selective  $\beta$ -adrenergic blocking agents have been overlooked, both for acute and chronic treatment of cocaine-related cardiac disease, due to the possibility of “unopposed  $\alpha$  effects.” The focus of treatment shifted from the cardiovascular effects to combating central nervous stimulation. As a result, benzodiazepines have been the drug of choice in treating the cerebrovascular and subsequent systemic hyperadrenergic complications of cocaine, and nitroprusside or phentolamine being advocated for peripheral vasodilatory effects. It is now becoming apparent that treatment of cardiovascular effects of cocaine should involve a multifactorial approach to combat both central nervous system and peripheral vasospastic effects of cocaine. In this regard  $\beta$ -adrenergic blocking agents, especially  $\beta$ -blocking agents with both  $\alpha$ - and  $\beta$ -blocking properties such as labetalol or carvedilol, may play an important role in treating cocaine-related cardiomyopathy or chronic heart failure. It should also be noted that  $\beta$ -blockers are not recommended to be used in the acute setting of cocaine-related acute coronary syndrome.

**Anthracycline.** Cardiotoxicity is a well-known side effect of several cytotoxic drugs, especially of the anthracyclines and can lead to long-term morbidity (see also Chapter 58). Anthracyclines, such as doxorubicin (Adriamycin) and daunorubicin, produce cardiac toxicity, possibly by increasing oxygen-free radical generation, platelet activating factor, prostaglandins, histamine, calcium, and C-13 hydroxy metabolites, or by interfering with sarcolemmal sodium potassium pump and mitochondrial electron transport chain. The formation of oxygen-free radicals that are generated by iron-catalyzed pathways appears to be the most important pathway in the pathogenesis of anthracycline-induced cardiomyopathy because it has been noted that iron-chelating agents that prevent generation of oxygen-free radicals, such as dexrazoxane, are cardioprotective. The prognosis of anthracycline-induced cardiomyopathy relates to the time course of treatment and pre-existing additional risk factors for myocardial injury such as radiation, coexisting coronary artery disease, and preexisting cardiac dysfunction. In general, patients with anthracycline-induced cardiomyopathy have a worse survival than that seen with idiopathic DCM (Figure 24-6). Prevention of anthracycline-induced myocardial damage by use of free radical “scavengers” and antioxidants may reduce cardiotoxicity in some patients. Other chemotherapeutic agents in cancer associated with cardiac toxicity complications are the monoclonal antibody trastuzumab (Herceptin), high-dose cyclophosphamide,

taxoids, mitomycin-C, 5-fluorouracil, and the interferons. In contrast to anthracycline-induced cardiac toxicity, trastuzumab-related cardiac dysfunction does not appear to increase with cumulative dose or to be associated with ultrastructural changes in the myocardium and is generally reversible. This topic is discussed in further detail in Chapter 58.

**Other Myocardial Toxins.** In addition to the classic toxins described previously, as shown in Table 24-1, there are a number of other toxic agents that may lead to LV dysfunction and heart failure, including cobalt and catecholamines. One such agent, ephedra, which has been used for the purposes of athletic performance enhancement and weight loss, has been linked to a high rate of serious adverse outcomes including LV systolic dysfunction, development of heart failure, and cardiac deaths ultimately resulting in the ban of this agent by the U.S. Food and Drug Administration.

## Inflammation-induced Cardiomyopathy

Over the past 10 to 15 years there has been increasing evidence, which suggests that inflammation and/or inflammatory processes may contribute to the overall pathogenesis of dilated cardiomyopathy. Moreover, there is increasing evidence that biological properties of inflammatory mediators, such as proinflammatory cytokines, are also sufficient to produce a dilated cardiac phenotype.<sup>41</sup> As will be discussed later and in Chapter 11, both infectious and noninfectious inflammatory processes may lead to the development of DCM. Although a great many infections and noninfectious processes may impact the myocardium, and may transiently lead to systolic dysfunction and congestive symptomatology, the great majority of these infections and noninfectious processes do not lead to the development of DCM. Therefore, in the section that follows, we will focus primarily on those disease states that are considered to lead to DCM.

### Inflammation-induced Cardiomyopathy: Infectious Causes

**Viral Cardiomyopathy.** The subject of viral myocarditis and is covered in detail in Chapter 31.

**FIGURE 24-6** Survival according to different causes of dilated cardiomyopathy. In a cohort of patients who underwent endomyocardial biopsy as part of an evaluation for heart failure due to unexplained cardiomyopathy, when compared with the patients with idiopathic cardiomyopathy, survival significantly better in patients with peripartum cardiomyopathy and significantly worse among the patients with cardiomyopathy due to infiltrative myocardial disease, HIV infection, therapy with doxorubicin, and ischemic heart disease. (Felder GM, Thompson RE, Hare JM, et al. Underlying causes and long-term survival in patients with initially unexplained cardiomyopathy. *N Engl J Med* 2000;342:1077-1084, reproduced with permission from the *New England Journal of Medicine*.)

**Acquired Immunodeficiency Syndrome (AIDS).** Several investigators have reported that there is an association between AIDS and dilated cardiomyopathy. Reviews and studies published before the introduction of highly active antiretroviral therapy regimens have correlated the incidence and course of human immunodeficiency virus (HIV) infection in relation to dilated cardiomyopathy in both children and adults. In a long-term echocardiographic follow-up by Barbaro et al,<sup>42</sup> 8% of initially asymptomatic HIV-positive patients were diagnosed with dilated cardiomyopathy during the 60-month follow-up. All patients with dilated cardiomyopathy were in NYHA functional class III or IV. The mean annual incidence rate was 15.9 cases per 1000 patients. The extent of immunodeficiency of the patients, as assessed by the CD4 count, influenced the incidence of dilated cardiomyopathy; specifically, there was a higher incidence among patients with a CD4 count of less than 400 cells per cubic millimeter.

Current hypotheses concerning the pathogenesis of cardiomyopathy associated with infection with the human immunodeficiency virus include infection of myocardial cells with HIV type 1 or coinfection with other cardiotropic viruses, postviral cardiac autoimmunity, autonomic dysfunction, cardiotoxicity from illicit drugs, and pharmacological agents (such as nucleoside analogues and pentamidine), nutritional deficiencies, and prolonged immunosuppression. Recently it has been demonstrated that targeted myocardial expression of HIV transactivator in transgenic mice results in cardiomyopathy and mitochondrial damage,<sup>43</sup> emphasizing the role of the HIV infection itself in AIDS cardiomyopathy. The role of HIV type 1 infection of cardiac myocytes in the development of dilated cardiomyopathy in HIV has not been fully characterized. Even though human myocardial cells are not known to express CD4 cells, autopsy series of persons dying from AIDS-related illnesses demonstrate histological evidence of myocarditis in approximately 50% of the patients.<sup>44</sup> By in situ hybridization techniques in cardiac tissue sections, HIV nucleic acid sequences were detected in 27% of the patients who died of AIDS (Figure 24-7).<sup>45</sup> Symptomatic heart failure is seen in approximately half of these patients with myocardial involvement. Whether early treatment with angiotensin-converting enzyme inhibitors and/or  $\beta$ -blockers will prevent and/or retard disease progression in these patients is unknown at this time. The treatment of patients with symptomatic HIV

**FIGURE 24-7** In situ hybridization of HIV RNA probe in a section of myocardial tissue obtained at autopsy from AIDS patients. There is intense staining within and around one myocyte. Using sulfur-35-labeled ribonucleic acid probes, HIV nucleic acid sequences were detected in cardiac tissue sections (hematoxylin and eosin, 400 $\times$ ). (From Grody WW, Cheng L, Lewis W. Infection of the heart by the human immunodeficiency virus. *Am J Cardiol* 1990;66:203-206, reproduced with permission from the *American Journal of Cardiology*.)

cardiomyopathy is the same as the conventional treatment for patients with DCM. The prognosis of HIV cardiomyopathy remains poor, with more than a 50% mortality rate in 2 to 3 years (see Figure 24-6).

**Chagas Disease (see also Chapter 33).** Although Chagas disease is a relatively uncommon cause of DCM in North America, Chagas disease remains a leading cause of death in many areas of Central and South America (see Chapter 33). Indeed, 50,000 people die of Chagas disease each year.<sup>46</sup> *Trypanosoma cruzi*, the causative organism for Chagas disease is found only in the Western hemisphere, where it primarily infects wild and domestic mammals and insects. Humans become involved when infected vectors infest the simple houses that are common in Latin America. It is estimated that 16 to 18 million people have chronic *T. cruzi* infection. Chagas control programs in certain South American countries have demonstrated significant decline in the seropositive subjects from 47.8% to 17.1%, most marked among children and teenagers from 29.9% to 1.9%, suggesting reduction in transmission of the disease.<sup>46</sup> There are three different clinical and pathophysiological phases of disease: the acute, indeterminate, and chronic phases. Sudden cardiac death can occur during each phase; however, DCM is a late manifestation of the disease and is generally seen during the chronic phase. Acute Chagas disease is usually a mild illness with a case fatality rate of less than 5%. The systemic spread of the parasites from the site of entry and their initial multiplication may be accompanied by fever, malaise, and edema of the face and lower extremities, and generalized lymphadenopathy and hepatosplenomegaly. Muscles, including the heart, are often heavily parasitized, and severe myocarditis develops in a small proportion of patients. The acute illness resolves spontaneously over a period of 4 to 6 weeks in most patients, who then enter the indeterminate phase of *T. cruzi* infection. In this phase there are no symptoms, but there are lifelong, low-grade parasitemias in association with antibodies to many *T. cruzi* antigens. Many people in this phase have subtle signs of cardiac or gastrointestinal involvement long before the disease becomes symptomatic. Most infected people remain in the indeterminate phase for life. However, this carrier state can be a major cause of transfusion-associated transmission of the parasite. Symptomatic chronic Chagas disease develops in an estimated 10% to 30% of infected persons, years or even decades after the *T. cruzi* infection is acquired. The heart is most commonly affected, and the pathological changes may include biventricular enlargement, thinning of ventricular walls, apical aneurysms, and mural thrombi. Widespread lymphocytic infiltration is often seen in stained specimens of cardiac tissue and diffuse interstitial fibrosis and atrophy of myocardial cells. The conduction system is often affected, typically resulting in right bundle branch block, left anterior fascicular block, or complete atrioventricular block. The symptoms reflect the dysrhythmias, cardiomyopathy, and thromboembolism that develop over time. Death usually results from rhythm disturbances or progressive heart failure. The overall prognosis for patients with Chagas cardiomyopathy and heart failure is poor, with 50% of patients dying within a period of 47 months. The presence of complete heart block, atrial fibrillation, left bundle branch block, and complex ventricular ectopy auger a poor prognosis.

The leading hypothesis with respect to the pathogenesis of Chagas cardiomyopathy is that patients develop progressive myocardial damage due to parasite persistence and autoimmune responses.<sup>46</sup> The neurogenic hypothesis of Chagas cardiomyopathy suggests that the cardiac parasympathetic neurones are irreversibly damaged by the parasite during the acute phase of the disease. As a consequence, the cardiac sympathetic nervous system is unopposed and the cardiotoxic effects of a permanent and excessive sympathetic activation are responsible for the relentless progression of myocardial

damage. However, activation of the sympathetic nervous system and of the renin-angiotensin-aldosterone system, is a late event in the natural history of Chagas disease and patients with parasite persistence but no segmental myocardial damage do not have neurohormonal activation.<sup>46</sup> Myocardial ischemia and coronary microcirculation abnormalities have also been demonstrated in animal models and in humans with Chagas disease.

The pharmacological treatment for *T. cruzi* infection remains unsatisfactory. Extensive clinical experience has been accumulated with two drugs: benznidazole and nifurtimox. Both shorten the acute phase of *T. cruzi* infection and decrease mortality, but they achieve parasitological cures in only about 50% of treated patients; moreover, these drugs cause substantial toxicity.<sup>46</sup> Other than treatment of the infection, treatment of cardiomyopathy is the same as the conventional treatment of patients with DCM.

#### **Inflammation-induced Cardiomyopathy: Noninfectious Causes**

**Hypersensitivity Myocarditis.** Hypersensitivity to a variety of agents may result in allergic reactions that involve the myocardium, characterized by peripheral eosinophilia, and a perivascular infiltration of the myocardium by eosinophils, lymphocytes, and histiocytes. These infiltrates may be occasionally associated with necrosis. A variety of drugs, most commonly the sulfonamides, penicillins, methyldopa, and other agents such as amphotericin B, streptomycin, phenytoin, isoniazid, tetanus toxoid, hydrochlorothiazide, and chlorthalidone have been reported to cause allergic hypersensitivity myocarditis. Most patients are not clinically ill, but may die suddenly, presumably secondary to an arrhythmia. Hypersensitivity myocarditis is recognized only rarely clinically, but may be sufficient to produce global and/or regional myocardial dysfunction detected by noninvasive methods. This entity is often first diagnosed on postmortem examination, and occasionally on endomyocardial biopsy.<sup>47</sup>

**Systemic Lupus Erythematosus (SLE).** Although a number of cardiac abnormalities have been reported in patients with SLE, the development of DCM is not a prominent manifestation of this disease process. Global LV dysfunction has been reported in 5%, segmental LV wall motion abnormalities in 4%, and right ventricular enlargement in 4% of patients with SLE. In general the abnormalities in cardiac function usually correlate with disease activity. The myocardial involvement is frequently found at autopsy or at endomyocardial biopsy and is less easily detected clinically. The myocardial lesions are characterized by an increase in interstitial connective tissue and myocardial scarring. Recent studies suggest that depolarization abnormalities on signal average ECG accompanied with echocardiographic evidence of abnormal LV filling may reflect the presence of myocardial fibrosis and could be a marker of subclinical myocardial involvement in SLE patients.<sup>48</sup> Cardiac involvement may manifest itself by conduction system abnormalities such as complete atrioventricular heart block. Neonatal lupus especially is characterized by congenital heart block, and cardiomyopathy, cutaneous lupus lesions, hepatobiliary disease, and thrombocytopenia.

**Scleroderma.** The development of DCM is rare in patients with scleroderma. A recent echocardiographic study showed that although there was no difference in LV dimensions or fractional shortening in patients with scleroderma, there was indication of systolic impairment in the majority of patients.<sup>49</sup> A distinctive focal myocardial lesion ranging from contraction band necrosis to replacement fibrosis without morphological abnormalities of the coronary arteries is noted in approximately half of the patients with scleroderma. This is postulated to be due to intermittent vascular spasm with intramyocardial Raynaud phenomenon. Thus progressive systemic sclerosis can lead to conduction abnormalities, arrhythmias, heart failure, angina pectoris with normal

coronary arteries, myocardial fibrosis, pericarditis, and sudden death. Late contrast enhancement with gadolinium may be used to characterize patchy fibrosis and myocardial edema interspersed with normal myocardium in scleroderma. Cardiac involvement in systemic sclerosis portends an ominous prognosis, and is probably most directly related to the extent of myocardial fibrosis.

**Rheumatoid Arthritis.** Cardiac involvement in rheumatoid arthritis generally results from the development of myocarditis and/or pericarditis. However, the development of DCM is rare in these patients. In a retrospective study of 172 patients with juvenile rheumatoid arthritis, symptomatic cardiac involvement occurred in 7.6% of patients, including pericarditis, perimyocarditis, and myocarditis. Both myocarditis and pericarditis are regarded as poor prognostic factors in rheumatoid arthritis.<sup>50</sup> Myocardial involvement in rheumatoid arthritis is thought to be secondary to disturbances in the microcirculation secondary to microvasculitis, and occurs in the absence of any clinical symptoms of ECG changes.

**Kawasaki Disease.** Kawasaki disease is an acute febrile illness associated with mucosal inflammation, skin rash, and cervical lymphadenopathy. This disease is recognized most often in children less than 4 years of age. Kawasaki disease represents an acute vasculitic syndrome of unknown cause that primarily affects small- and medium-sized arteries, including coronary arteries. Coronary arterial aneurysms are seen in 25% to 55% of the acute Kawasaki cases. Of these, 4.7% progress to premature atherosclerotic ischemic heart disease. Myocardial infarction is noted in approximately 2% of patients, and cardiovascular death is reported in 0.8%. Although the development of DCM is not typical for Kawasaki disease, repetitive infarctions secondary to coronary arterial aneurysms may lead to a dilated cardiomyopathic phenotype.

**Peripartum Cardiomyopathy.** Peripartum cardiomyopathy is a disease of unknown cause in which severe LV dysfunction occurs during the last trimester of pregnancy or the early puerperium. It is reported in 1 in 1300 to 1 in 4000 live births. In the past, the diagnosis of this entity was made on clinical grounds; however, modern echocardiographic techniques have allowed more accurate diagnoses by excluding cases of diseases that mimic the clinical symptoms and signs of heart failure. Risk factors for peripartum cardiomyopathy include advanced maternal age, multiparity, African descent, twinning, and long-term tocolysis. Anticoagulation is strongly recommended, especially if ventricular dysfunction is persistent. Although its cause remains unknown, most theories have focused on the hemodynamic and immunological stresses of pregnancy. An immune pathogenesis is supported by the frequent finding of lymphocytic myocarditis on myocardial biopsy and the fact that multiparity or previous exposure to fetal antigens is a significant risk factor.<sup>51</sup>

The prognosis of peripartum cardiomyopathy is related to the recovery of ventricular function. In contrast to patients with idiopathic dilated cardiomyopathy, significant improvement in myocardial function is seen in 30% to 50% of patients in the first 6 months after presentation (see Figure 24-6).<sup>51</sup> However, for those patients who do not recover to normal or near-normal function, the prognosis is similar to other forms of dilated cardiomyopathy.<sup>52</sup> Cardiomegaly that persists for more than 4 months after diagnosis indicates a poor prognosis, with a 50% mortality at 6 years.

Diagnosis is based upon the clinical presentation of congestive heart failure and objective evidence of LV systolic dysfunction. Conventional pharmacological therapy for congestive heart failure, such as diuretics, digoxin, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and  $\beta$ -adrenergic blockers, are routinely used and are quite effective. Aggressive use of implantable defibrillators and advances in medical therapy have significantly reduced the risk of sudden death and all-cause mortality

rates. More recently, the use of bromocriptine, a dopamine D2 receptor agonist, has been investigated in the treatment of PPM. Oxidative stress in the setting of pregnancy or in the postpartum period leads to the cleavage of the conventional prolactin molecule into a form which appears to have a detrimental effect on the myocardium by promoting apoptosis, vasoconstriction, and inflammation. In several human case reports of postpartum cardiomyopathy, treatment with bromocriptine resulted in improvement in clinical status and LV function. For those patients who remain refractory to conventional pharmacological therapy, cardiac transplantation and mechanical circulatory support are viable options. For greater than 50% of peripartum cardiomyopathy patients, LV function normalizes with pharmacological therapy. However, subsequent pregnancies almost always are associated with recurrence of LV systolic dysfunction. Caution is advised against subsequent pregnancy, especially if LV dysfunction is persistent.

#### Endocrine and Metabolic Causes of Cardiomyopathy

**Obesity.** Obesity cardiomyopathy is defined as congestive heart failure due entirely or predominantly to obesity. Heart failure in the markedly obese usually develops over a long period of time, and can be directly related to the duration of obesity (see chapter 20). Initially the dyspnea and edema in these patients are simply related to alterations in LV compliance, diastolic heart failure with resultant elevated filling pressures. However, with chronicity, some of these patients will develop significant LV hypertrophy, increased LV mass, and some subsequently develop DCM. Although the precise reasons for obesity-related heart failure are not known, it is thought that the excessive adipose accumulation results in an increase in circulating blood volume; subsequently, it results in a persistent increase in cardiac output, cardiac work, and systemic blood pressure, which ultimately lead to myocardial failure.<sup>53</sup> Furthermore, there is increased prevalence of hypertension and coronary artery disease in obese patients, which may also contribute to the development of DCM in these patients. Recently, cardiac myocyte injury by lipotoxicity has been implicated as a potential mechanism, especially in individuals with metabolic syndrome and insulin resistance. Cardiac lipotoxicity is hypothesized to arise from an imbalance between fatty acid uptake and use, leading to the inappropriate accumulation of free fatty acids and neutral lipids within cardiomyocytes. This lipid overload causes cellular dysfunction, cell death, and eventual organ dysfunction.<sup>54</sup> Obesity-related hypoventilation and sleep apnea may also contribute to the pathophysiology. A recent study examining the relation between obesity and heart failure in participants in the Framingham Heart Study<sup>55</sup> reported that after adjustment for established risk factors, there was an increase in the risk of heart failure of 5% for men and 7% for women for each increment of 1 in the body mass index. When compared with subjects with a normal body mass index, obese subjects had a doubling of the risk of heart failure. Obesity alone was estimated to account for 11% of cases of heart failure in men and 14% of those in women.<sup>55</sup> Given the high prevalence of obesity in Western countries in the past decade, strategies to promote optimal body weight may reduce the population burden of heart failure. In addition to its recognized risk for development of heart failure, intuitively, one would anticipate that obesity would adversely affect the outcome of patients with established heart failure. Interestingly however, there is a recognized paradox with obesity and heart failure, and that is, in patients with established heart failure, obesity is associated with better clinical outcomes.<sup>56</sup> (Figure 24-8). This paradox, though not clearly understood, may partly be due to comparison of individuals in a non-catabolic state with the ability to gain weight to individuals who are lean or cachectic due to advanced heart failure;

**FIGURE 24-8** Kaplan-Meier survival curves by body mass index in the obese, overweight, and normal-weight groups in patients with heart failure. The number of patients at risk for death at each 6-month interval is shown below the figure. (From Bozkurt B, Deswal A. Obesity as a prognostic factor in chronic symptomatic heart failure. *Am Heart J* 2005;150:1233-1239, reproduced with permission from *American Heart Journal*.)

selective survival of different subtypes of obese individuals; earlier detection or misdiagnosis of heart failure in obese patients due to increased prevalence of dyspnea and edema; differences in cause of heart failure in obese (hypertension, diabetes) versus nonobese (coronary artery disease); the endocrine/paracrine role of the adipose tissue, which may also participate in metabolic turnover or rapid degradation of certain chemokines; and neurohormones including natriuretic peptides. Ongoing studies will provide more insight into the obesity paradox in heart failure. Although there are anecdotal reports regarding symptomatic improvement following weight reduction in obesity-induced heart failure, large-scale clinical trials on the role of weight loss in heart failure patients with obesity have not yet been performed.<sup>57,58</sup> The safety and efficacy of weight loss drugs, such as orlistat or sibutramine, have not been tested in large-scale trials in cardiac patients. There has been concern against use of sibutramine in heart failure due to reports of development of cardiomyopathy, and this medication is contraindicated in heart failure.<sup>59</sup> In small-scale pilot studies, orlistat appeared to be tolerated and effective in weight loss in heart failure patients with obesity, but ongoing investigations are under way regarding its hepatic safety profile.<sup>60</sup> Similarly, there are no large-scale studies on safety or efficacy of weight loss with lifestyle modification with diet or exercise in obese heart failure patients. Since the prevalence of obesity is increasing in the general and in the heart failure population, examination of obesity and prevention and treatment options will be critical in heart failure patients.

**Diabetic Cardiomyopathy (see chapter 24).** Since its first description in 1972, a considerable amount of experimental, pathological, epidemiological, and clinical data have accumulated to support the existence of “diabetic cardiomyopathy.” So far, a large body of literature suggests that the occurrence of diabetic cardiomyopathy is an independent phenomenon from macroangiographic changes in coronary arteries and hypertension. Diabetes is now well recognized as an independent risk factor for the development of heart failure despite correcting for age, hypertension, obesity, hypercholesterolemia, and coronary artery disease. This subject is covered in further detail in Chapter 20 of this textbook.

**Hyperthyroidism.** Hyperthyroidism has been implicated in causing dilated cardiomyopathy; however, in view of the increased cardiac contractile function of patients with hyperthyroidism, the development of heart failure is unexpected and raises the question whether there truly is a direct causal association between hyperthyroidism and cardiomyopathy. Patients with hyperthyroidism may occasionally have exertional dyspnea or other symptoms and signs of heart failure. Many of these clinical manifestations may be attributed to the direct effects of thyroid hormone on cardiovascular hemodynamics. In most patients with hyperthyroidism, cardiac output is high, and the subnormal response to exercise may be the result of an inability to increase heart rate maximally or to lower vascular resistance further, as normally occurs with exercise. The term “high-output failure” is not appropriate for all cases of cardiomyopathy related to hyperthyroidism because the ability of the heart to maintain increased cardiac output at rest and with exercise is usually preserved.<sup>61</sup> Occasional patients with severe, long-standing hyperthyroidism have poor cardiac contractility, low cardiac output, and symptoms and signs of heart failure, including a third heart sound and pulmonary congestion. This complex of findings most commonly occurs with persistent sinus tachycardia or atrial fibrillation and is the result of so-called tachycardia-related heart failure. In older patients with heart disease, the increased workload that results from hyperthyroidism may further impair cardiac function and thus result in dilated cardiomyopathy. The presence of ischemic or hypertensive heart disease may compromise the ability of the myocardium to respond to the metabolic demands of hyperthyroidism. Histological examination usually reveals a nonspecific pattern, including foci of lymphocytic and eosinophilic infiltration, fibrosis, fatty infiltration, and myofibrillar hypertrophy. Although enhanced adrenergic activity contributes to the hyperdynamic state in hyperthyroidism,  $\beta$ -adrenergic blockade does not fully return the heart rate or contractility to normal, which may suggest a primary cardiac effect of thyroid hormone with contributory effects of catecholamines.<sup>61</sup>

**Hypothyroidism.** Abnormalities in cardiac systolic and diastolic performance have been reported both in experimental and clinical studies of hypothyroidism; however, the

classic findings of myxedema do not usually indicate cardiomyopathy. The most common signs are bradycardia, mild hypertension, a narrowed pulse pressure, and attenuated activity on the precordial examination. Pericardial effusions and nonpitting edema (myxedema) can occur in patients with severe, long-standing hypothyroidism. The low cardiac output is caused by bradycardia, a decrease in ventricular filling, and a decrease in cardiac contractility. Systemic vascular resistance may increase by as much as 50%, and diastolic relaxation and filling are slowed.<sup>61</sup> However, heart failure is rare, because the cardiac output is usually sufficient to meet the lowered demand for peripheral oxygen delivery. Positron-emission tomographic studies of oxygen consumption in patients with hypothyroidism have revealed that myocardial work efficiency is lower than in normal subjects. From 10% to 25% of patients have diastolic hypertension, which combined with the increase in vascular resistance, raises cardiac afterload and cardiac work.<sup>61</sup> Abnormal systolic force may improve with thyroid hormone replacement but does not return to normal levels, suggesting the possibility of persistent myocardial dysfunction.<sup>62</sup> Thyroid hormone replacement should be initiated at low doses and titrated slowly as LV failure may be precipitated. Interestingly, patients with heart failure also have low serum triiodothyronine concentrations, and the decrease is proportional to the degree of heart failure. Whether such changes in thyroid hormone metabolism contribute to further impairment of cardiovascular function in patients with heart failure is not known.<sup>61</sup>

**Acromegaly and Growth Hormone Deficiency.** Impaired cardiovascular function has recently been demonstrated to potentially reduce life expectancy both in growth hormone deficiency and excess. Experimental and clinical studies have supported the evidence that growth hormone and insulin-like growth factor-1 (IGF-1) are implicated in cardiac development.<sup>63</sup> In most patients with acromegaly, a specific cardiomyopathy, characterized by myocardial hypertrophy with interstitial fibrosis, lymphomononuclear infiltration, and areas of monocyte necrosis, results in biventricular concentric hypertrophy.<sup>63</sup> Myocardial dysfunction is a major cause of morbidity and mortality in acromegaly, and appears to be related to both the severity and duration of growth hormone excess. In contrast, patients with childhood or adult-onset growth hormone deficiency may suffer both from structural cardiac abnormalities, such as narrowing of cardiac walls, and functional impairment that combine to reduce diastolic filling and impair LV response to peak exercise. In addition, growth hormone deficiency patients may have an increase in vascular intima-media thickness and a higher occurrence of atheromatous plaques, which can further aggravate the hemodynamic conditions and contribute to increased cardiovascular and cerebrovascular risk. Several studies have suggested that the cardiovascular abnormalities can be partially reversed by suppressing growth hormone and IGF-1 levels in acromegaly or after growth hormone replacement therapy in growth hormone deficiency patients.<sup>63</sup> Receptors for both growth hormone and IGF-1 are expressed by cardiac myocytes; therefore, growth hormone may act directly on the heart or via the induction of local or systemic IGF-1, while IGF-1 may act by endocrine, paracrine, or autocrine mechanisms. Animal models of pressure and volume overload have demonstrated upregulation of cardiac IGF-1 production and expression of growth hormone and IGF-1 receptors, implying that the local regulation of these factors is influenced by hemodynamic changes.<sup>63</sup> Moreover, experimental studies suggest that growth hormone and IGF-1 have stimulatory effects on myocardial contractility, possibly mediated by changes in intracellular calcium handling. Thus recently, much attention has been focused on the ability of growth hormone to increase cardiac mass, suggesting its possible use in the treatment of chronic heart failure.

Initial studies demonstrated that treatment with growth hormone may result in improvement in the hemodynamic and clinical status of patients with heart failure; however, two randomized, placebo-controlled studies did not show any significant growth hormone-mediated improvement in cardiac performance in patients with dilated cardiomyopathy despite significant increases in IGF-1.<sup>64</sup> Although these data need to be confirmed in more extensive studies, such promising results seem to open new perspectives for growth hormone treatment in humans.

#### *Nutritional Causes of Cardiomyopathy*

**Thiamine Deficiency.** Thiamine serves as a cofactor for several enzymes involved primarily in the carbohydrate catabolism and is found in high concentrations in the heart, skeletal muscle, liver, kidneys, and brain. The most common cause of thiamine deficiency in Western countries is chronic alcoholism and anorexia nervosa. AIDS and pregnancy can account for other rare causes of thiamine deficiency.<sup>65</sup> A state of severe depletion can develop in patients on a strict thiamine-deficient diet in approximately 18 to 21 days. The major manifestations of thiamine deficiency in humans involve the cardiovascular (wet beriberi) and nervous (dry beriberi, or neuropathy and/or Wernicke-Korsakoff syndrome) systems. The cardiovascular signs and symptoms include dyspnea, fatigue, leg edema, and palpitations. Tachycardia is common and there are usually increased jugular venous pressure and warm extremities. Biventricular heart failure is present and the circulation is usually hyperkinetic. Ultimately circulatory collapse, metabolic acidosis, or shock can develop, at which time the disease has advanced from chronic beriberi to fulminating beriberi heart failure (Shoshin beriberi). Severe lactic acidemia in the presence of a high cardiac output and extremely low oxygen consumption are the classic features of acute fulminant cardiovascular beriberi, which, if unrecognized and untreated, can lead to high cardiac output failure and death. Treatment for beriberi should consist of administration of thiamine along with other conventional treatment of circulatory support and heart failure.

**Carnitine Deficiency.** L-carnitine and its derivative, propionyl-L-carnitine, are organic amines necessary for oxidation of fatty acids, the deficiency of which may be associated with a syndrome of progressive skeletal myopathy and lipid vacuoles on muscle biopsy.<sup>66</sup> They have also been shown to reduce intracellular accumulation of toxic metabolites during ischemia, demonstrate protective effects on muscle metabolism injuries, inhibit caspases, and decrease the levels of TNF- $\alpha$  and sphingosine, and reduce apoptosis of skeletal muscle cells and thus have been implied in the treatment of congestive heart failure. Several metabolic genes, including the muscle carnitine palmitoyl transferase-1, the key enzyme for the transport of long-chain acyl-coenzyme A (acyl-CoA) compounds into mitochondria, are downregulated in the failing human heart.<sup>67</sup> Inhibitors of carnitine palmitoyl-transferase I (CPT I), such as etomoxir, have been developed as agents for treating diabetes mellitus. Despite initial promising preclinical and phase II clinical results, a double-blind randomized multicenter clinical trial with etomoxir in heart failure was stopped prematurely, because unacceptably high liver transaminase levels were detected in four patients taking etomoxir.<sup>68</sup>

**Selenium Deficiency.** Selenium deficiency is associated with cardiomyopathy and congestive heart failure in geographic areas where dietary selenium intake is low.<sup>69</sup> This has been named as the Keshan disease due to the geographical prevalence of a specific form of dilated cardiomyopathy in northeast China, in which the soil has a low selenium content. Chronic selenium deficiency may also occur in individuals with malabsorption and long-term selenium-deficient parenteral nutrition. Selenium deficiency is implicated in causing

cardiomyopathy as a result of the depletion of selenium-associated antioxidant enzymes; selenoenzymes, which protect cell membranes from damage by free radicals. The cardiomyopathy is manifested by insidious onset of congestive heart failure or a complication of sudden death or thromboembolic phenomena. The heart shows biventricular enlargement and histologically exhibits edema, mitochondrial swelling, hypercontraction bands, widespread myocytolysis, and extensive fibrosis.<sup>69</sup>

### Hematological Causes of Cardiomyopathy

**Cardiomyopathy Due to Iron Overload: Hemochromatosis and Thalassemia.** Iron-overload cardiomyopathy manifests itself as systolic or diastolic dysfunction secondary to increased deposition of iron in the heart and occurs with common genetic disorders such as primary hemochromatosis and  $\beta$ -thalassemia major.

Hereditary hemochromatosis is an inherited disorder of iron metabolism and is the most common hereditary disease of northern Europeans with a prevalence of approximately 5 per 1000. It is an autosomal recessive disorder of iron metabolism characterized by increased iron absorption and deposition in the liver, pancreas, heart, joints, and pituitary gland. Without treatment, death may occur from cirrhosis, primary liver cancer, diabetes, or cardiomyopathy. In 1996, HFE, the gene for hereditary hemochromatosis, was mapped on the short arm of chromosome 6.<sup>70</sup> Two mutations have been implicated in hereditary hemochromatosis: C282Y and H63D, resulting in excessive iron absorption. The former occurs in a homozygous state seen in 75% to 100% of the patients. The frequency of the latter mutation, the H63D mutation, is significantly increased in patients with idiopathic dilated cardiomyopathy.<sup>70</sup> The high correlation of the HFE to hemochromatosis has caused it to be considered as a candidate gene for population-based genetic testing for diagnosis and detection of predisposition to hemochromatosis. In addition, mechanisms of iron transport and metabolism are unfolding and are providing clues to the enigma of iron homeostasis and the pathophysiology of iron overload.

The complications of hemochromatosis can be devastating, but its clinical management is simple and effective if the disease is identified early in its progression.

Although the exact mechanism of iron-induced heart failure remains to be elucidated, the toxicity of iron in biological systems is attributed to its ability to catalyze the generation of oxygen-free radicals. It has been shown that chronic iron overload results in dose-dependent increases in myocardial iron burden, decreases in the protective antioxidant enzyme activity, increased free-radical production, and increased mortality.<sup>71</sup> These findings suggest that the mechanism of iron-induced heart dysfunction involves, at least in part, free radical-mediated processes. Myocardial iron deposition is most prominent in and around contractile elements and less common in the conduction system, in contrast to sarcoidosis and amyloidosis in which the pathological process commonly involves the conduction system.<sup>71</sup> The mechanism by which iron produces cellular dysfunction is not yet clear, as fibrosis may not be prominent. This also implies that the disease process is reversible if the tissue iron concentration can be controlled. Myocardial iron deposits do not occur until other organs such as liver, pancreas, and connective tissues are saturated with iron. Thus the extracardiac manifestations are present before the cardiomyopathy develops.<sup>71</sup>

Iron overload can occur either as a result of inappropriate excess iron absorption, as in the case of hemochromatosis or thalassemia major, or due to multiple transfusions. The most important manifestations of heart disease in hemochromatosis are congestive heart failure and cardiac arrhythmia. During the initial phases of the cardiomyopathy, the hemodynamic profile represents a restrictive pattern. As the severity

of cardiomyopathy advances, dilated cardiomyopathy with biventricular enlargement and heart failure ensues. The spectrum of arrhythmia ranges from minor abnormalities on the electrocardiogram to supraventricular arrhythmia, atrioventricular conduction block, and ventricular tachyarrhythmia presumably due to myocardial dysfunction and iron deposition in the conduction system and AV node. The ECG most commonly shows decreased voltage and nonspecific ST- and T-wave changes; Q waves are uncommon. Among patients with  $\beta$ -thalassemia major, biventricular, dilated cardiomyopathy remains the leading cause of mortality. In some patients, a restrictive type of LV cardiomyopathy or pulmonary hypertension is noted. The clinical course, although variable and occasionally fulminant, is more benign in recent than in older series.

The diagnosis of hemochromatosis is suggested by elevated serum ferritin and increased ratio of iron to total iron binding capacity (TIBC). The most sensitive screening test for hemochromatosis is saturation of the transferrin with iron; a fasting value greater than 50% is strongly suggestive of the disease. The most definitive test for calculation of iron stores in the body is by measurement of iron concentration by liver biopsy. Magnetic resonance imaging can also be very useful to identify the iron-laden organs and cardiac involvement. Though not required to demonstrate cardiac involvement in every case, endomyocardial biopsy can be useful in assessment of cardiac iron deposition. The echocardiogram usually reveals increased systolic and diastolic ventricular dimensions and reduced LV ejection fraction.

Before phlebotomy and chelation therapy, survival among patients with hemochromatosis and heart failure was less than 20% in 5 years. The actuarial survival rates of the individuals who are homozygous for the C282Y mutation of the hemochromatosis gene C282Y have been reported to be 95%, 93%, and 66%, respectively at 5, 10, and 20 years.<sup>72</sup> Similarly, in patients with thalassemia major, cardiac failure is one of the most frequent causes of death. Chelation therapy, including newer forms of oral chelators, such as deferoxamine, and phlebotomy have dramatically improved the outcome of hemochromatosis. Similarly, chelation therapy has improved prognosis in  $\beta$ -thalassemia major both by reducing the incidence of heart failure and by reversing cardiomyopathy. It is important to start therapy early because treatment may prevent or reverse cardiac involvement. Early diagnosis and treatment by phlebotomy before tissue damage has occurred are essential because life span seems to be normal in treated patients but markedly shortened in those who are not. Additionally, genetic counseling with evaluation of first-degree relatives is mandatory.<sup>71</sup> New imaging modalities, especially magnetic resonance imaging, are expected to improve early diagnosis and risk stratification for treatment. By increasing the proportion of patients on optimal chelation, survival in patients with hemochromatosis or  $\beta$ -thalassemia may further improve.

### Physical Agents

**Tachycardia-induced Dilated Cardiomyopathy.** The concept that incessant or chronic tachycardia can lead to reversible LV dysfunction is supported both by animal models of chronic pacing and human studies documenting improvement in ventricular function with tachycardia rate or rhythm control. Sustained rapid pacing in experimental animal models can produce severe biventricular systolic dysfunction. In humans, descriptions of reversal of cardiomyopathy with rate or rhythm control of incessant or chronic tachycardias have been reported with atrial tachycardias, accessory pathway reciprocating tachycardias, atrioventricular node reentry, and atrial fibrillation with rapid ventricular responses.<sup>73</sup> Control of the rapid ventricular responses in atrial fibrillation has been shown to improve ventricular function. It should also

be noted that in patients with atrial fibrillation and congestive heart failure, a routine strategy of rhythm control does not reduce cardiovascular mortality, but may improve quality of life and LV function when compared with a strategy of rate control alone.<sup>74</sup> The diagnosis of tachycardia-induced cardiomyopathy is usually made following observation of a marked improvement in systolic function after normalization of heart rate. Clinicians should be aware that patients with unexplained systolic dysfunction may have tachycardia-induced cardiomyopathy, and that controlling the arrhythmia may result in improvement and even complete normalization of systolic function.<sup>73</sup> Tachycardia-induced cardiomyopathy may be a more common mechanism of LV dysfunction than recognized and aggressive treatment of the arrhythmia should be considered.

## Autoimmune Mechanisms

There has been increasing evidence suggesting that abnormalities in cellular and humoral immunity may contribute to the overall pathogenesis of dilated cardiomyopathy. Circulating autoantibodies to a variety of cardiac antigens including G protein-linked receptors (such as those to  $\beta_1$ -adrenoreceptors and muscarinic receptors), mitochondrial antigens, adenosine diphosphate, adenosine triphosphate carrier proteins, and cardiac myosin heavy chain have been identified in patients with dilated cardiomyopathy.<sup>75</sup> In this regard it is interesting to note that immunization with certain cardiac muscle (but not skeletal) antigens such as  $\alpha$ -myosin heavy chain can result in the development of a dilated cardiac phenotype in certain susceptible strains of mice. Moreover, a recent meta-analysis has shown that there is increased expression of the antigens of genes located at the major histocompatibility complex (MHC) on chromosome 6, which is the locus that is responsible for regulating immune responses. This study showed that HLA class II antigens such as DR4 or DQw4 were present in 63% of the patients with cardiomyopathy as compared with 26% in the control subjects.<sup>76</sup> Features that support an autoimmune cause in patients who have myocarditis and DCM include familial aggregation, a weak association with HLA-DR4 haplotype, abnormal expression of HLA class II antigens in cardiac tissue, and detection of organ- and disease-specific cardiac autoantibodies by immunofluorescence and immunoabsorption techniques. Nonetheless, a precise interpretation of the previous findings has been complicated by the knowledge that low titers of autoantibodies, which can be part of the normal immunological repertoire, are not always pathogenic. For example, tissue injury secondary to ischemia or infection may lead to autoantibody production because of alterations of self-antigens or exposure of antigens that are normally sequestered from the immune system. In such situations, the generation of autoantibodies is the result, and not the cause, of the tissue injury. Furthermore, observations about autoimmune responses are generally made in patients with established disease; accordingly, any inferences regarding cause and effect are, invariably, indirect and circumstantial.

## CLINICAL RECOGNITION

The most common initial presenting manifestations of DCM are related to the presence of left heart failure, and include progressive exertional dyspnea, fatigue, weakness, diminished exercise capacity, orthopnea, paroxysmal nocturnal dyspnea, nocturnal cough, fluid retention, and edema. With the development of right heart failure, abdominal distention, right upper quadrant pain, early satiety, postprandial fullness, and nausea appear and edema worsens. Some cases will eventually develop cardiac cachexia and wasting from

advanced heart failure. In systemic embolization, pulmonary emboli can be seen in 1% to 4% of cases and are more commonly seen with cardiomegaly. Palpitations can occur with atrial fibrillation and ventricular arrhythmias. Ventricular arrhythmias are common toward advanced stages of cardiomyopathy; however, syncope and sudden cardiac death are rare initial presentations.

## Diagnostic Evaluation

The diagnostic evaluation of patients with dilated cardiomyopathy is, in general, similar to that for patients with ischemic heart disease and is further discussed in Chapter 35.

### Laboratory Testing

**Initial Laboratory Tests.** Initial laboratory evaluation of patients having heart failure should include complete blood count, urinalysis, serum electrolytes (including calcium and magnesium), blood urea nitrogen, serum creatinine, fasting blood glucose (glycohemoglobin), lipid profile, liver function tests, and thyroid-stimulating hormone.<sup>37</sup> Furthermore, screening for hemochromatosis and human immunodeficiency virus is reasonable in suspected patients who have cardiomyopathy. Diagnostic tests for rheumatological diseases, amyloidosis, or pheochromocytoma are reasonable in patients with clinical suspicion.<sup>37</sup> Beyond these routine tests, the positive predictive value and/or utility of additional laboratory studies remains low unless supported by specific elements of the history and physical. One possible exception to this statement is the use of the natriuretic peptides: brain natriuretic peptide (BNP) or N-terminal pro BNP (NT-proBNP), as biochemical markers for both diagnostic and prognostic strategies in heart failure patients (see Chapter 34).

**BNP.** B-type natriuretic peptide (BNP) is a neurohormone secreted mainly in the cardiac ventricles in response to volume expansion and pressure overload. BNP or NT-proBNP can be used for identifying patients with asymptomatic LV systolic dysfunction for diagnosis of heart failure in patients with dyspnea,<sup>77</sup> and for prognosis and risk stratification of patients with heart failure.<sup>78</sup> Despite recognition that falling BNP levels during hospitalization correlate with clinical improvement and lower readmission rates,<sup>79</sup> so far it cannot be assumed that BNP levels can be used effectively as targets for adjustment of therapy in individual patients. Many patients taking optimal doses of medications continue to show markedly elevated levels of BNP,<sup>80</sup> and some patients demonstrate BNP levels within the normal range despite advanced heart failure. The value of serial measurements of BNP to guide therapy for patients with HF is also not well established.<sup>80</sup> Furthermore, the use of BNP measurements to guide the titration of drug doses has not been shown conclusively to improve outcomes more effectively than achievement of the target doses of drugs shown in clinical trials.<sup>79</sup> BNP is elevated probably in all forms of cardiomyopathy including DCM. There have been reports of higher BNP levels in patients with hypertrophic cardiomyopathy than patients with idiopathic DCM.<sup>81</sup> This may be related to the difference in proportional production of BNP by markedly hypertrophied and pressure-loaded ventricles.

**Chest Radiography.** In the early phases of DCM, cardiac enlargement may be minimal and may not be detected by chest radiography. However, in general the chest x-ray usually reveals LV enlargement or generalized cardiomegaly that involves all four cardiac chambers. Depending upon the patient's volume status there may or may not be findings of pulmonary congestion. Cephalization of blood flow or pulmonary vascular redistribution are early signs of volume overload, followed by the development of interstitial edema with appearance of Kerley B lines and fluid in the interlobar fissures, followed by frank alveolar edema in advanced volume

overload. Pleural effusions may be present and the azygous vein and superior vena cava may be dilated, especially with right ventricular failure. Current heart failure guidelines recommend that a chest radiograph (PA and lateral) should be performed initially in all patients having heart failure.<sup>37</sup>

**Electrocardiography (ECG).** If the patient with DCM has signs or symptoms referable to heart failure, the ECG usually reveals sinus tachycardia. However, it is important to note that sinus bradycardia may also be present in many patients with end-stage DCM. The ECG morphology is seldom normal, and often shows nonspecific repolarization or ST-segment abnormalities. Conduction abnormalities, especially left bundle branch block, left anterior hemiblock, nonspecific intraventricular conduction delays, and occasionally first-degree atrioventricular block are common in patients with long-standing symptoms, and they may be markers of increasing interstitial fibrosis or myocyte hypertrophy. Left atrial or biatrial enlargement may be present. Pathological anterior, anterolateral, or diffuse Q waves mimicking myocardial infarction, or poor R wave progression may be seen with viral myocarditis or when there is extensive LV fibrosis even without a discrete myocardial scar. A variety of atrial and ventricular tachyarrhythmias and atrioventricular conduction disturbances may also be seen. Atrial fibrillation develops in approximately 20% of the patients. Premature ventricular contractions are not an uncommon finding on routine ECGs in patients with DCM. Current heart failure guidelines recommend that a twelve-lead electrocardiogram should be performed initially in all patients having heart failure.<sup>37</sup>

**Ambulatory Electrocardiographic (Holter) Monitoring.** There is an inverse relationship between the severity of ventricular arrhythmia and LV ejection fraction. Thus it is perhaps not surprising that the majority of DCM patients will have PVCs when monitored over a 24-hour period; moreover, approximately half of the patients with DCM will have nonsustained ventricular tachycardia on routine ambulatory 24-hour Holter monitoring. However, the predictive value of ambulatory Holter monitoring as a routine screening tool in asymptomatic patients for identification of risk for sudden cardiac death has not been validated. There are conflicting data from studies involving small groups of patients regarding the role of routine ambulatory ECG monitoring as a significant independent risk factor for sudden cardiac death. Thus at the present time routine screening with Holter monitoring in asymptomatic heart failure patients is not recommended as a reliable means to predict those patients who will develop sudden cardiac death.<sup>37</sup>

**Signal Average ECG.** In patients with syncope or coronary artery disease, the presence of late potentials on a signal average ECG identifies those patients at high risk for developing ventricular tachycardia and sudden death. Although late potentials are less frequent in patients with DCM, the current evidence suggests that an abnormal signal average ECG also can predict ventricular arrhythmias and sudden cardiac death in patients with DCM. However, studies evaluating the utility of a positive signal-averaged electrocardiogram to identify a subgroup of dilated heart failure patients at risk for sudden death have yielded disparate results. Indeed, the sensitivity of the signal average ECG varies between 22% and 100% and the specificity ranges from 45% to 96% in various studies.<sup>82</sup> Therefore, although the signal average ECG may be useful for predicting future events in some patients with DCM, the inherent problems with the sensitivity, specificity, and predictive value suggest that the signal average ECG may not be a reliable tool for screening asymptomatic patients who are at a high risk for sudden cardiac death. Current heart failure guidelines do not recommend routine use of signal-averaged electrocardiography for the evaluation of patients having heart failure.<sup>37</sup>

**Echocardiography.** Two-dimensional and Doppler echocardiography are extremely useful techniques for assessing LV function, LV dimensions, and valvular structures in DCM patients (see also Chapter 36). Generally, patients will have global LV dilation, LV wall thinning, global hypokinesis, and an LV ejection fraction less than 35% to 40%. Segmental wall motion abnormalities may be seen with altered regional wall stress due to elevated filling pressures and depressed contractility, or with acute myocarditis due to segmental myocardial injury. Interestingly, the presence of segmental wall motion abnormalities suggests a more favorable outcome than if global hypokinesis is present.<sup>83</sup> Left ventricular apical thrombi can be identified in as many as 40% of the patients with DCM. Small pericardial effusion can sometimes be demonstrated, especially if an infectious or noninfectious inflammatory cause is responsible for producing the DCM.

Doppler echocardiography usually reveals mild degrees of mitral and tricuspid regurgitation and sometimes trace pulmonary insufficiency. The mechanisms of mitral and tricuspid regurgitation have been attributed to ventricular enlargement, annular dilation, lengthening of chordae tendineae, abnormalities in contractility of the papillary muscles, and displacement of the coaptation point of the mitral leaflets. The Doppler mitral inflow patterns can also provide useful information on elevated LV filling pressures, which are suggested by the appearance of high E/A ratio ("pseudonormalization") and short isovolumic relaxation time and deceleration time. The elevated early filling wave results from an elevated left atrial pressure, whereas the rapid deceleration time reflects a further decrease in LV compliance. These Doppler findings have been associated with a poor prognosis in DCM.

Newer modalities of echocardiography have been instrumental in diagnosis and risk stratification of heart failure and selection of appropriate therapies in heart failure patients. Doppler tissue imaging is widely used in documentation of dyssynchrony, diastolic dysfunction, evaluation of filling pressures, wall motion abnormalities, demonstration of myocardial structural abnormalities, and characterization of infiltrative or hypertrophic cardiomyopathy. Speckled strain imaging has been useful in assessment of load independent contractile performance of the left ventricle. Three-dimensional imaging has been useful in better delineation of valvular abnormalities and structural abnormalities of the heart. At present time, according to the ACCF/AHA Guidelines for the Diagnosis and Management of Heart Failure in Adults, two-dimensional echocardiography with Doppler should be performed during initial evaluation of all patients having heart failure to assess LVEF, LV size, wall thickness, and valve function.<sup>37</sup>

**Radionuclide Techniques (see Chapter 36).** Multigated radionuclide angiography (MUGA) is a very useful test for the initial assessment of LV ejection fraction in patients with DCM. Both the right and LV ejection fractions can be quantified reliably with this technique; moreover, the interobserver and intertest variability appear to be less than with echocardiography. Electrocardiographically gated myocardial perfusion single-photon emission computed tomography SPECT imaging is also a state-of-the-art technique for the combined evaluation of myocardial perfusion and LV function with LVEF quantification within a single study. Due to shorter half life, <sup>99m</sup>Tc-sestamibi or <sup>99m</sup>Tc-tetrofosmin are the preferred agents for a gated SPECT study. Though frequently used to determine presence of ischemia as a potential cause of cardiomyopathy, stress testing with thallium 201 myocardial scintigraphy may not be a highly specific technique for differentiating patients with ischemic heart disease from those with DCM because patients with DCM may have both reversible and fixed perfusion abnormalities that are related to the presence of myocardial fibrosis.<sup>84</sup> Nevertheless, noninvasive

imaging with nuclear perfusion scanning may be considered to determine presence of ischemia and coronary artery disease in patients with heart failure and LV dysfunction (see also Chapter 36).<sup>37</sup> In addition to the previous methodologies, radionuclide techniques have also been used to detect the presence of myocardial inflammation. Both gallium-67 (a marker for inflammation) and indium-III labeled antimyosin antibodies (a marker for myocyte necrosis) have been used to detect myocarditis in small uncontrolled studies.<sup>85</sup> These techniques are supportive of the diagnosis of myocarditis when clinically suspected (Figure 24-9), but do not have the specificity or the sensitivity to be used reliably as screening tools for patients with myocarditis.<sup>85</sup>

**Cardiovascular Magnetic Resonance (CMR) (see Chapter 36).** Cardiovascular magnetic resonance is very helpful in assessing myocardial anatomy, regional and global function, and viability in one setting in heart failure patients (see also Chapter 36). It allows assessment of perfusion and acute tissue injury (edema and necrosis), detection of fibrosis, infiltration, and iron overload, which can help diagnose the underlying cause of DCM. It is a reliable technique for

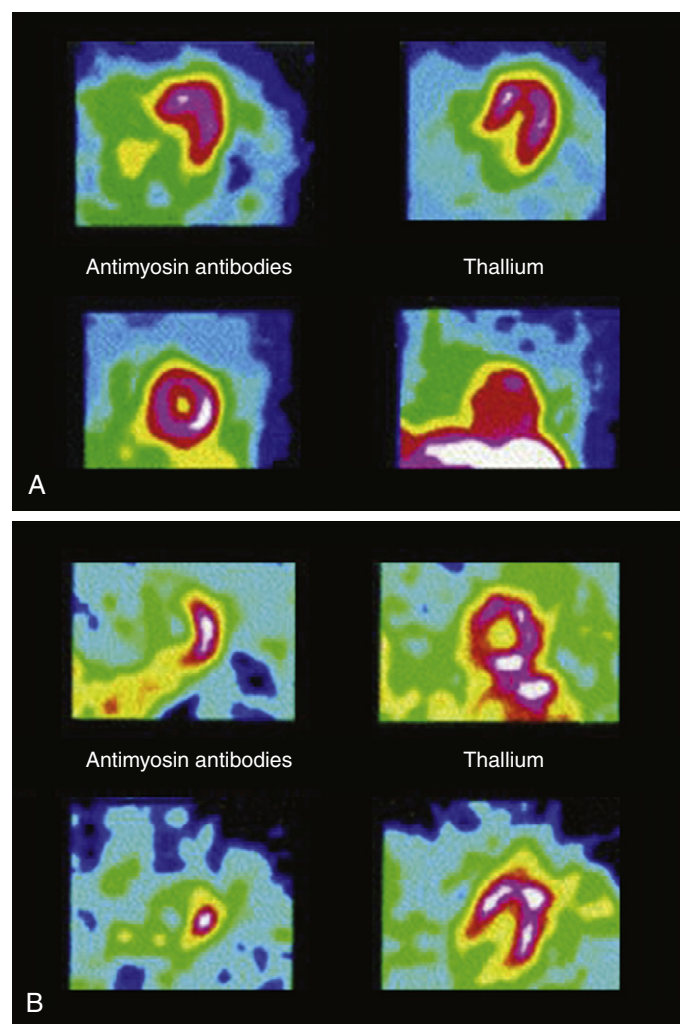

monitoring of disease progression, especially for infiltrative disease such as cardiomyopathy due to iron overload. It also has a prognostic role as evidence on the predictive value of CMR-derived parameters in heart failure is rapidly emerging. In the setting of ischemic cardiomyopathy, there is usually delayed hyperenhancement in segmental areas of subendocardium, whereas in nonischemic CMP, there is usually patchy midwall, epicardial, or global endocardial hyperenhancement (Figure 24-10). In DCM, midwall fibrosis determined by CMR is a predictor of the combined endpoint of all-cause mortality and cardiovascular hospitalization and sudden cardiac death. This suggests a potential role for CMR in the risk stratification of patients with DCM, which may have value in determining the need for device therapy.<sup>86</sup>

**Cardiac Catheterization.** Coronary arteriography is primarily used as a basis for planning further treatment options in patients who have ischemic heart disease. Current heart failure guidelines state that coronary arteriography is reasonable for patients having heart failure who have known or suspected coronary artery disease.<sup>37</sup> In the majority of patients with DCM, the coronary arteries are normal with no atherosclerotic lesions; however, in a small portion there may be evidence of mild, nonobstructive, isolated atherosclerotic lesions that may not be sufficient to explain the extent of cardiomyopathy. Therefore, in these cases, other causes for the cardiomyopathy should be sought. The ventriculogram generally reveals a dilated ventricle with depressed contractility. The LV end-diastolic pressures are usually elevated. Right heart catheterization may be considered a useful means for adjusting medical therapy in patients with advanced symptoms, with hemodynamic instability, or impaired perfusion in whom the adequacy of filling pressures cannot be determined from clinical assessment, especially when they are considered for vasodilator and/or inotropic and/or mechanical support, or for assessing the suitability of certain patients for cardiac transplantation.<sup>37</sup>

**Endomyocardial Biopsy.** The routine use of right ventricular endomyocardial biopsy as a diagnostic tool for evaluating patients with newly diagnosed DCM is not recommended.<sup>37</sup> However, endomyocardial biopsy can be useful in patients having heart failure when a specific diagnosis is suspected that would influence therapy. It may yield a new diagnosis in up to 20% of patients, and may provide a potentially new and/or beneficial form of therapy in 5% of the patients.<sup>87</sup> Therefore, it may be considered in patients with suspected treatable systemic or infiltrative myocardial diseases, such as sarcoidosis, hypereosinophilic syndrome, hypersensitivity myocarditis, amyloidosis, hemochromatosis, doxorubicin-induced cardiomyopathy, or fulminant myocarditis. Moreover, as noted previously, in certain types of fulminant myocarditis, especially giant cell myocarditis, there is the suggestion that aggressive immunosuppression may attenuate disease progression. Therefore, endomyocardial biopsy may be especially useful in diagnosing patients who have a fulminant course, and/or who progressively decompensate despite optimal medical therapy. In experienced laboratories, the risk of perforation of the heart from the biopsy is approximately 1/200 (0.5%) and the risk of death from the procedure is 3 in 10,000 (0.03%).<sup>87</sup> Therefore, in electing to perform a myocardial biopsy, the clinician must weigh the potential benefits of rendering a new diagnosis for which a specific form of therapy exists against the risks associated with performing myocardial biopsy in his or her institution.<sup>87</sup>

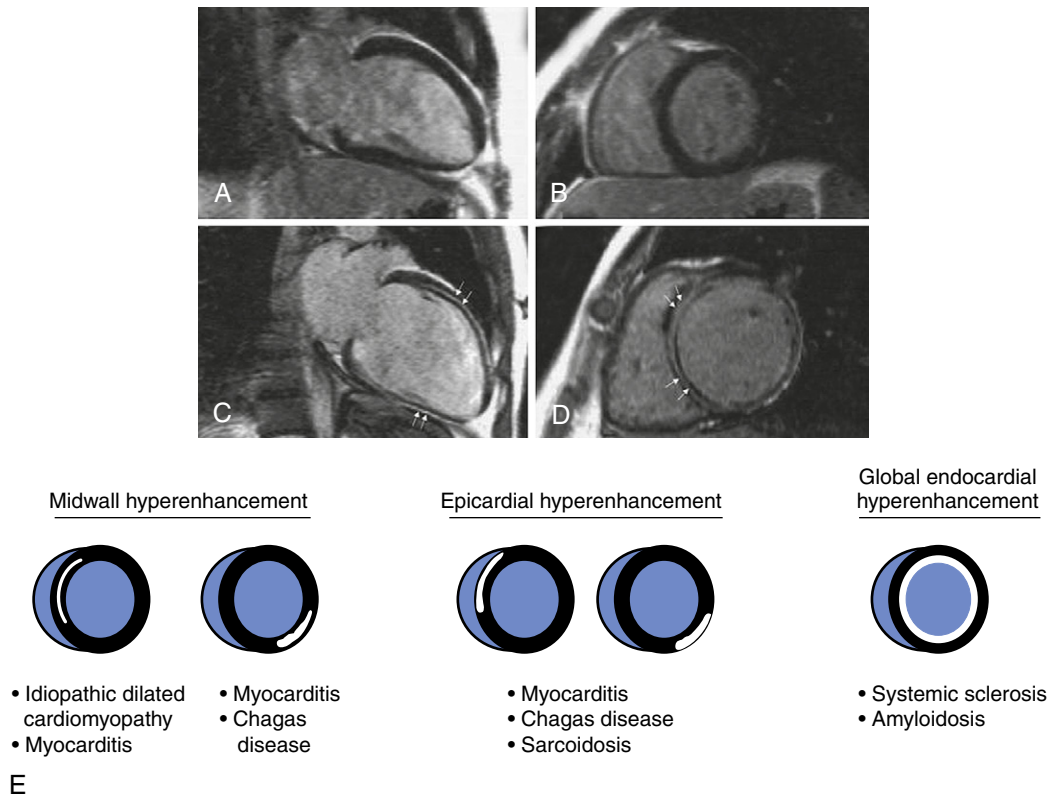

#### Treatment Strategies for Dilated Cardiomyopathy

The first priority in implementing treatment strategies for patients with DCM is to determine if the condition has a cause for which there is a specific form of treatment. Table 24-2 lists a number of “cause-specific” treatment strategies designed to treat the underlying disease process that is responsible for

**FIGURE 24-9** Dual-isotope rest imaging with <sup>111</sup>In-antimyosin antibody and <sup>201</sup>Thallium SPECT in patients with myocarditis. **A**, Scintigraphic pattern of diffuse myocarditis showing diffuse antimyosin antibody uptake throughout the whole LV myocardium and normal <sup>201</sup>Thallium uptake. **B**, Scintigraphic pattern of focal myocarditis showing antimyosin antibody uptake on the apex and the lateral LV wall, and a normal <sup>201</sup>Thallium scan. (From Sarda L, Colin P, Boccara F, et al. Myocarditis in patients with clinical presentation of myocardial infarction and normal coronary angiograms. *J Am Coll Cardiol* 2001;37(3):786-792, reproduced with permission from *Journal of American College of Cardiology*.)

**FIGURE 24-10** Late gadolinium enhancement patterns in dilated cardiomyopathy in vertical long axis (**A** and **C**) and short axis (**B** and **D**). A patient without late enhancement is shown in **A** and **B**, and a patient with marked midwall enhancement is shown in **C** and **D**. The enhancement pattern (arrows) is distinct from that associated with coronary artery disease because of endocardial sparing and noncoronary territory distribution. **E**, A schematic representation of hyperenhancement patterns that are characteristic for nonischemic cardiomyopathy. Note that midwall or epicardial hyperenhancement strongly suggests a nonischemic cause. (A-D, From Assomull RG, Prasad SK, Lyne J, et al. Cardiovascular magnetic resonance, fibrosis, and prognosis in dilated cardiomyopathy. *J Am Coll Cardiol* 2006;48(10):1977-1985. E, Reprinted with permission from Shah DJ, Judd RM, Kim RJ. Myocardial viability. In Edelman RR, Hesselink JR, Zlatkin MB, et al, editors. *Clinical magnetic resonance imaging*, ed 3, New York, 2006, Elsevier.)

TABLE 24-2 Primary Treatment Approaches to Dilated Cardiomyopathies	
Cause for DCM	Primary Treatment
Alcoholic	Abstinence
Cocaine	Abstinence
Anthracycline	Cessation of anthracycline therapy
Systemic lupus erythematosus	Steroids, cytotoxic agents
Viral myocarditis	Prednisone and immunosuppressant therapy for fulminant course
Chagas disease	Benzonidazole, nifurtimox
Scleroderma	Steroids, Ca channel blockers for Raynaud
Kawasaki disease	IV immunoglobulin replacement
Thiamine, selenium, or carnitine deficiency	
Hyperthyroidism/hypothyroidism	Achieve euthyroid state
AIDS	Increase CD4 count
Uremia	Dialysis
Pheochromocytoma	Removal of tumor
Tachycardia induced	AV nodal ablation, $\beta$ -blockers

causing the dilated cardiomyopathy. The second priority in implementing treatment strategies for DCM is to initiate supportive “heart failure” therapy, the goals of which should be to (1) prolong life; (2) avoid the need for future hospitalizations; (3) improve functional capacity and the quality of life; and (4) to prevent heart failure progression. In the section that follows, we will only discuss those treatment strategies that appear (at the time of this writing) to be unique to the treatment of heart failure for patients with DCM.

**Standard Medical Therapy.** Current ACCF/AHA Guidelines for the Diagnosis and Management of Heart Failure recommend use of standard medical therapy for patients with chronic heart failure regardless of ischemic or nonischemic cause, or DCM diagnosis.<sup>37</sup> Existing studies suggest that both patients with ischemic cardiomyopathy and DCM have significant survival benefit from the use of angiotensin-converting enzyme (ACE) inhibitors and  $\beta$ -blockers (see Chapters 45 and 46),<sup>2,13,88</sup> and they are indicated for all patients with current or prior symptoms of heart failure and reduced LVEF.<sup>37</sup> In patients who are ACE inhibitor-intolerant, angiotensin II receptor blockers are recommended as alternatives. Currently, the recommended  $\beta$ -blockers for treatment of heart failure include metoprolol succinate, carvedilol, and bisoprolol both for ischemic or nonischemic cardiomyopathy patients. Additionally, diuretics and salt restriction are recommended in patients with current or prior symptoms of heart failure who have evidence of fluid retention.<sup>37</sup> There is no information on potential differential effects of diuretics on morbidity or mortality in ischemic versus nonischemic heart failure.

Aldosterone antagonism with spironolactone has been reported to reduce mortality in patients with advanced heart failure, both in dilated or ischemic cardiomyopathy.<sup>89</sup>

According to the results of the RALES trial,<sup>89</sup> spironolactone (25 to 50 mg/day) is recommended for patients with recent or current symptoms of heart failure at rest despite the use of ACE inhibitors, diuretics, digoxin, and a  $\beta$ -blocker, regardless of the cause of heart failure, in patients with NYHA class III-IV heart failure and LVEF less than 35%, with adjustment of potassium supplements and close laboratory follow-up. Current ACCF/AHA Guidelines for the Diagnosis and Management of Heart Failure recommend the addition of an aldosterone antagonist in selected patients with moderately severe to severe symptoms of heart failure and reduced LVEF who can be carefully monitored for preserved renal function and normal potassium concentration.<sup>37</sup> Under circumstances where monitoring for hyperkalemia or renal dysfunction is not anticipated to be feasible, the risks may outweigh the benefits of aldosterone antagonists.<sup>90,91</sup> Routine combined use of an ACE inhibitor, ARB, and aldosterone antagonist is not recommended.<sup>37</sup>

In the past decade, several studies have shown that angiotensin receptor blockers (ARBs), when added to background therapy with ACE inhibitors, can result in improvement in combined morbidity and mortality in patients with chronic heart failure,<sup>3,92</sup> both in ischemic or nonischemic dilated cardiomyopathy patients. According to current guidelines, in persistently symptomatic patients with reduced LVEF who are already being treated with conventional therapy, the addition of angiotensin II receptor blockers may be considered.<sup>37</sup> It is important to recognize that in chronic heart failure, the angiotensin receptor blocker trials<sup>3,92</sup> were conducted predominantly in patients with mild to moderate heart failure (NYHA class II to III), whereas the RALES trial<sup>89</sup> (the only aldosterone receptor antagonist trial in chronic heart failure including patients with nonischemic cause) was conducted in patients with severe heart failure (NYHA class III-IV). At the present time, there are no large-scale, prospective, randomized clinical trials with aldosterone receptor blockers in mild to moderate chronic heart failure patients, and there are no head-to-head trials comparing ARBs and aldosterone receptor blockers in the treatment of heart failure, either for ischemic or nonischemic patients.

Digitalis can be beneficial in patients with current or prior symptoms of heart failure and reduced LVEF to decrease hospitalizations for heart failure.<sup>37</sup> Pooled results from the Prospective Randomized Study of Ventricular Function and Efficacy of Digoxin (PROVED) and the Randomized Assessment of Digoxin and Inhibitors of Angiotensin-Converting Enzyme (RADIANCE) trials indicate that digoxin increases LV ejection fraction more in patients with DCM than in patients with ischemic heart disease, and that withdrawal of digoxin leads to a significantly greater likelihood of clinical deterioration in the DCM patients.<sup>93</sup> In the Digitalis Investigators' Group trial,<sup>26</sup> digoxin was associated with a significant reduction in a combined endpoint of death or hospitalization as a result of worsening heart failure in patients in sinus rhythm. This benefit was somewhat greater in patients with nonischemic cause than in those with ischemic cause.<sup>26</sup> That is, patients with DCM were noted to have a 33% risk reduction in the combined endpoint of death and heart failure hospitalization compared with a 21% risk reduction in patients with ischemic cardiomyopathy. The cause of this therapeutic difference is unclear at this point. In a recent retrospective cohort of hospitalized patients with heart failure with LV systolic dysfunction on contemporary background, heart failure treatment including angiotensin-converting enzyme inhibitors and  $\beta$ -blockers, digoxin use was not associated with improvement in survival either in DCM or ischemic cardiomyopathy patients.<sup>94</sup>

Recently, the addition of a fixed dose of isosorbide dinitrate plus hydralazine to standard therapy for heart failure including ACE inhibitors and  $\beta$ -blockers has been shown to

be efficacious in increasing survival among black patients with advanced (NYHA class III-IV) heart failure and LV systolic dysfunction.<sup>95</sup> Interestingly, in 77% to 78% of the patients in this trial, the cause of heart failure was categorized as nonischemic (40% due to hypertension), but the subgroup analysis of outcomes according to the cause of heart failure has not been reported.<sup>95</sup> At the present time, the combination of hydralazine and nitrates is recommended to improve outcomes in African Americans, with moderate to severe symptoms of heart failure on optimal therapy with ACE inhibitors,  $\beta$ -blockers, and diuretics.<sup>95</sup> A combination of hydralazine and a nitrate might be reasonable in patients with current or prior symptoms of heart failure and reduced LVEF who cannot be given an ACE inhibitor or ARB because of drug intolerance, hypotension, or renal insufficiency.<sup>37</sup>

The use of the first generation of calcium antagonists (diltiazem, verapamil, or nifedipine) with negative inotropic effects is considered potentially harmful in patients with heart failure.<sup>37</sup> Recent studies with the second generation of calcium channel blockers, such as amlodipine and felodipine, suggest that these agents may be safer, but do not confer survival benefit in patients with heart failure. Initial reports of survival benefit with amlodipine (PRAISE-I)<sup>29</sup> in patients with dilated but not ischemic cardiomyopathy have failed to be reproduced by the subsequent large-scale randomized trial (PRAISE-II), in which the survival was similar in both the ischemic and nonischemic HF patients. Studies with felodipine showed similar results. In the V-HeFT III trial, felodipine when used as supplementary vasodilator therapy in patients with chronic heart failure was safe but had no additional benefit.<sup>96</sup> At the present time, regardless of the cause of heart failure, calcium channel blockers with negative inotropic effects are not recommended in patients with heart failure and reduced LVEF. Similarly, other drugs known to adversely affect the clinical status of patients with heart failure and reduced LVEF should be avoided or withdrawn whenever possible, including nonsteroidal antiinflammatory drugs and most antiarrhythmic drugs.<sup>37</sup>

**Antiarrhythmic Therapy Implantable Devices.** The role of implantable defibrillators for secondary prevention of sudden cardiac death is clearly established both for the ischemic and nonischemic cardiomyopathy patients (see Chapter 47). Implantable defibrillators decrease sudden death risk in patients with LV dysfunction who have survived sudden cardiac death or sustained ventricular tachycardia or fibrillation.<sup>37,97</sup> For primary prevention, there is a large body of literature supporting the prophylactic use of implantable defibrillators to prevent sudden cardiac death in ischemic cardiomyopathy patients with reduced LVEF postmyocardial infarction.<sup>37,98</sup> and there is recent evidence supporting use in patients with nonischemic dilated cardiomyopathy.<sup>99</sup> Two earlier studies, the Amiodarone versus Implantable Cardioverter-Defibrillator Trial (AMIOVIRT)<sup>100</sup> and the DEFINITE trial,<sup>101</sup> failed to show a significant survival benefit with implantable cardioverter-defibrillator (ICD) therapy in patients with nonischemic cardiomyopathy and heart failure, whereas the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) trial<sup>99</sup> provided the first large-scale evidence of survival benefit with ICDs for primary prevention of sudden cardiac death in patients with DCM. In this trial, in patients with NYHA class II or III heart failure and an LV ejection fraction of 35%, the single-lead, shock-only ICD therapy reduced overall mortality by 23%, whereas amiodarone had no favorable effect on survival. The cause of heart failure was nonischemic in 48%, and the results did not vary according to either ischemic or nonischemic cause. A recent meta-analysis of trials enrolling 1854 heart failure patients with nonischemic cardiomyopathy suggested a 31% significant reduction in total mortality among patients with an ICD or cardiac resynchronization therapy defibrillator (CRT-D) therapy (Figure 24-11).<sup>102</sup>

**FIGURE 24-11** All-cause mortality among patients with nonischemic cardiomyopathy randomized to ICD or CRT-D versus medical therapy in primary prevention revealing significant survival benefit with device therapy in nonischemic cardiomyopathy patients. Number of patients with nonischemic cardiomyopathy enrolled is reported. Size of the data marker corresponds to the relative weight assigned in the pooled analysis using fixed-effects models. ICD indicates implantable cardioverter-defibrillator; CRT-D, cardiac resynchronization plus defibrillator; CI, confidence interval. (From Desai AS, Fang JC, Maisel WH, et al. Implantable defibrillators for the prevention of mortality in patients with nonischemic cardiomyopathy: a meta-analysis of randomized controlled trials. *JAMA* 2004;292:2874-2879, reproduced with permission from *JAMA*. Copyright © (2011) American Medical Association. All rights reserved.)

It should be noted that for patients with standard indications for ICD therapy, but without indication for cardiac pacing, dual-chamber pacing offers no clinical advantage over ventricular backup pacing and may be detrimental by increasing the combined endpoint of death or hospitalization for heart failure.<sup>103</sup> Current ACCF/AHA Guidelines for the Diagnosis and Management of Heart Failure recommend implantable cardioverter-defibrillator therapy for primary prevention of sudden cardiac death to reduce total mortality in patients with nonischemic dilated cardiomyopathy or ischemic heart disease with an LVEF less than or equal to 35%, and NYHA functional class II or III symptoms while receiving chronic optimal medical therapy, and who have reasonable expectation of survival with a good functional status for more than 1 year.<sup>37</sup>

**Medical Antiarrhythmic Therapy.** Studies addressing the role of antiarrhythmic therapy in prolonging survival or preventing sudden death in heart failure have yielded disparate results. The Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure with Amiodarone (CHF-STAT)<sup>27</sup> revealed that amiodarone treatment was effective in suppressing ventricular arrhythmias and improving ventricular function; however, it did not reduce the incidence of sudden death or prolong survival among patients with heart failure, except for a trend toward reduced mortality among those with nonischemic cardiomyopathy. In the trial by Grupo de Estudio de la Sobrevida en la Insuficiencia Cardíaca en Argentina (GESICA),<sup>104</sup> low-dose amiodarone resulted in reduction in total mortality, sudden cardiac death, and heart failure death in both the dilated nonischemic and ischemic patients. As mentioned previously, in the SCD-HeFT trial,<sup>99</sup> amiodarone failed to have any beneficial effect on survival when compared against a placebo in heart failure patients regardless of cause. Presently, antiarrhythmic medical therapy is reserved for individualized treatment of symptomatic arrhythmias, especially for suppression of ventricular arrhythmias after ICD implantation or supraventricular arrhythmias such as atrial fibrillation.

It is important to emphasize that  $\beta$ -blockers have also been shown to reduce sudden cardiac death risk by approximately 30% in patients with ischemic or nonischemic heart failure in addition to their overall benefit in reducing mortality and heart failure hospitalizations.<sup>2,28,88</sup>

**Cardiac Resynchronization Therapy.** Many patients with dilated cardiomyopathy have cardiac conduction abnormalities, such as left bundle branch block or intraventricular conduction delays, which can lead to ventricular dyssynchrony and reduction in stroke volume as a consequence. In patients with heart failure, the presence of left bundle branch block (LBBB) or IVCD further degrades ventricular function, contributing directly to the severity of their heart failure symptoms. Biventricular pacing with transvenous leads in the right atrium, right ventricle, and left ventricle via the coronary sinus can restore cardiac resynchronization (see Chapter 47). Several recent studies: the Multicenter InSync Randomized Clinical Evaluation (MIRACLE)<sup>105</sup>; Multisite Stimulation in Cardiomyopathy (MUSTIC)<sup>106</sup>; Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure (COMPANION)<sup>107</sup>; and Cardiac Resynchronization-Heart Failure (CARE-HF)<sup>108</sup> trials validated the safety and efficacy of cardiac resynchronization therapy in advanced heart failure. Data from these studies have shown statistically significant improvements in LV ejection fraction, New York Heart Association class, exercise tolerance, and quality of life. Furthermore, the COMPANION trial demonstrated that in patients with advanced heart failure and a prolonged QRS interval, cardiac-resynchronization therapy decreased the combined risk of death from any cause or first hospitalization, and when combined with an implantable defibrillator, significantly reduced mortality.<sup>107</sup> However, in the COMPANION trial, the decrease in the risk of death was not significant with cardiac resynchronization therapy alone. The more recent CARE-HF trial<sup>108</sup> demonstrated that in patients with heart failure, class III or IV heart failure due to LV systolic dysfunction (LVEF <35%) and cardiac dyssynchrony (QRS >120 msec and or other evidence of dyssynchrony), cardiac resynchronization improved symptoms and the quality of life, and reduced the risk of death. In these trials the benefit was present both in ischemic or nonischemic heart failure patients. The proposed mechanisms involved in improving ventricular function with biventricular pacing include improved septal contribution to ventricular ejection, increased diastolic filling times, reduced mitral regurgitation, and prevention of progressive remodeling. Resynchronization therapy may also reduce arrhythmias by stabilization of the arrhythmia substrate and by improving the heart failure status. The current ACCF/AHA Guidelines for the Diagnosis and Management of Heart Failure

recommend that patients with LVEF of less than or equal to 35%, sinus rhythm, and NYHA functional class III or ambulatory class IV symptoms, on optimal medical therapy, and a QRS duration greater than or equal to 0.12 seconds, should receive cardiac resynchronization therapy, with or without an ICD.<sup>37</sup> It should be noted that the most recent MADIT-CRT trial demonstrated that in heart failure patients with mild cardiac symptoms (NYHA class I or II), with an ejection fraction of 30% or less and a QRS duration of 130 msec or more, cardiac resynchronization with defibrillator therapy using biventricular pacing did not reduce all-cause mortality, but reduced the combined endpoint of heart failure free survival.<sup>109</sup> The benefit did not differ between ischemic or nonischemic cause. The superiority of cardiac resynchronization therapy was driven by a 41% reduction in the risk of heart failure events, a finding that was evident primarily in a prespecified subgroup of patients with a QRS duration of 150 msec or more. Cardiac resynchronization therapy was associated with a significant reduction in LV volumes and improvement in the ejection fraction. There was no significant difference between the two groups in the overall risk of death, with a 3% annual mortality rate in each treatment group. The result of this, and other future trials, may expand the indication for cardiac resynchronization therapy to relatively asymptomatic patients (NYHA class I or II) with a low ejection fraction and wide QRS complex. It should also be noted that cardiac resynchronization therapy does not confer benefit in heart failure patients with narrow QRS.<sup>110</sup> In a recent trial conducted in patients with heart failure with LVEF less than 35%, QRS of 130 msec, and NYHA class III heart failure, approximately 47% of the patients had heart failure due to nonischemic cause. There was a significant improvement in NYHA class and the 6-minute walking test in the nonischemic stratum but no difference in peak oxygen consumption or quality of life scores with cardiac resynchronization therapy.<sup>110</sup>

**Anticoagulants (see also Chapter 52).** Patients with dilated cardiomyopathy have multiple factors that predispose to thromboembolic events. However, the appropriateness of chronic anticoagulant therapy in DCM has been controversial. The Warfarin and Antiplatelet Therapy in Chronic Heart failure (WATCH) trial, a multicenter, randomized, international trial comparing the efficacy of aspirin, clopidogrel, and warfarin in heart failure patients, was the largest trial of antithrombotic therapies conducted in chronic heart failure patients. It reportedly failed to show any major differences among the three medications to prevent the combined endpoint of nonfatal myocardial infarction, stroke, and mortality.<sup>111</sup> Currently, the Warfarin versus Aspirin in Patients with Reduced Cardiac Ejection Fraction (WARCEF) study, a National Institutes of Health-funded, randomized, double-blind clinical trial, is continuing enrollment to determine whether aspirin or warfarin would improve event-free survival (death or stroke) among patients with LVEF at 35%, who do not have atrial fibrillation or mechanical prosthetic heart valves, and will provide valuable information regarding the role of anticoagulation in heart failure patients. In the absence of controlled trials, the available data do not support the use of anticoagulants in heart failure patients other than those with a history of atrial fibrillation, previous stroke, or other thromboembolic events, or with visible protruding or mobile thrombus on echocardiography.

#### Lipid Modifying Agents

**Statins.** The non-lipid-lowering or pleiotropic effects of 3-hydroxy-3-methylglutaryl coenzyme A reductase inhibitors (statins) have been hypothesized to beneficially alter mechanisms involved in heart failure. In the past, evidence from experimental studies, retrospective analyses, and limited clinical investigations have suggested that statin therapy may

improve ventricular function, heart failure status, and clinical outcomes independent of heart failure cause, and through mechanisms other than statin effects on dyslipidemia. However, two recently published, large, prospective randomized trials did not demonstrate any significant clinical benefit of statins in heart failure patients.<sup>112,113</sup> Despite significant reduction in low-density lipoprotein and high sensitivity C-reactive protein, data from Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto miocardico—Heart Failure (GISSI-HF) trial suggested that rosuvastatin at a 10-mg daily dose did not have any effect on clinical outcomes in chronic heart failure patients of any cause.<sup>112</sup> In the Controlled Rosuvastatin in Multinational Trial in Heart Failure (CORONA), again rosuvastatin treatment did not show any benefit in cardiovascular mortality in older patients with systolic heart failure.<sup>113</sup> At the present time, there is no evidence to support initiating statin therapy in patients with DCM or nonischemic heart failure. This is concept was covered in detail in Chapter 50.

**Polyunsaturated Fatty Acids (PUFA).** Interestingly, in the GISSI-HF trial, long-term administration of 1 g per day of omega n-3 polyunsaturated fatty acids was very effective in reducing both all-cause mortality and cardiovascular admissions, both in ischemic or nonischemic chronic heart failure patients (Figure 24-12). In this trial, 30% of the patients enrolled were with dilated cardiomyopathy, and the benefit of n-3 PUFA was demonstrated in all predefined subgroups, including nonischemic causes.<sup>114</sup> This trial suggests that omega n-3 polyunsaturated fatty acids are helpful in improving clinical outcomes in patients with heart failure.

**Immunosuppression and Immunomodulation in DCM.** Although an autoimmune pathogenesis has been postulated for dilated cardiomyopathy, immunosuppressive therapy has not been shown to be effective in clinical trials. The failure of the Myocarditis Treatment Trial<sup>115</sup> to show a significant benefit for immunosuppressive therapy is discussed in Chapter 31.

Based on its possible immunomodulatory effects, intravenous immunoglobulin has been studied as a potential beneficial agent in patients with dilated cardiomyopathy. Although the exact mechanism of action of intravenous immunoglobulin is not known, a number of different mechanisms have been proposed, including Fc receptor blockade, neutralization of autoantibodies, modulation of cytokine activity, and activation of an inhibitory Fc receptor. It is an effective therapy for Kawasaki disease in children, and it has been reported to improve ventricular function in children with new-onset dilated cardiomyopathy, and in women with postpartum cardiomyopathy.<sup>116</sup> The initial promising results observed in the adult population were not confirmed by the randomized, placebo-controlled, multicenter Intervention in Myocarditis and Acute Cardiomyopathy (IMAC) trial. This topic was further covered in Chapter 11.

The technique of immunoabsorption, removal of autoantibodies with immunoabsorption by passing a patient's plasma over columns that contain immobilized antibodies against immunoglobulin (IgG) kappa and lambda light chains and IgG heavy chains has been reported to be beneficial in DCM. Wallukat et al were the first to show that this technique efficiently removed circulating antibodies directed against the  $\beta_1$ -adrenoreceptor and were associated with an improvement in NYHA functional class in patients with dilated cardiomyopathy.<sup>117</sup> This study was soon followed by other small studies that reported improvement in short-term hemodynamic effects, significant lowering of anti- $\beta_1$ -adrenoreceptor antibodies, significant improvement in LV ejection fraction, and a decrease in LV end-diastolic dimension.<sup>118,119</sup> Therapy with immunoabsorption and subsequent immunoglobulin G substitution has been demonstrated to result in a marked decrease in myocardial HLA-class II antigen expression (Figure 24-13), reduction in CD4 and CD8 lymphocyte cell

**FIGURE 24-12** Kaplan-Meier curves for time to all-cause death or admission to hospital for cardiovascular reasons with n-3 polyunsaturated fatty acids (n-3 PUFA) versus placebo. Estimates were calculated with a Cox proportional hazards model, with adjustment for admission to hospital for heart failure in the previous year, previous pacemaker, and aortic stenosis. (From Tavazzi L, Maggioni AP, Marchioli R, et al. Effect of n-3 polyunsaturated fatty acids in patients with chronic heart failure (the GISSI-HF trial): a randomised, double-blind, placebo-controlled trial. *Lancet* 2008;372:1223-1230, reproduced with permission from *Lancet*.)

HLA-class II antigen before immunoadsorption and IgG therapy

HLA-class II antigen after immunoadsorption and IgG therapy

**FIGURE 24-13** Changes in HLA class II antigen expression of same patient before and after 3-month therapy with IA and subsequent IgG substitution (magnification 400×). (From Staudt A, Schäper F, Stangl V, et al. Immunohistological changes in dilated cardiomyopathy induced by immunoadsorption therapy and subsequent immunoglobulin substitution. *Circulation* 2001;103:2681-2686.)

counts after 3 months, and improvements in LV function and functional status in selected patients with dilated cardiomyopathy.<sup>120</sup> Despite the evidence of mitigation of certain features of myocardial inflammation in select patients, it is important to emphasize the existing gaps in our knowledge with respect to immunoadsorption in patients with dilated cardiomyopathy. At the present time it is unclear whether all patients with dilated cardiomyopathy will benefit from immunoadsorption therapy, or whether patients with elevated levels of circulating autoantibodies should be treated. Second, the mechanism(s) of action of immunoadsorption is

not known. Although studies have demonstrated decreases in circulating autoantibodies, it is not at all clear that a cause-and-effect relationship has been established. Immunoadsorption can lead to a decline in systemic vascular resistance independent of the removal of circulating autoantibodies. Thus part of the hemodynamic benefit that has been observed may be related to vasodilation and not an improvement in LV function. Third, the optimal strategy for immunoadsorption has yet to be determined. Different investigators use different protocols and different immunoadsorbent devices. It is not clear from existing studies whether immunoadsorption alone, which would be expected to modulate humoral immunity, will be sufficient in the long term, or whether it may be necessary to incorporate strategies that lead to suppression of cellular-mediated immunity as well.

One recent strategy of device-based nonspecific immunomodulation therapy, involving reinjection of patients' blood that has been exposed to ex vivo oxidative stress by ozone and ultraviolet light, failed to show any reduction in mortality and cardiovascular hospitalizations in chronic heart failure patients with NYHA functional class II-IV and LV systolic dysfunction. Interestingly, by subgroup analysis, patients with nonischemic cause and NYHA class II heart failure appeared to benefit from immunomodulation therapy (see also Chapter 11). Immunomodulation or immunosuppressive therapies await further validation and identification of specific patients these treatment strategies may benefit.

**Growth Hormone (see chapter 21).** There has been growing enthusiasm for the use of growth hormone in patients with DCM, based on the rationale that there may be inadequate compensatory cardiac hypertrophy in this disorder. Growth hormone and insulin-like growth factor 1 are involved in several physiological processes such as the control of muscle mass and function, body composition, and regulation of nutrient metabolism. Earlier reports suggested that growth hormone therapy could increase myocardial mass and reduce the size of the LV chamber, resulting in improvement in hemodynamics, myocardial energy metabolism, and the clinical

status of the patients with heart failure.<sup>121</sup> Subsequent randomized, placebo-controlled studies of recombinant human growth hormone did not show significant improvement in cardiac performance or clinical status of patients with dilated cardiomyopathy, despite significant increases in LV mass related to changes in serum IGF-1 concentrations.<sup>64</sup> Whether longer treatment with recombinant growth hormone would result in an improved clinical outcome in the patients with DCM is unknown.

**Gene Therapy (see also Chapter 50).** After a decade of preclinical and early phase 1 clinical investigations, gene therapy is proving likely to be a viable alternative to conventional therapies for heart failure. So far in preclinical studies, three types of gene transfer studies have been investigated to enhance myocardial contractility. These include modulating calcium homeostasis (overexpression of SERCa2 by rat or transgenic mice DCM models), manipulating  $\beta$ -adrenergic receptor signaling (transfection or overexpression of the  $\beta$ -adrenergic receptor gene in rat or rabbit DCM models), and augmenting cardiomyocyte resistance to apoptosis (adenoviral gene transfer of antiapoptotic Bcl-2 and Akt in gp130 knockout mice with dilated cardiomyopathy associated with massive cardiomyocyte apoptosis).<sup>122</sup> However, at present, it has been difficult to develop highly effective gene delivery techniques in the myocardium.

Since the identification of the gene for Duchenne muscular dystrophy in 1987, many groups have reported successful approaches for the adenoviral vector delivery of dystrophin, the Duchenne muscular dystrophy gene product, resulting in restoration of dystrophin-associated glycoprotein complex proteins to the sarcolemma and amelioration of muscular dystrophy symptoms in animal models.<sup>123</sup> Although dystrophin is the most extensively studied gene that is implicated in DCM, correction of the dystrophin defects, associated with X-linked cardiomyopathy, has not been fully studied in humans yet.<sup>122</sup>

Angiogenesis and cell therapy are discussed in Chapter 51.

**Treatment of Anemia.** Anemia is very common in heart failure both in nonischemic and ischemic cardiomyopathy patients, and is associated with very poor outcomes. Preliminary data have suggested that treatment of anemia with erythropoietin-stimulating agents is associated with improvement in cardiac function, functional class, and reduction in hospitalizations.<sup>124</sup> However, in a recent randomized placebo-controlled trial of 319 patients, treatment with darbepoetin alfa did not significantly improve exercise duration, NYHA class, or quality of life score in heart failure patients, regardless of ischemic or nonischemic cause.<sup>125</sup> A more definitive, randomized, multicenter clinical trial (Reduction of Events With Darbepoetin Alfa in Heart Failure—RED-HF) is being conducted to determine the efficacy of treatment of anemia with darbepoetin alfa on mortality or heart failure hospitalizations in subjects with symptomatic LV systolic dysfunction and anemia. Until more data are available, the safety or efficacy of these agents or other strategies of treatment of anemia remains unclear in heart failure patients.

**Vitamins, Nutritional Supplements.** Except for omega n-3 polyunsaturated fatty acids, which have been proven to be beneficial in improving clinical outcomes in heart failure patients (see Lipid Modifying Agents section), other dietary or nutritional supplements such as vitamin E or coenzyme Q-10 failed to consistently or significantly improve LV systolic function, quality of life, or other clinical outcomes in patients with heart failure and LV systolic dysfunction in Western populations.<sup>126</sup> At the present time, use of nutritional supplements as treatment for heart failure is not indicated in patients with current or prior symptoms of heart failure or DCM.<sup>37</sup>

**Exercise Training (see also chapter 57).** Many observational or small studies have advocated exercise training to improve clinical outcomes in heart failure patients, but most

did not have adequate statistical power to measure the effects of exercise training on clinical outcomes. The recent Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION), the largest randomized trial on the role efficacy and safety of exercise training among patients with heart failure, enrolled over 2000 patients with heart failure and reduced ejection fraction, 48% of whom had nonischemic causes. In this trial, exercise training resulted in nonsignificant trends for reductions in all-cause mortality, cardiovascular mortality, and hospitalizations. After adjustment for highly prognostic predictors, exercise training was associated with modest but significant reductions for all-cause mortality or hospitalization and cardiovascular mortality or heart failure hospitalizations.<sup>127</sup> The results did not differ according to ischemic or nonischemic cause. Current guidelines recommend that exercise training be considered for medically stable outpatients with heart failure, both for ischemic or nonischemic cardiomyopathy patients. This topic is discussed further in detail in Chapter 57.

**Treatment of Acute Decompensated Heart Failure in DCM.** The standard management of acute decompensated heart failure in hospitalized patients, including identification and treatment of precipitating factors such as hypertension, arrhythmias, infections, pulmonary emboli, renal failure, and medical or dietary noncompliance; diagnostic strategies, including measurement of B-type natriuretic peptide; assessment of adequacy of systemic perfusion, monitoring of volume status; treatment with diuretics, oxygen, salt restriction, vasodilators, inotropic agents, or vasopressors when indicated; invasive hemodynamic monitoring in certain patients with instability and uncertainty of filling pressures; continuation of standard oral heart failure therapies; close monitoring of renal function and electrolytes; and coordination of pre-hospital and posthospital care are very similar in ischemic or nonischemic DCM patients.<sup>37</sup> Recent trials with vasopressin receptor antagonists, nesiritide, or adenosine receptor antagonists initiated for acute treatment of patients hospitalized with heart failure failed to demonstrate any benefit in long-term mortality or heart failure-related morbidity, regardless of ischemic or nonischemic cause. This topic is further discussed in detail in Chapter 43.

**Mechanical Circulatory Support Devices.** Over the past 2 decades, mechanical circulatory support devices have steadily evolved in the clinical management of end-stage heart failure and have emerged as a standard of care for the treatment of acute and chronic heart failure refractory to conventional medical therapy for both ischemic or nonischemic dilated cardiomyopathy patients. Possible indications for using mechanical circulatory support are acute cardiogenic shock as a bridge to transplantation, a bridge to recovery, and more recently, as destination therapy. Because of potential of tissue recovery, DCM patients have been of special interest for studying the reversal of remodeling and improvement in contractile function with cardiac support devices. These modalities are further discussed in Chapter 56.

**Surgical Treatment of Dilated Cardiomyopathy.** For decades, there have been numerous surgical interventions to improve LV performance, reverse or attenuate LV remodeling, lessen contribution from valvular regurgitation in patients with DCM. These interventions ranged from ventricular reconstruction surgery, LV support with dynamic cardiomyoplasty (with use of latissimus dorsi muscle), passive containment devices or Mysplint devices, and mitral valve surgery to partial left ventriculectomy. Despite initial enthusiasm, most long-term studies with partial left ventriculectomy have not demonstrated sustained improvement in clinical outcomes; thus partial left ventriculectomy is not recommended in patients with nonischemic CMP.<sup>37</sup> Left ventricular support with passive containment devices has been associated with sustained beneficial impact on LV size and shape in patients

with DCM, but long-term survival benefit has not been demonstrated. Further studies are being conducted and may provide insight into which patients may benefit from these procedures. This topic is discussed in detail in Chapter 55.

obstruction as a major phenotypic feature of HCM soon led to the description of surgical septal myectomy through a transaortic approach as an effective technique to reduce the outflow tract obstruction, a procedure that is widely known as the Morrow procedure.<sup>9</sup> More recently, Sigwart introduced catheter-based septal ablation typically performed through injection of alcohol into the septal branches of the left anterior descending coronary artery.<sup>10</sup> The latter technique is also effective in reducing the LV outflow tract gradient and for symptomatic relief.

The widespread use of M mode and 2-dimensional echocardiography in the 1970s expanded the phenotypic spectrum of HCM beyond the obstructive form to include concentric LV hypertrophy and asymmetric septal hypertrophy (ASH).<sup>11</sup> Soon Doppler echocardiography emerged as a robust noninvasive method to demonstrate and quantify the LV flow tract obstruction and to characterize cardiac diastolic dysfunction in HCM.<sup>12-14</sup> More recently, tissue Doppler imaging has been applied to delineate myocardial dysfunction, despite preserved global systolic function, and to demonstrate its potential utility to diagnose the disease early and independent of expression of cardiac hypertrophy.<sup>15</sup>

Seidman et al discovered the first causal gene for HCM in 1990 and ushered in the era of molecular genetics.<sup>16</sup> The discovery was a watershed event and it was soon followed by identification of over a dozen causal genes and several hundred mutations and modifier loci.<sup>17</sup> These advances in the molecular genetic basis of HCM have raised interest in genetic-based screening, diagnosis, and risk stratification. However, it has also become clear that the phenotype in HCM is determined not only by the causal mutations but also by the modifier genes and various other genetic and nongenetic factors.

Sudden cardiac death (SCD) has always been the main concern of the patients and physicians alike. The concern is highlighted by the fact that HCM is a major cause of SCD in the young and that SCD often occurs in apparently healthy and asymptomatic individuals.<sup>18</sup> The difficult challenge is in appropriate risk stratification and identification of the subgroup of individuals who are

at high risk for SCD considering that HCM overall is a relatively benign disease.<sup>19</sup> SCD in the young is always tragic, particularly when it occurs in apparently healthy and athletic individuals without any noticeable warnings. In those with warning signs, however, conventional pharmacological interventions, while effective for symptomatic relief, are not known to reduce the risk of SCD. Thus the choice is primarily limited to the effective use of implantable defibrillators in those at high risk for SCD.<sup>20</sup> Recent experimental data in animal models of HCM have raised the potential utility of new pharmacological interventions in the prevention and regression of cardiac phenotype and possibly reducing the risk of cardiac arrhythmias.<sup>21-23</sup> Clinical studies are needed to test the potential utility of new pharmacological interventions in reversing or preventing cardiac phenotype and reducing the risk of SCD in humans with HCM.

## DEFINITION

HCM is a genetic disease of cardiac myocytes. Thus it is primarily a disease of the myocardium. Clinically HCM is diagnosed by the presence of primary cardiac hypertrophy (i.e., cardiac hypertrophy that cannot be fully explained by the loading conditions, valvular diseases, or other external factors).<sup>17</sup> Typically the LV cavity is normal or even small in size because of concentric hypertrophy and global LV systolic function is normal or even hyperdynamic.<sup>17</sup>

## Diagnostic Challenges

Clinical diagnosis, typically based on the echocardiographic findings of cardiac hypertrophy, is usually straightforward. However, there are many diagnostic challenges. The most common is the presence of systemic hypertension, which affects approximately one third of the adult population in the United States and hence may exist concomitantly in patients with HCM. In the presence of systemic hypertension, it is difficult to diagnose HCM with a high level of certainty and yet a significant number of patients with systemic hypertension exhibit a disproportionate hypertrophic response. Such patients

may have an underlying causal mutation for HCM or may have a genetic background that renders them prone to an enhanced hypertrophic response to systemic hypertension. In the former scenario, systemic hypertension could serve as a contributing factor to phenotypic expression of cardiac hypertrophy in HCM. Nevertheless, while conventional, the presence of systemic hypertension or even valvular abnormalities alone is not sufficient to exclude HCM definitively. This dilemma is often encountered in competitive professional athletes who exhibit significant cardiac hypertrophy, necessitating the distinction between pathological hypertrophy of HCM and the physiological hypertrophy of exercise. The distinction is crucial because HCM is the most common discernible cause of SCD in professional athletes and its diagnosis bars them from competitive sports. Clinical clues such as the extent, severity, and the type of cardiac hypertrophy, hyperdynamic left ventricle, small LV cavity size, the presence of outflow tract obstruction, and tissue Doppler or magnetic resonance abnormalities of the myocardium could help to differentiate true HCM from other hypertrophic conditions.

The clinical diagnosis of HCM based on the presence of primary cardiac hypertrophy is also compounded by phenocopy conditions, which are diseases that cause gross cardiac hypertrophy and mimic HCM. Phenocopy conditions include various storage diseases, mitochondrial diseases, triplet repeat syndromes, and others.<sup>24,25</sup> The distinction between true HCM and phenocopy conditions is important as their pathogenesis and treatment differ significantly. The clinical distinction, however, is often difficult because the gross phenotype, namely cardiac hypertrophy, is very similar between true HCM and its phenocopy conditions. Phenotypic features such as the presence of a hyperdynamic left ventricle and outflow tract obstruction would favor the diagnosis of true HCM. In contrast, the presence of depressed global cardiac systolic function, cardiac dilation, conduction defects, or involvement of other organs—such as deafness, neurological abnormalities, and skeletal myopathy—suggest the possibility of a phenocopy condition. Often it is necessary to perform an endomyocardial biopsy for histological examination, including detection of myocyte disarray, which is considered the pathological hallmark of true HCM. Likewise, specific histological staining of myocardial sections could help to diagnose storage diseases. As an example, the phenocopy condition caused by mutations in the  $\gamma 2$  subunit of adenosine monophosphate kinase (AMPK) is due to storage of glycogen in the heart.<sup>25-27</sup> The phenotype is characterized by cardiac hypertrophy, conduction defect, and the preexcitation pattern on the electrocardiogram. Finally, genetic-based diagnosis is expected to provide a clear distinction between true HCM and phenocopy conditions. With advances in the molecular genetic basis of HCM and the phenocopy conditions, one would expect genetic-based screening to provide for a robust distinction between true HCM and its phenocopy. The genetic-based distinction is likely to gain clinical significance as new specific treatments for HCM and phenocopy conditions are developed.

The shortcomings of the current clinical diagnosis of HCM, which is primarily based on an echocardiographic finding of “unexplained” cardiac hypertrophy, have raised the interest in genetic-based diagnosis. Genetic-based diagnosis is expected to provide the opportunity for the preclinical diagnosis of those with causal mutations. Genetic-based diagnosis not only provides the opportunity for an early diagnosis but could have considerable implications for early interventions to prevent the evolution of the phenotype and the risk of SCD. However, for the genetic-based diagnosis to supplant the clinical diagnosis of HCM and become routine, further advances in our understanding of the genetic causes of HCM and in genetic screening techniques would be necessary. Despite the apparent advantages of genetic-based diagnosis and intervention, phenotypic variability of HCM, even in those with an

identical causal mutation, and the complexity of factors that determine the clinical outcome somewhat limit the clinical utility of genetic-based risk stratification. Thus clinical decision making in the management of the patients with HCM should comprise all constituents of the determinants of the phenotype, whether genetic or environmental.

## PREVALENCE

HCM is a relatively common disease with an estimated prevalence of approximately 1 in 500 in the general population.<sup>28</sup> The estimate was based on the presence of LV wall thickness of 15 mm or greater on an echocardiogram in a relatively young population between the ages of 23 and 35 years. This estimate may underestimate the true prevalence of HCM because of the stringent diagnostic criteria used to define HCM because many patients with the causal mutation may express a milder degree of cardiac hypertrophy. Likewise, the estimate was determined in a relatively young population and many young individuals with causal mutations may not exhibit the phenotype yet because of age-dependent expression of the phenotype. Thus a higher prevalence in an older population would be expected. Another caveat is the potential presence of concomitant systemic hypertension, which by definition in most situations excludes the diagnosis of HCM. The prevalence estimate, however, potentially includes those with the phenocopy conditions, defined as conditions that grossly are similar to HCM but are not true HCM as their pathogenesis differs significantly. The prevalence of phenocopy conditions in those with the clinical diagnosis of HCM is unknown but may comprise a significant number of all cases diagnosed clinically as HCM. Thus to determine the precise prevalence of true HCM, large-scale genetic studies in conjunction with clinical studies will be needed.

## PHENOTYPIC MANIFESTATIONS

### Clinical Presentation

Patients with HCM exhibit a diverse array of clinical phenotypes, ranging from a benign asymptomatic course to that of severe diastolic heart failure and SCD. Most patients with HCM are asymptomatic or mildly symptomatic. The most common symptoms are dyspnea, which typically occurs upon exertion; chest pain, which is atypical for being of coronary origin; palpitations, lightheadedness and less frequently syncope. Syncope is usually due to cardiac arrhythmias and less frequently due to hypotension. Recurrent syncope often is a major predictor of SCD and merits full evaluation and treatment.<sup>29,30</sup> Supraventricular arrhythmias including atrial fibrillation and ventricular arrhythmias are the most common cardiac arrhythmias and are important determinants of clinical outcomes.<sup>31,32</sup> Likewise, a small subgroup of patients with HCM exhibits electrocardiographic findings of Wolff-Parkinson-White (WPW) syndrome and therefore may develop AV nodal reciprocating arrhythmias. In the presence of an electrocardiographic pattern of preexcitation, the possibility of phenocopy conditions should be considered.<sup>26,27</sup>

### SCD in HCM

Despite the heterogeneity of the clinical phenotype, the most pressing issue for patients, whether symptomatic or not, and physicians is the risk of SCD. The risk is of particular concern in young competitive athletes because HCM is the most common cause of SCD in this group in the United States.<sup>18,33</sup> Indeed HCM is responsible for approximately half of the cases of SCD in athletes younger than 35 years of age in the U.S. population.<sup>18</sup> This is in contrast to Italy where arrhythmogenic right ventricular cardiomyopathy appears to be the

most common cause of SCD in professional athletes.<sup>34</sup> In both conditions the death is tragic, as SCD often occurs as the first manifestation of the disease in apparently young healthy individuals.<sup>18</sup> SCD typically occurs during or immediately after exercise and often on the sports field.

There is no reliable predictor of SCD in HCM. However, several clinical, pathological, and genetic factors have been identified as major risk factors for SCD in patients with HCM, including a previous episode of cardiac arrest, recurrent syncope, severe cardiac hypertrophy, presence of multiple runs of nonsustained ventricular tachycardia or sustained ventricular tachycardia, and a strong family history of SCD.<sup>35-38</sup> The putative risk factors for SCD in patients with HCM are listed in Box 25-1.

SCD also may occur in the absence of discernible risk factors but the overall risk is low. In the risk stratification and counseling of patients with HCM for SCD, it is important to consider the global risk because the positive predictive value of each putative risk marker is relatively low.<sup>37,38</sup> In general, HCM is a relatively benign disease with an estimated annual mortality of about 1% in the adult population but higher, ranging from 2% to 3%, in children.<sup>19,39-41</sup>

### Morphological and functional features

Cardiac hypertrophy is the quintessential morphological phenotype of HCM, though the degree of cardiac hypertrophy may be mild and gross hypertrophy may be absent in a small fraction of the patients. Likewise, a typical feature of HCM is the asymmetric nature of cardiac hypertrophy with the predominant involvement of the interventricular septum. Indeed, an interventricular septal to posterior wall thickness ratio of 1:3 is considered a major feature. However, cardiac hypertrophy involves the septum and the posterior wall in approximately one third of cases and in a small group of patients hypertrophy is localized to the apex, lateral wall, or posterior wall. Patients with apical HCM may exhibit the unique phenotype of giant T wave inversion in the precordial leads on an electrocardiogram. Patients with apical HCM may experience significant cardiovascular morbidity but have a relatively benign prognosis with a 15-year survival rate of approximately 95%.<sup>42</sup>

The LV cavity size is usually small or at least not dilated. The LV outflow tract is often narrow and could be obstructed to blood flow further because of systolic anterior motion (SAM) of the anterior leaflet of the mitral valve. In a small fraction of patients, the mitral valve may have anatomic malposition and/or an elongated anterior leaflet. The left ventricle is hyperdynamic and LV ejection fraction, a global index of

systolic function, is usually increased or preserved. However, more sensitive indices of LV regional function such as tissue Doppler imaging show impaired myocardial systolic and diastolic function.<sup>43</sup> The typical feature of HCM is impaired cardiac diastolic function and elevated LV end-diastolic pressure, which is the primary reason for symptoms of heart failure in HCM. Occasionally the phenotype of HCM (i.e., concentric cardiac hypertrophy with hyperdynamic left ventricle) evolves into the phenotype of dilated cardiomyopathy (DCM).

Left ventricular outflow tract obstruction (LVOT) at rest is present in approximately 25% of patients with HCM (Figure 25-1). The obstruction is in part caused by anatomical narrowing of the LVOT because of septal and subaortic hypertrophy and in part by dynamic obstruction due to a hyperdynamic left ventricle with a small cavity and SAM of the mitral valve leaflet. LVOT gradient could be provoked using amyl nitrate, exercise, or dobutamine in the majority of patients with HCM. The presence of LVOT obstruction is associated with significant mortality and morbidity in patients with HCM.<sup>44</sup> The LVOT obstruction has characteristic LV systolic pressure peripheral pulse waveforms with two components of early and late systolic waves, the latter referred to as a “bifid pulse.”

### Histopathological features

Cardiac myocyte hypertrophy with pleiotropic nuclei is a common feature. However, the histopathological hallmark of HCM is cardiac myocyte disarray, which is defined as malaligned, distorted, and often short and hypertrophic myocytes oriented in different directions (Figure 25-2). Disarray may comprise 20% to 30% of the myocardium as opposed to less than 5% of the myocardium in the normal heart.<sup>45</sup> Myocyte disarray is commonly found throughout the myocardium but considered more remarkable in the interventricular septum. Myocyte disarray is associated with the risk of SCD in young patients with HCM.<sup>46</sup> Likewise, interstitial fibrosis is a common feature of HCM and is associated with cardiac arrhythmias.<sup>46</sup> Other histopathological phenotypes include a subaortic thickening of the endocardium further compromising the outflow tract, thickening of media of intramural coronary arteries, malpositioned mitral valve, and elongated leaflets. Histopathological phenotypes such as myocyte disarray, hypertrophy, and interstitial fibrosis are associated with the risk of SCD, mortality, and morbidity in patients with HCM.

### MOLECULAR GENETICS

HCM is a genetic disease. It is familial in approximately two thirds of cases and sporadic in the remainder. The mode of inheritance in familial HCM is autosomal dominant.<sup>47</sup> Therefore, 50% of the offspring, males and females equally, will inherit the mutation and will develop the disease sometime in life. An autosomal recessive mode of inheritance has also been described.<sup>48</sup> Sporadic cases are caused by inheritance of germ line de novo mutations from the parents.<sup>49</sup> The causal mutation in a sporadic case will be passed on to the offspring in an autosomal dominant fashion.

The pioneering work of Dr. Christine Seidman et al led to identification of the first causal mutation, namely the R403Q mutation in *MYH7* encoding the  $\beta$ -myosin heavy chain (MyHC) protein in families with HCM.<sup>16</sup> The discovery was soon followed by identification of mutations in *TNNT2* and *TPM1*, coding for cardiac troponin T and  $\alpha$ -tropomyosin proteins, respectively, in families with HCM. Since then more than a dozen causal genes and several hundred mutations in families with HCM have been identified (Table 25-1). Thus HCM is a genetically heterogeneous disease. Nevertheless, all known causal genes, with the exception of those that cause phenocopy states, encode sarcomeric proteins (Figure 25-3).

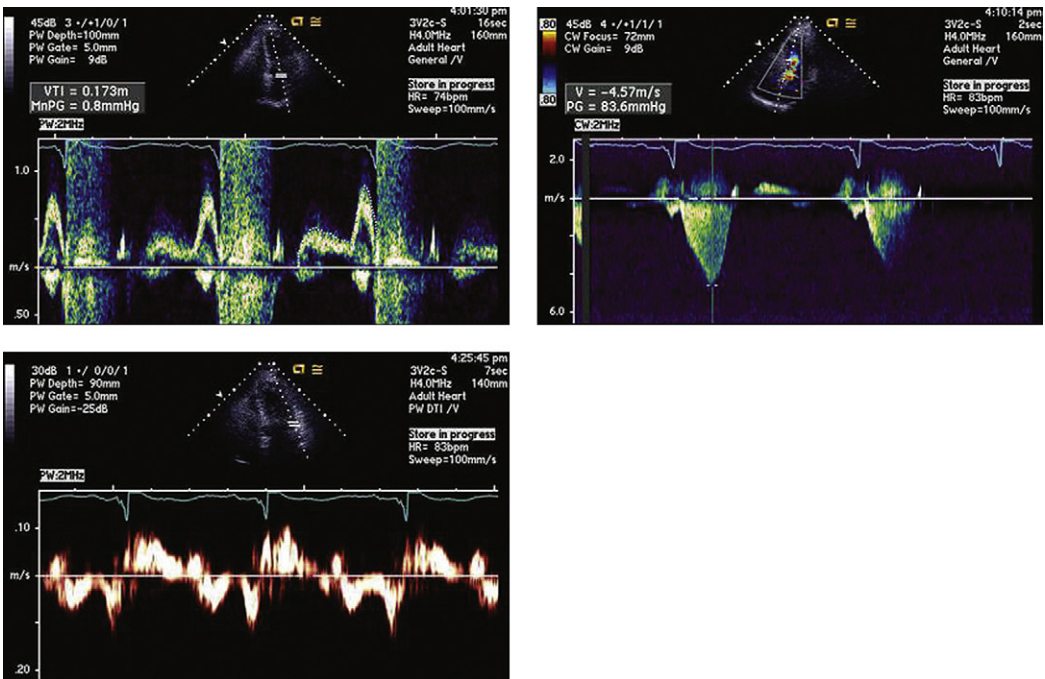

#### BOX 25-1 Potential Risk Factors for SCD in Patients with HCM

##### Established Risk Factors

- Prior episode of cardiac arrest (aborted SCD)
- Family history of SCD (more than 1 premature SCD)
  - Causal mutations, including double mutations
  - Modifier genes
- History of syncope
- Sustained and repetitive nonsustained ventricular tachycardia
- Severe cardiac hypertrophy

##### Probable Risk Factors

- Left ventricular outflow tract obstruction
- Abnormal blood pressure response to exercise
- Severe interstitial fibrosis and myocyte disarray
- Early onset of clinical manifestations (young age)
- Presence of myocardial ischemia

**FIGURE 25-1** Echo/Doppler evaluation of cardiac function in a patient with HCM and severe outflow tract obstruction. **A**, Mitral inflow velocities showing diastolic dysfunction evidenced by decreased E and increased A velocities. **B**, Doppler measurement of left ventricular outflow tract gradient, which is about 40 mm Hg. **C**, Reduced systolic and early diastolic velocities, which are early markers for HCM.

Therefore, HCM is considered a disease of sarcomeric proteins.<sup>50</sup> Perhaps clinically diagnosed HCM could be differentiated into those caused by sarcomeric protein mutations and true HCM, and those caused by mutations in nonsarcomeric proteins and phenocopy conditions, such as glycogen storage disorders.

Causal Genes

Causal genes by definition are those that, whenever mutated, cause HCM, albeit with variable penetrance and expressivity. During the past 2 decades about two thirds of all causal genes for HCM have been identified. The most common causal genes for HCM are *MYH7* and *MYBPC3*, encoding  $\beta$ -MyHC and myosin binding protein C (MyBP-C). Each is responsible for approximately 25% of the HCM cases.<sup>51-54</sup> Several hundred different mutations in *MYH7* and *MYBPC3* in families and individuals with HCM have been identified. Most *MYH7* mutations are located within the globular head of the  $\beta$ -MyHC, which is the site of ATPase activity and binding to cardiac  $\alpha$ -actin. A few mutations in the hinge arm and the rod tail of the  $\beta$ -MyHC also have been described.<sup>55,56</sup> Otherwise, there is no obvious predilection toward concentration of the mutations in a specific domain. A noteworthy difference in the *MYH7* and *MYBPC3* mutations is the prevalence of insertion/deletion mutations in *MYBPC3* as opposed to *MYH7* wherein the vast majority of the mutations are missense mutations. The next most common causal genes are *TNNT2* and *TNNI3*, which encode cardiac troponin T and cardiac troponin I, respectively, each accounting for approximately 3% to 5% of HCM families.<sup>51,57,58</sup>

There are a large number of uncommon causal genes for HCM, including *TPM1* encoding  $\alpha$ -tropomyosin, *ACTC* encoding cardiac  $\alpha$ -actin, *TTN* encoding titin, *MYL3* encoding essential myosin light chain, and *MYL2*, which codes for the regulatory myosin light chain.<sup>59-61,62-64</sup> The spectrum of the causal gene expands beyond the thin and thick filaments of the sarcomere to include genes encoding the Z-disk proteins, such as *TCAP* encoding telethonin, *MYOZ2* coding for myozenin 2 or calsarcin 1 and muscle LIM protein (*CSRP3*).<sup>65-67</sup> Finally, mutations in *TNNC1*, *MYH6*, *MYLK2*,

Established Causal Gene	Protein	Prevalence
<i>MYH7</i>	$\beta$ -Myosin heavy chain	~25%
<i>MYBPC</i>	Myosin binding protein-C	~25%
<i>TNNT2</i>	Cardiac troponin T	~2%-5%
<i>TNNI3</i>	Cardiac troponin I	~2%-5%
<i>TPM1</i>	$\alpha$ -tropomyosin	~2%-5%
<i>MYOZ2</i>	Myozenin 2 (calsarcin 1)	1:250
<i>ACTA1</i>	Cardiac $\alpha$ -actin	<1%
<i>TTN</i>	Titin	<1%
<i>MYL3</i>	Essential myosin light chain	<1%
<i>MYL2</i>	Regulatory myosin light chain	<1%
<i>TCAP</i>	Tcap (Telethonin or titin-cap)	Rare
Possible Causal Genes		
<i>PLN</i>	Phospholamban	Rare
<i>CAV3</i>	Caveolin 3	Rare
<i>MYH6</i>	$\alpha$ -Myosin heavy chain	Rare
<i>MYLK2</i>	Cardiac myosin light peptide kinase	Rare
<i>TNNC1</i>	Cardiac troponin C	Rare

*PLN*, and *CAV3* coding for cardiac troponin C,  $\alpha$ -MyHC, myosin light chain kinase, phospholamban, and caveolin 3 have been reported in patients with HCM.<sup>65,68-71</sup> However, their causal role in HCM is less certain.

Most HCM mutations are missense mutations that typically affect a highly conserved amino acid. However, frame-shift

mutations resulting from an insertion or a nucleotide and splice junction mutations are also found more commonly in *MYBPC3* than the other causal genes.<sup>51,53,72</sup> The frameshift mutations typically lead to premature truncation of the protein, which may not be stably expressed.<sup>73</sup> An important point with implications for genetic testing is the low frequency of each causal HCM mutation and that most mutations are “private.” Another noteworthy point is the presence of double mutations, which have been reported in a small fraction of patients with HCM but are recognized more often because systemic screening of many genes are included in genetic analysis.<sup>74,75</sup>

An important point in genetic studies of HCM is the issue of causality, which is often difficult to establish particularly in sporadic cases or small families whereby the cosegregation of the phenotype with inheritance of the disease cannot be established. Likewise, “there is no perfect protein” because any protein may have a polymorphic variant, including non-synonymous variants. Thus identification of a nonsynonymous variant in an individual with the phenotype should not be interpreted as a causal mutation. One should consider the frequency of the variant in the general population, conservation of the involved amino acid across species, and the biological and functional effects of variants when considering causality. In general, the analogous element of the Koch postulates of causality needs to be fulfilled as much as possible.<sup>76</sup>

### Modifier Genes

Genes that have variants that affect the expression and severity of the phenotype of a single gene disorder are referred to as “modifier genes.” The variants are referred to as the “modifier alleles.” Modifier alleles, unlike causal mutations, are neither necessary nor sufficient to cause HCM. However, when present, they influence phenotypic expression of the disease. In the case of HCM, variants of the modifier genes could influence the severity of cardiac hypertrophy, risk of SCD, and susceptibility to cardiac arrhythmias or heart failure. Modifier genes are partially responsible for the phenotypic variability of HCM.<sup>77</sup> Phenotypic variability of HCM is notable among individuals with different causal mutations and among individuals who have identical causal mutations<sup>77</sup> (Figure 25-4). The influence of the modifier genes on phenotypic expression of HCM is best illustrated in familial HCM, wherein members of the family share an identical causal mutation and yet exhibit significant variation in phenotypic expression.

The interindividual variability in the phenotypic expression of HCM is partially due to the presence of single-nucleotide polymorphisms (SNPs) and structural variants often referred to as copy number variants (CNVs) in the genome. There are several million SNPs and several thousands CNVs in the genome.<sup>78,79</sup> The CNVs, although less frequent than the SNPs, affect about three fourths of all variant nucleotides in the genome.<sup>78</sup> Accordingly, patients with HCM are expected to have considerable SNPs and SVs in their genome, which could affect phenotypic expression of HCM.

We recently performed a genomewide scan in members of a very large family with HCM caused by an insertion mutation in *MYBPC3* and mapped five modifier loci that influence expression of cardiac hypertrophy.<sup>80</sup> The loci, located on 3q26.2 (two separate loci), 10p13, 17q24, and 16q12.2 impart considerable effect on the magnitude of cardiac hypertrophy. The effect sizes range from an approximately 8-to approximately 90-g shift in the LV mass, depending on the heterozygosity or homozygosity of the modifier alleles. The mapped modifier loci encompass several biologically plausible candidate genes including *Grb2* and *ITGA8*, which have been implicated in modulating cardiac hypertrophy and fibrosis in mice.<sup>81,82</sup>

Through candidate gene analysis, several genes have been implicated as the modifiers for cardiac hypertrophy in HCM. Among them is the *ACE*, which encodes the

angiotensin-1-converting enzyme 1.<sup>83,84</sup> The insertion/deletion polymorphism in the *ACE*, which is associated with plasma and tissue levels of ACE1,<sup>85</sup> is associated with the severity of cardiac hypertrophy and the risk of SCD in HCM.<sup>83,84,86</sup> Several other genes have been implicated but not established as potential modifiers in HCM.<sup>17,77</sup> Overall, given the complexity of the molecular biology of cardiac hypertrophy, a large number of genes are expected to influence phenotypic expression of HCM, each imparting a modest effect on the severity of cardiac hypertrophy or the risk of SCD.

### PATHOGENESIS

Identification of the causal genes for HCM has provided the impetus for molecular mechanistic studies that have led to partial elucidation of the molecular pathogenesis of HCM. Nonetheless, the precise molecular events that link the causal mutations to the clinical or morphological phenotypes are largely unknown but appear to involve a diverse array of signaling pathways.<sup>87</sup> One may simplify the link between the genetic mutations and the clinical phenotype into three major stages: initial structural and functional defects (Figure 25-5) in the protein encoded by the causal mutation, which affect not only the protein itself but also its interactions with the other proteins. This is then followed by activation of the signaling molecules, which in turn leads to transcriptional activation of gene expression. The latter leads to molecular, histological, and morphological phenotypes of HCM.<sup>87</sup> The initial functional defects are diverse, which is partly reflective of the diversity of the causal genes and mutations and partly reflective of the diversity of the function of each protein. Among the initial functional defects are altered  $\text{Ca}^{+2}$  sensitivity of myofibrillar ATPase activity,<sup>88-90</sup> actomyosin cross-bridge kinetics,<sup>91</sup> and  $\text{Ca}^{+2}$  sensitivity of myofibrillar force generation.<sup>92-94</sup> The initial functional abnormalities could impart mechanical, biochemical, and bioenergetic stress on cardiac myocytes and activate a series of stress-responsive signaling molecules that induce gene expression. It appears that diverse arrays of genes are expressed and signaling molecules are activated in response to the causal mutations.<sup>95,96</sup> Myocardial bioenergetic deficit as evidenced by changes in the ratio of cardiac phosphocreatine (PCr) to adenosine triphosphate (ATP) has been implicated as a common intermediary phenotype in HCM.<sup>97-99</sup> Metabolic abnormalities including altered myocardial bioenergetics, however, are common to various forms of cardiac hypertrophy and may be a consequence of cardiac stress.<sup>100,101</sup> Other mechanisms may include a direct role for the sarcomeric or Z-disk proteins in instigating the hypertrophic signaling pathways, such as potential activation of the protein phosphatase 2B calcineurin pathway by mutations in myozenin 2.<sup>13,67</sup> Likewise, preferential degradation of the truncated mutant proteins by the ubiquitin-proteasome pathway has been implicated in the pathogenesis of HCM.<sup>102</sup> The initial functional defect is reflected in the whole heart by impaired myocardial contraction and relaxation, which is present before and in the absence of cardiac hypertrophy.<sup>103,104</sup> Thus cardiac hypertrophy and interstitial fibrosis are considered secondary to activation of a diverse array of hypertrophic and profibrotic molecules in response of the initial functional defects imparted by the causal mutation. Accordingly, cardiac hypertrophy, the clinical diagnostic phenotype of HCM, and interstitial fibrosis are potentially reversible through blockade of the intermediary signaling molecules.

In patients with an autosomal-dominant HCM, only one copy of the causal gene and only half of the sarcomeric protein is mutated. Therefore, in HCM caused by missense mutations, which encompasses the majority of the cases, the mutant protein exerts a dominant-negative effect to express the phenotype (poison-peptide hypothesis). A small number of the causal

mutations in HCM are splice-junction or frame-shift mutations. They lead to expression of truncated proteins that could be degraded by the ubiquitin-proteasome pathway and hence lead to a null allele status. The effect of such mutations, therefore, is “haplo-insufficiency.”<sup>73,102</sup> The molecular event that leads to HCM in haplo-insufficiency states remains unclear.

The pathogenesis of myocyte disarray, the pathological hallmark of HCM, appears to be independent of the pathogenesis of cardiac hypertrophy and fibrosis. We have implicated impaired myocyte alignment through the  $\beta$ -catenin-cadherins at the adherens junctions as a potential mechanism for myocyte disarray.<sup>23</sup> Alternative mechanisms include activation of the signaling pathways involved in myocyte axis formation and altered myocardial architecture by excess extracellular matrix proteins.

### Determinants of Cardiac Phenotype in Hypertrophic Cardiomyopathy

The clinical phenotype is the outcome of complex and intertwined interactions between the constituents that contribute to the phenotype. In monogenic diseases such as HCM, the causal mutation is the prerequisite and a major determinant of the phenotype. The phenotype, however, ensues from interactions of the causal mutation with a variety of genetic and nongenetic factors (Figure 25-6). In a sense, the clinical phenotype of single gene disorders is a complex phenotype, determined not only by the causal mutation but also by the modifier genes, noncoding RNAs including microRNAs, posttranslational modification of proteins, and environmental factors. While there is considerable information on the significance of each component in influencing cardiac structure and function in general, their roles in affecting expression of the phenotype in HCM are poorly understood. Nevertheless, the complexity of the factors that determine the clinical phenotype points to the limitation of the genotype-phenotype correlation studies in humans with HCM. Thus in risk stratification of patients with HCM, it is important that all components that contribute to the phenotype are included in the analysis. Likewise, the findings in a small subset of patients with HCM could be restricted to the particular study population and not applicable to the general population of HCM.

Despite the recognized limitations of the genotype-phenotype correlation studies performed in relatively small populations, the causal mutations impart significant impact on the clinical phenotype, including the severity of cardiac hypertrophy and the risk of SCD.<sup>72,105,106</sup> The data suggests that, despite the presence of considerable variability, mutations in *MYH7*, as

opposed to those in *MYBPC3*, are associated with a relatively high penetrance with the expression of significant cardiac hypertrophy relatively early in life.<sup>105</sup> Conversely, mutations in *MYBPC3* generally appear to be associated with a mild phenotype that typically occurs late in life.<sup>72</sup> The relatively low penetrance of certain mutations raises an important clinical point in the management of the relatives of patients with HCM because the normal phenotype in those at risk may reflect the low penetrance. Such individuals may develop the disease later in life.<sup>107</sup> Thus unless the inheritance of the causal mutation is excluded through genetic screening, those at risk should be evaluated periodically. The prognostic impact of the mutations on the risk of SCD is associated with the influence on the severity of cardiac hypertrophy.<sup>108</sup> It also appears that individuals with mutations leading to premature truncation of the protein are associated with more severe phenotypes than the missense mutations.<sup>53</sup> Mutations in *TNNT2* and *TNNI3* are associated with a relatively milder degree of cardiac hypertrophy but more prominent cardiac myocyte disarray and increased risk of SCD.<sup>109</sup> Nonetheless, no phenotype is specific to a specific gene or mutations, and benign and malignant phenotypes have been associated with the common causal genes.<sup>110</sup>

A noteworthy determinant of the clinical phenotype in HCM is the presence of double mutations, whether in *cis* or in *trans*.<sup>51,74,75</sup> Likewise, the presence of concomitant diseases such as hypertension could increase the penetrance and accelerate expression and severity of cardiac hypertrophy. The impact of hypertension on the phenotypic expression of HCM mutations could be illustrated in “hypertensive hypertrophic cardiomyopathy of the elderly,” which may prove to be a form of HCM in conjunction with concomitant hypertension.<sup>111</sup> The impacts of heavy physical exercise, particularly isometric exercises on expression of cardiac hypertrophy and the risk of SCD are yet to be clarified. One may surmise that since hypertrophy is the secondary response of the heart to the causal mutations, heavy exercise could promote cardiac growth and enhance expression of cardiac hypertrophy, and consequently the risk of SCD HCM. Experimental data in a mouse model suggest otherwise.<sup>112</sup> Regardless, because HCM is the most common cause of SCD in young competitive athletes, patients with HCM are advised not to participate in competitive or contact sports.<sup>113</sup>

A fascinating feature of mutations in the sarcomeric protein is phenotypic plasticity. Accordingly, patients with HCM caused by mutations in *MYH7*, *TNNT2*, or *TNNI3* can develop the phenotypes of dilated cardiomyopathy (DCM) or restrictive cardiomyopathy (RCM) during the course of the disease.<sup>114-116</sup> Moreover, mutations in sarcomeric proteins could present from the outset with HCM, DCM, RCM, or LV noncompaction syndrome.<sup>117-119</sup> The molecular basis of such phenotypic plasticity is largely unknown but may reflect the topography of the causal mutations imparting different structural and functional effects on the mutant proteins and/or the effects of modifier genes and noncoding RNAs. The data suggest mutations that cause HCM are associated with enhanced  $\text{Ca}^{+2}$  sensitivity of the myofibrillar force generation and ATPase activity.<sup>93,120-126</sup> In contrast, mutations leading to DCM are associated with reduced  $\text{Ca}^{+2}$  sensitivity of the myofibrillar force generation and ATPase activity.<sup>93,120-126</sup> Likewise, we have shown that mutations in *TNNT2* that cause the contrasting phenotypes of HCM and DCM in humans impart differential effects on protein-protein interactions among the constituents of the sarcomeric filaments.<sup>89</sup>

### Hypertrophic Cardiomyopathy Phenocopy

A phenocopy is a phenotype that falsely mimics the true phenotype. In the case of HCM, a phenocopy condition will express a phenotype that grossly resembles HCM, mainly “unexplained cardiac hypertrophy.” Phenocopy conditions

**FIGURE 25-2** H&E stained thin myocardial section from a patient with hypertrophic cardiomyopathy who died suddenly. There is altered myocardial architecture with evidence of myocyte hypertrophy and disarray.

typically have a different cause and their pathogenesis differs from the disease that they imitate. Accordingly, the phenotype of cardiac hypertrophy in the absence of increased loading conditions could occur in a variety of other conditions, such as storage diseases, mitochondrial disorders, and triplet repeat syndromes (Table 25-2). The prevalence of phenocopy in patients with the clinical diagnosis of HCM is unclear but is estimated to be around 5% to 10%. The prevalence of phenocopy conditions may be higher in children, probably because of early manifestations of the phenocopy conditions.

The most common HCM phenocopy in children is Noonan syndrome, an uncommon autosomal dominant disorder characterized by dysmorphic facial features, pulmonic stenosis, mental retardation, bleeding disorders, and cardiac hypertrophy. In one report approximately one third of children with the clinical diagnosis of HCM had Noonan syndrome.<sup>127</sup> The known causal genes are protein-tyrosine phosphatase, non-receptor type 11 (*PTPN11*), *SOS*, *KRAS*, and *RAF1* genes that collectively account for approximately two thirds of the cases.<sup>128-131</sup> Leopard syndrome (lentiginos, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonic stenosis, abnormal genitalia, retardation of growth, and deafness) is an allelic variant of Noonan syndrome. It is caused primarily by mutations in *RAF1*.<sup>129</sup>

Glycogen storage diseases are relatively common causes of HCM phenocopy. Danon disease is a storage disease caused by mutations in *LAMP2* that codes for lysosome-associated membrane protein 2.<sup>25</sup> Likewise, mutations in *PRKAG2*, which encode the  $\gamma 2$  regulatory subunit of AMP-activated protein kinase (AMPK), lead to glycogen storage in the heart and cardiac hypertrophy, AV conduction defects, and a pattern of preexcitation on the electrocardiogram.<sup>26,27,132,133</sup> Another example of storage diseases mimicking HCM is the Fabry disease, which is an autosomal recessive lysosomal storage disease.<sup>134,135</sup> The estimated prevalence of Fabry disease in the adult population with a clinical diagnosis of HCM is approximately 3%.<sup>135</sup> Cardiac phenotype results from the deposits of glycosphingolipids in the heart. Other features of Fabry disease are angiokeratoma, renal insufficiency, proteinuria, neuropathy, transient ischemic attack, stroke, anemia, and corneal deposits.<sup>136,137</sup> The cardiac phenotype includes hypertrophy, which is often indistinguishable from true HCM, high QRS voltage, conduction defects, cardiac arrhythmias, valvular regurgitation, coronary artery disease, myocardial infarction, and aortic annular dilation. Fabry disease is caused by mutations in the *GLA* gene on chromosome Xq22, which encodes the lysosomal hydrolase  $\alpha$ -Gal A protein.<sup>136</sup> Mutations lead to deficient activity of  $\alpha$ -galactosidase A ( $\alpha$ -Gal A), also known as “ceramide trihexosidase.” Because the causal gene is located on the X chromosome, the disease predominantly affects males and to a lesser extent, female carriers. Fabry disease is diagnosed by the measuring  $\alpha$ -Gal A levels and activity in leukocytes. The distinction between true HCM and Fabry disease is important because enzyme replacement therapy using human  $\alpha$ -Gal A (agalsidase  $\alpha$ ) or recombinant human  $\alpha$ -Gal A (agalsidase  $\beta$ ), is somewhat effective in slowing progression of Fabry disease.<sup>138-140</sup>

Cardiac involvement in triplet repeat syndromes, a group of disorders caused by the expansion of naturally occurring trinucleotide repeats in the genes, includes cardiac hypertrophy that is usually diagnosed as HCM. HCM phenocopy is found frequently in patients with Friedreich ataxia, an autosomal recessive neurodegenerative disease caused by expansion of *GAA* repeat sequences in the intron of *FRDA*.<sup>141</sup> HCM phenocopy in patients with Friedreich ataxia could evolve into DCM. Likewise, cardiac involvement may present as DCM from the outset.

Another important cause of HCM phenocopy is defective mitochondrial oxidative phosphorylation pathways. A prototypic example is Kearns-Sayre syndrome (KSS), which is characterized by a triad of progressive external

**FIGURE 25-3** The vast majority of clinically diagnosed HCM is caused by mutations in sarcomeric proteins. Sarcomeres are comprised of thick and thin filaments and the S disk.

TABLE 25-2	HCM Phenocopy Conditions	
Disease	Causal Gene	Protein
AMPK-mediated glycogen storage	<i>PRKAG2</i>	Protein kinase A, $\gamma$ subunit
Pompe disease	<i>GAA</i>	$\alpha$ -1,4-glucosidase (acid maltase)
Fabry disease	<i>GLA</i>	$\alpha$ -galactosidase A
Danon disease	<i>LAMP2</i>	Lysosome-associated membrane protein 2
Myosin VI	<i>MYO6</i>	Unconventional myosin 6
Kearns-Sayre syndrome	<i>MtDNA</i>	Mitochondrial DNA
Friedreich ataxia	<i>FRDA</i>	Frataxin
Myotonic dystrophy	<i>DMPK</i>	Myotonin protein kinase
	<i>DMWD</i>	
Noonan syndrome	<i>PTPN11</i>	Protein tyrosine phosphatase, nonreceptor type 11
	<i>SOS</i>	Son of Sevenless
	<i>RAF1</i>	Murine leukemia viral oncogene homolog 1
	<i>KRAS</i>	Kirsten rat sarcoma virus homolog
Neimann-Pick disease	<i>NPC</i>	Neimann-Pick
Refsum disease	<i>PAHX (PHYH)</i>	Phytanoyl-CoA hydroxylase

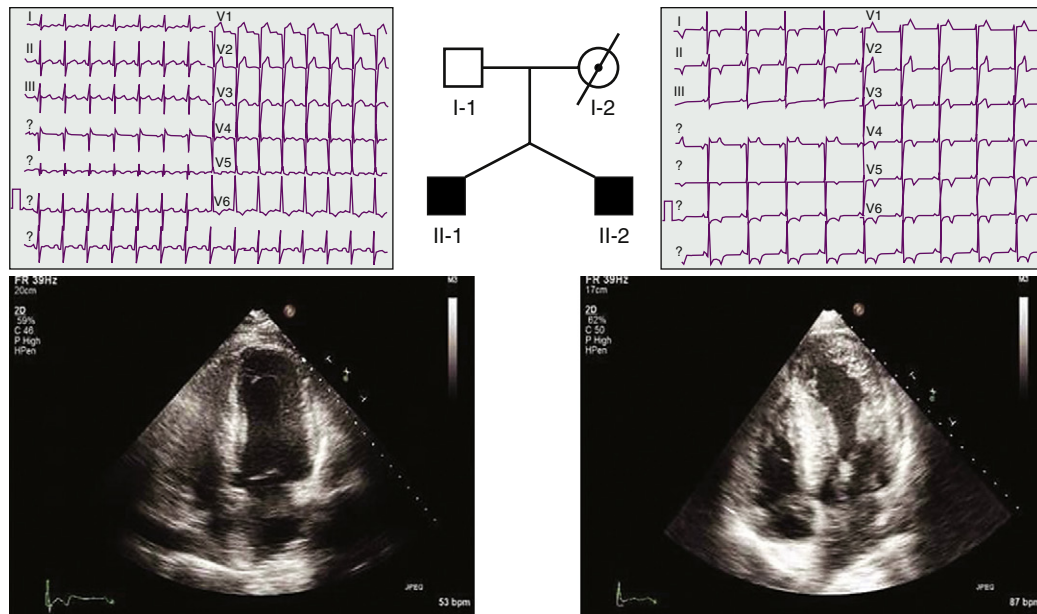

ophthalmoplegia, pigmentary retinopathy, and cardiac conduction defects.<sup>142</sup> Patients with KSS frequently exhibit cardiac hypertrophy diagnosed as HCM. The list of conditions that cause HCM phenocopy is extensive and involves metabolic diseases, such as Refsum disease, glycogen storage disease type II (Pompe disease), Niemann-Pick disease, Gaucher disease, hereditary hemochromatosis, and CD36 deficiency.

## MANAGEMENT OF PATIENTS WITH HYPERTROPHIC CARDIOMYOPATHY

### Genetic Screening

There is considerable interest in genetic testing for HCM by patients and physicians. The interest stems from the potential clinical utility of genetic testing for an accurate diagnosis

**FIGURE 25-4** Phenotypic variability. A truncated pedigree shows twin brothers with HCM caused by S48P mutation in *MYO22*. There is significant variability in the degree of cardiac hypertrophy on 12-lead ECGs and echocardiograms between the two brothers.

**FIGURE 25-5** Pathogenesis of HCM, simplified into three stages of initial structural and functional defects followed by activation of signaling molecules, which lead to secondary gene expression and to HCM phenotype.

of HCM, preclinical diagnosis of mutation carriers independent of and before clinical manifestations of the disease, and possibly prognostication, particularly as it regards the risk of SCD. The demand for genetic testing has led to the development of academic and commercial centers for genetic testing of HCM. Clinicians and patients, therefore, need to familiarize themselves with the strengths and limitations of genetic testing and the implications of the findings. Perhaps the best case scenario for genetic testing is in familial HCM wherein the causal mutation has already been identified and all members of the family could be tested for inheritance of the causal mutation. Genetic testing in such a scenario could lead to accurate distinction of those who have or have not inherited the causal mutation. The implications are twofold: First, with an early and accurate identification of the mutation carriers, the physician could closely monitor such individuals and intervene early. Early pharmacological interventions in animal models of HCM show the potential to prevent evolution of cardiac phenotype in HCM.<sup>22</sup> Inheritance of the causal mutations indicates that the individual will develop HCM, but the severity of HCM cannot be predicted accurately based on the inheritance of the causal mutation. The second implication

**FIGURE 25-6** Major expected determinants of clinical phenotype in patients with hypertrophic cardiomyopathy.

is the accurate identification of those who have not inherited the causal mutation and, for practical purposes, are not at risk of developing HCM except for very rare circumstances.

In the most common scenario for genetic testing, neither the causal gene nor the mutation is known. In large families, one may perform linkage analysis and map the causal gene and identify the mutation. The approach, however, is possible in research laboratories only and is expensive. In smaller size families, linkage analysis does not offer sufficient power to map and identify the causal mutation. In small size families and in sporadic cases, therefore, one is restricted to the candidate gene approach. The screening is complicated by the allelic and nonallelic heterogeneity of HCM and the relatively low prevalence of each causal mutation. Therefore the approach currently focuses on the screening of each individual for the most common causal genes, namely, *MYH7*, *MYBPC3*, *TNNI3*, *TNNT2*, *TPM1*, and *ACTC1*. Typically, the coding regions and the exon-intron boundaries are sequenced to identify the causal mutation. The approach is successful in approximately half of cases. Inclusion of less common causal genes and genes coding for the relatively common phenocopy conditions are expected to increase the chance of finding the

causal mutation slightly. The overall yield of genetic screening at the present time is at best about 60%.

One major clinical implication of genetic testing is the distinction between the phenocopy conditions and sarcomeric HCM. The distinction is important because the treatment of the two conditions differs significantly and enzyme replacement therapy for many phenocopy conditions has shown beneficial effects, as discussed previously. The utility of genetic testing for prognostication is hindered by the presence of considerable phenotypic variability and influence of many other factors on the phenotype, as discussed earlier. Accordingly, information garnered through identification of the causal mutation alone in the assessment of the risk of SCD is inadequate but could supplement the clinical data for risk stratification and management of patients with HCM. In this aspect, a comprehensive approach that uses not only the information content of the causal genes and mutations but also encompasses the potential impacts of the double causal mutations and the modifier alleles and the clinical predictors is necessary to improve risk stratification in patients with HCM.

### Management of Risk of Sudden Cardiac Death

The risk of SCD is the primary concern of patients and physicians alike. The risk factors for SCD were discussed previously and listed in [Box 25-1](#). Pharmacological treatment has not been shown to reduce the risk of SCD in HCM. In contrast, implantation of AICD is effective in secondary and primary prevention of SCD in patients with HCM.<sup>143</sup> However, the specific indication of AICD implantation in various clinical scenarios is less settled. Those with a prior episode of cardiac arrest should undergo complete cardiovascular evaluation and AICD implantation, which has been shown to be effective in secondary prevention of SCD.<sup>143</sup> Coronary angiography to detect atherosclerosis should be performed in a subgroup considered susceptible to atherosclerosis followed by appropriate intervention. A family history of premature SCD is an important risk factor for SCD, particularly whenever it occurs in two or more individuals. Whether a family history of premature SCD alone is sufficient for AICD implantation is debatable. Given the presence of extensive phenotypic variability, additional risk stratification and an individual-based approach is preferable. Recurrent syncope is a major risk factor and necessitates extensive evaluation to determine the cause. In addition to detailed history taking, physical examination, 12-lead ECG, and comprehensive echocardiography, the evaluation should include extended Holter monitoring and event recording, tilt-table testing whenever autonomic dysfunction and orthostatic hypotension are suspected, and electrophysiological studies in specific circumstances. Those with sustained or repetitive episodes of nonsustained ventricular tachycardia on Holter or rhythm monitoring are candidates for AICD implantation. AICD is effective in reducing the risk of SCD in those at high risk of SCD.<sup>143</sup>

Severe LV hypertrophy, while a risk factor for SCD, and LV outflow tract obstruction, probably are not sufficient indications for routine implantation of an AICD. Those with risk factors for SCD undergoing surgical septal myectomy should be reevaluated postoperatively, as surgical septal myectomy appears to impart a favorable outcome on the risk of SCD.<sup>144</sup> In contrast, patients with risk factors for SCD undergoing catheter-based alcohol septal ablation probably should also undergo an AICD implantation because there have been occasional reports of ventricular tachycardia postcatheter-based alcohol septal ablation.<sup>145,146</sup>

### Pharmacological Treatment

Current pharmacological treatment of patients with HCM is largely empirical and unchanged over the past two decades. A large number of patients with HCM are asymptomatic or

minimally symptomatic. Therefore, only periodic clinical and laboratory evaluations that also include assessment of the risk of SCD are recommended. Routine periodic evaluation of such patients should include obtaining 12-lead ECG, 2-dimensional and Doppler echocardiography, and Holter monitoring, the latter particularly in those who have risk factors for SCD. The main focus is on the risk of SCD and early interventions, as AICD appears to be effective even in primary prevention of SCD in high-risk patients with HCM.<sup>143</sup> In asymptomatic individuals at low risk of SCD, no intervention is necessary because none of the existing therapies has been shown to slow or reverse evolution of the cardiac phenotype in HCM.

The cornerstone of pharmacological treatment of symptomatic patients is  $\beta$ -blockers.  $\beta$ -blockers with intrinsic sympathetic activity should be avoided as they could worsen the symptoms. Calcium channel blockers, namely, verapamil and diltiazem but not nifedipine, are the agents of choice in those who do not tolerate  $\beta$ -blockers or are added to  $\beta$ -blockers, whenever symptoms persist. However, in patients with LV outflow tract obstruction, the vasodilatory effects of  $\text{Ca}^{2+}$  channel blockers could precipitate or worsen LV outflow tract obstruction. Disopyramide, which possesses a negative inotropic effect, is effective in reducing LV outflow tract obstruction and ameliorating symptoms.<sup>147</sup> However, it does not affect the overall survival or the risk of SCD.<sup>147</sup> Diuretics are used in those with symptoms of diastolic heart failure, albeit cautiously to avoid volume depletion and precipitation of hypotension. Amiodarone is used primarily for treatment of atrial and ventricular arrhythmias. Patients with new-onset atrial fibrillation should be treated with electrical cardioversion to restore normal sinus rhythm. In general, patients with severe cardiac hypertrophy or outflow tract obstruction who develop atrial fibrillation develop severe symptoms. Every attempt should be made to convert to and maintain such patients in normal sinus rhythm. However, this may prove difficult because of the underlying pathology in HCM. Those with chronic or intermittent atrial fibrillation should be anticoagulated to reduce risk of systemic embolization and stroke. Pharmacological treatment of such patients includes  $\beta$ -blockers, verapamil, and amiodarone, and possibly d-l, sotalol, and dofetilide. Catheter-based ablation should be considered in HCM patients with atrial fibrillation refractory to medical therapy.

### Surgical Myectomy (Morrow Technique) and Catheter-based Septal Ablation (Alcohol Septal Ablation)

A subset of patients with HCM remain symptomatic and refractory to medical therapy, some because of severe diastolic heart failure and others because of severe outflow tract obstruction. Those with a significant LV outflow tract obstruction at rest or provoked and an interventricular septal thickness of 15 mm or greater are candidates for surgical myectomy or catheter-based alcohol septal ablation. Both approaches are effective in relieving the outflow tract obstruction and improving symptoms. Therefore, the choice is largely determined by the presence of concomitant diseases, such as significant valvular lesions and coronary artery disease, which necessitates concomitant surgery and preference for surgical myectomy. Likewise, surgical myectomy is more desirable in those at high risk for SCD. In contrast, the presence of comorbidities that increase the surgical risk significantly favors percutaneous interventions. The advantages and disadvantages of these two techniques are summarized in [Table 25-3](#).

Surgical myectomy (myomectomy), which is referred to as the "Morrow procedure," involves partial resection of the base of the septum through a transaortic approach. It is the procedure of choice in HCM patients who have concomitant

**TABLE 25–3 Comparison of Surgical Myectomy and Ethanol Septal Ablation**

	Surgical Myectomy	Ethanol Septal Ablation
Approach	Cardiopulmonary bypass	Cardiac catheterization
Hospital stay	5-7 days	1-2 days
Perioperative mortality	1%-5%	1%-5%
Procedural success	>95%	>85%
Short-term symptomatic relief	Excellent	Excellent
Long-term symptomatic relief	Excellent	Excellent
Long-term safety	Established	Risk of ventricular arrhythmias
Impact on survival	Favorable	Unknown
Septal infarction/fibrosis	None	Present
Recurrence of LVOT gradient	Rare	Uncommon
Repeat procedure	Rare	Uncommon
Atrioventricular block requiring permanent pacemaker	~2%	10%-20%
Late ventricular arrhythmias	Rare	Uncommon
Postoperative atrial fibrillation	Common	Rare
Significant aortic regurgitation	Infrequent	None
Ventricular septal defect	Rare	None
Correction of concomitant problems	Amenable	NA

coronary artery disease or valvular disorders or have an anatomy that is not amenable to catheter-based septal ablation. It is also preferable in patients at high risk for SCD because the risk of SCD appears to be low after a surgical myectomy.<sup>144</sup> The overall surgical mortality is 1% to 5% but higher in the elderly and those requiring concomitant surgeries, such as coronary artery bypass surgery or valvular repair/replacement.<sup>148,149</sup> The long-term beneficial effects of surgical myectomy in relieving the outflow tract gradient and improving symptoms are well established.<sup>148,149</sup> The recurrence rate and the need for permanent pacemaker implantation are relatively low.

Transcatheter alcohol septal ablation is performed by infusing 1 to 3 mL of pure ethanol into the main septal perforators of the left anterior descending artery. It is also very effective in reducing the outflow tract gradient and improving symptoms.<sup>146,150</sup> Infusion of ethanol into the septal branches induces local myocardial necrosis, which is associated with LV remodeling and partial regression of cardiac hypertrophy.<sup>150,151</sup> The periprocedure mortality rate is low. A major complication is the development of advanced conduction defect requiring permanent pacemaker implantation in 10% to 20% of the patients.<sup>152,153</sup> An uncommon and sometimes late complication of alcohol septal ablation is ventricular arrhythmias, mandating implantation of AICD.<sup>145,146</sup> Overall, transcatheter septal ablation is a very effective procedure for reduction of LV outflow tract obstruction and improvement of symptoms. Its effects on long-term survival and risk of SCD remain to be established.

## Experimental Therapies

The ultimate goal of pharmacological interventions in human patients with HCM is not only to improve symptoms and reduce the risk of SCD but also to prevent the clinical manifestation of the disease in total. However, current pharmacological agents have not been shown to reduce mortality, regress cardiac hypertrophy, or prevent the development of the phenotype. Experimental data in animal models of human HCM have raised the potential utility of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins), inhibitors of the renin-angiotensin-aldosterone system, and antioxidant *N*-acetylcysteine in prevention, attenuation, and regression of evolving phenotypes in HCM.<sup>21-23,154,155</sup> However, whether the results obtained in animal models caused by specific mutations in a more homogeneous genetic background and under controlled environmental conditions could be extended to humans who have heterogeneous genetic and environmental factors remains to be determined. Two pilot studies have shown the potential beneficial effects of the angiotensin II receptor blocker losartan in human patients with HCM.<sup>156,157</sup> A pilot study with atorvastatin, however, showed no beneficial effect on cardiac mass or function in patients with HCM.<sup>158</sup> Large-scale clinical studies in HCM patients genotyped for the causal mutations would be necessary to establish the potential beneficial effects of experimental therapies.

## THE EPIDEMIOLOGY OF DIABETES AND HEART FAILURE

Diabetes mellitus (DM) is a burgeoning public health problem. In the United States, its incidence increased by 61% between 1990 and 2001.<sup>1</sup> It is estimated that more than 20 million Americans now have DM with an additional 50 million categorized as pre-

diabetic based on elevated fasting blood glucose levels.<sup>2</sup> Thus in view of its magnitude as a public health problem and, as is discussed later, its prominent importance as a risk factor for heart failure (HF), DM can be viewed as an epidemic that is directly contributing to the prevalence of another epidemic, that being heart failure.

The Framingham investigators were the first to quantify and call attention to the markedly increased risk of HF in patients with DM (see Chapter 22). In their seminal study,<sup>3</sup> the presence of DM increased the risk of HF by about twofold in men and fivefold in women. This effect, which is *independent of the presence of coexistent coronary artery disease (CAD) and/or hypertension*, has been confirmed in numerous subsequent studies (see references 4-9 for examples) and holds true for both type 1 and type 2 DM. Most studies report an overall independent relative risk for development of HF in patients with DM on the order of 1.5 to 2.0. In a more recent Framingham report,<sup>4</sup> the percentage of HF cases accounted for *solely by DM* was 6% in men and 12% in women. Conversely, among Medicare recipients with a primary hospital discharge diagnosis of HF, a striking 38% had concomitant DM.<sup>10</sup> Both the risk of development of HF<sup>11</sup> and the chance of hospitalization for HF<sup>12</sup> are positively correlated with hemoglobin A1c levels.

As will be seen, the most common clinically recognized effect of DM on the myocardium is diastolic dysfunction (see also Chapter 14). However, the population of patients with nonischemic, dilated cardiomyopathy has an overrepresentation of DM patients,<sup>13</sup> indicating a direct association of DM with both systolic and diastolic HF. Although the increased risk of HF associated with DM is unequivocal, the true magnitude of risk may be somewhat confounded by the fact that HF itself induces insulin resistance.<sup>14</sup>

In addition to its role as a major HF risk factor per se, DM also contributes independently to the risk of developing HF as a complication of acute myocardial infarction (MI), which is independent of infarct size,<sup>15</sup> and to the progression and mortality of established HF<sup>16-18</sup> (Figure 26-1). As noted earlier,<sup>1</sup> DM is a stronger risk factor for development of HF in women than men. It also appears that women with DM and HF have worse outcomes than their male counterparts.<sup>19-21</sup>

For a more detailed reading on this topic the reader is referred to the review by Masoudi and Inzucchi.<sup>22</sup>

## Diabetic Cardiomyopathy: Mechanisms of Myocardial Damage

The powerful epidemiologic evidence linking DM to HF led to consideration of the possibility that DM is directly causal in the development of cardiac dysfunction. The earliest suggestion of this is credited to Rubler et al,<sup>23</sup> who described four patients with diabetic nephropathy and cardiomyopathy in the absence of angiographically detectable CAD. Subsequently, the existence of a

diabetic cardiomyopathy has become well accepted.<sup>22,24-26</sup> Although diabetic cardiomyopathy can cause HF and/or evidence of myocardial dysfunction on its own, it is much more common for it to act in concert with the comorbidities of CAD, hypertension, and obesity. The contribution of diabetic cardiomyopathy to HF is inevitably difficult to sort out when these other common accompaniments of DM are present.

Diabetes is a complex disorder and multiple interconnected features of the disease mechanistically contribute to the development of diabetic cardiomyopathy.<sup>22,24-26</sup> Each of these features can cause multiple functional consequences and generally more than one is operative in an individual patient. Moreover, the relative importance of one or another underlying mechanism is dependent on whether the patient has type 1 or type 2 DM, the duration of disease, and very likely its management. In addition, much of the mechanistic information about diabetic cardiomyopathy has been derived from various animal models, all of which exhibit various differences when compared with the human disease. As shown in Figure 26-2, despite this complexity three key metabolic derangements—hyperglycemia, increased nonesterified fatty acid (FA) concentration, and hyperinsulinemia—appear to play central roles in this disease process (see also Chapter 20).<sup>24-26</sup>

### Hyperglycemia

**Reactive Oxygen Species (see Chapter 12).** In type 2 DM, where hyperinsulinemia is present, hyperglycemia may result in increased glucose oxidation and generation of superoxide, peroxynitrate, and other reactive oxygen species (ROS) in tissues such as the myocardium that are not strongly insulin resistant<sup>26-29</sup> (see Figure 26-2). ROS react with cellular proteins and nucleic acids, leading to various deleterious effects. These include oxidation and nitration of proteins directly involved in contraction and relaxation; uncoupling of mitochondrial oxidative phosphorylation, leading to impaired energetics; and DNA damage and cell death.<sup>24,26-33</sup> ROS can directly affect both calcium cycling and contractile protein function. DM-induced oxidative changes in both the sarcoplasmic reticulum ATPase

(SERCA-2) and myosin can directly inhibit the function of these proteins.<sup>33,35</sup> ROS also appear to play a central role in the pathogenesis of diabetic cardiomyopathy by directly contributing to hyperglycemia-mediated activation of protein kinase C<sup>33</sup> and protein glycation and the subsequent formation of advanced glycation end products (AGEs) (discussed in more detail later).

The importance of ROS is highlighted by the fact that increased expression of the antioxidants metallothionein or superoxide dismutase (SOD) in mouse models of DM prevented the development of cardiomyopathy.<sup>29,35,36</sup>

**FIGURE 26-1** The effect of diabetes on survival in patients with established heart failure (HF). (Reproduced from AM, Leibson CL, Bursi F, et al. Diabetes in heart failure: prevalence and impact on outcome in the population. *Am J Med* 2006;119:591-599 [reprinted with permission of the *American Journal of Medicine*].) DM, Diabetes mellitus

Inhibition of ROS production through overexpression of SOD in hyperglycemic endothelial cells has been shown to prevent increased glucose flux through the aldose reductase pathway, increased intracellular AGE formation, and the increase in PKC activation associated with hyperglycemia and DM.<sup>37</sup> Peroxynitrite (ONOO<sup>-</sup>), which causes protein nitration, has been specifically linked to mitochondrial dysfunction in a mouse model.<sup>38</sup>

**Protein Glycation and AGE Formation.** Protein glycation and the production of AGEs are important components of hyperglycemia-mediated myocardial damage.<sup>39-42</sup> Protein glycation results from enhanced production of dicarbonyl species (glyoxal, methylglyoxal, and 3-deoxyglucosone) that nonenzymatically react with protein amino groups under conditions of hyperglycemia and oxidative stress. The initial process of protein glycation involves the reaction of a carbonyl group of glucose with the amino group of a protein to form a Schiff base (Figure 26-3). This process differs from glycosylation because the reaction is not driven by an enzymatic catalyst. This initial reaction is reversible but the carbonyl-protein adduct is eventually converted to a more stable Amadori product. Amadori products are gradually modified to form AGEs, which are very long-lasting and retard the degradation of proteins, most notably collagen. This series of chemical reactions is known collectively as the Maillard reaction (see Figure 26-3). AGEs can also form protein cross-links.<sup>39,40,43-46</sup> Largely through the work of Cerami et al, protein glycation and AGE formation have been recognized for many years as important mechanisms of the complications of DM.<sup>47</sup>

The effects of protein glycation are twofold. Glycation can directly affect protein function<sup>34,35,39,40,45</sup> and AGEs interact with the cell membrane receptor for advanced glycation end products (RAGE),<sup>39,48-52</sup> which are present in a number of cells including fibroblasts. As shown in Figure 26-4, activation of

**FIGURE 26-2** An overview of the effects of hyperglycemia, increased nonesterified fatty acids, and insulin resistance as mechanisms of myocardial damage in diabetes (see text for details). NEFA, nonesterified fatty acids; ROS, reactive oxygen species; PKC, protein kinase C.

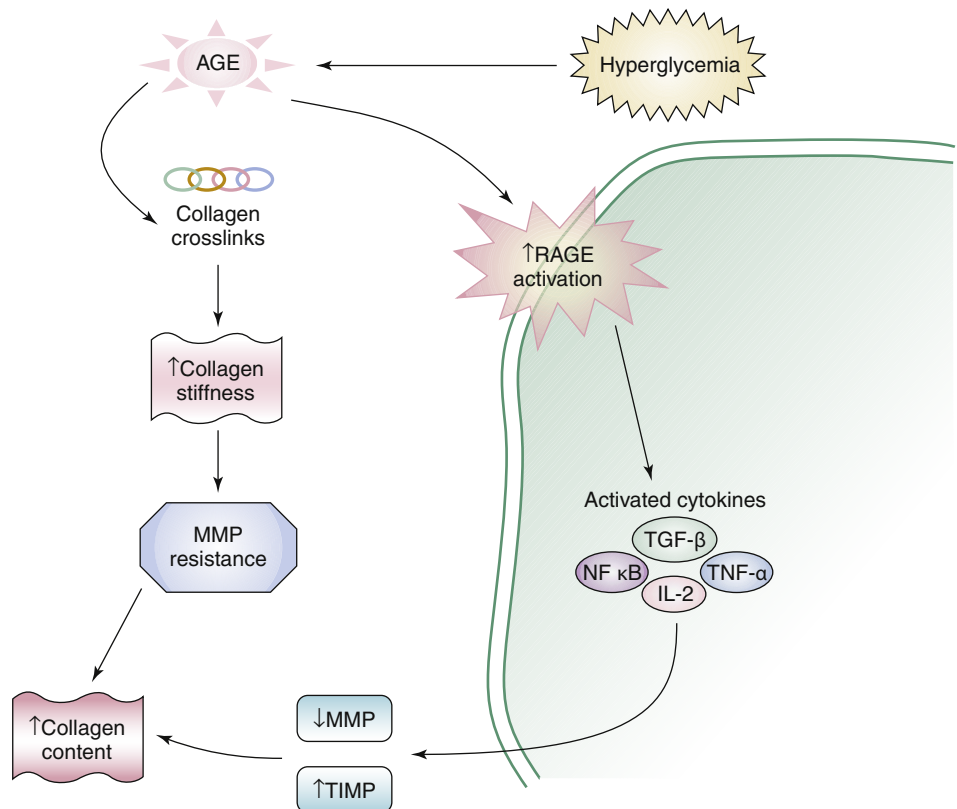

RAGE by AGEs increases the activity of several signaling proteins and inflammatory cytokines, most notably nuclear factor  $\kappa$ B (NF  $\kappa$ B), tissue growth factor- $\beta$  (TGF- $\beta$ ), interleukin-2 (IL-2), and tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ). In addition RAGE activation promotes ROS production. RAGE expression increases with increased abundance of its ligands, thus creating a vicious cycle. RAGE blockade slows the progression of experimental atherosclerosis,<sup>49-51</sup> whereas overexpression of RAGE in murine cardiocytes resulted in slowing of calcium dynamics leading to depressed myocyte contraction.<sup>52</sup>

Both contractile and calcium cycling proteins are modified by glycation and/or AGEs. In vitro, the function of myosin<sup>35,53</sup> and myofilament assembly are adversely affected by glycation.<sup>54</sup> In addition, SERCA-2 and the ryanodine receptor have been shown to be subject to glycation and AGE formation in the streptozotocin (STZ) rat model of DM.<sup>55,56</sup> SERCA-2 glycation was reversed by insulin treatment. Intracellular AGE formation is likely closely related to the aforementioned excess superoxide production.

As shown in Figure 26-4, AGEs can also form in the extracellular matrix of the myocardium as adducts to collagen.<sup>39,40,42,44-46,57</sup> Here, AGEs can form cross-links between adjacent fibrils, which increases the stiffness of collagen. Moreover, the presence of crosslinks renders collagen more resistant to degradation by matrix metalloproteinases (MMPs). The aforementioned AGE-RAGE interaction results in a pro-inflammatory, profibrotic signaling cascade that ultimately results in changes in MMPs and tissue inhibitors of MMPs (TIMPs) that favor collagen accumulation.<sup>34,35,39,40,45</sup> Thus the net result of AGEs is an increase in the content of collagen, which itself is abnormally crosslinked. These processes make AGEs a prime candidate mechanism in the development of DM-associated diastolic dysfunction in humans.<sup>58</sup> This concept is supported by the fact that AGEs stiffen collagen in nonmyocardial tissue in humans and in the hearts of animal diabetic models.<sup>59,60</sup> Although scant information is available in human myocardium, AGEs have been detected by light microscopy using antibody labeling.<sup>61,62</sup> Recently, using

**FIGURE 26-3** The Maillard reaction sequence, in which protein glycation gradually leads to the formation of AGEs. AFGP, antifreeze glycoprotein; CML, carboxymethyl lysine. (From Fraser D.A., Hanssen K.F.(2005). Making sense of advanced glycation endproducts and their relevance to diabetic complications. International Diabetes monitor. 17(3):1-7.)

**FIGURE 26-4** Schema of the effects of AGE formation on collagen cross-linking and content (see text).

immunoelectron microscopic techniques, we detected AGEs associated with collagen fibrils in human myocardial biopsies obtained from patients with DM at the time of coronary artery bypass grafting (Figure 26-5, *left panel*). Finally, in diabetic animal models the AGE crosslink breaker alagebrium has been shown to decrease myocardial fibrosis and improve ventricular function.<sup>59</sup>

**Protein Kinase C Signaling (see also Chapter 2).** A number of circulating neurohormones, most importantly angiotensin II, are increased in DM.<sup>63</sup> Angiotensin II can directly affect intracellular signaling by binding to one of a family of seven transmembrane receptors.  $\beta_1$ - and  $\beta_2$ -adrenergic,  $\alpha$ -adrenergic, and endothelin signaling occurs through this same receptor family<sup>64</sup> (Figure 26-6). Common to all of these receptors is the close intracellular association with specific GTP binding proteins (or G proteins, consisting of  $\alpha$ ,  $\beta$ , and  $\gamma$  subunits and an effector enzyme). When an agonist binds to the receptor, GDP is released from the  $\alpha$  subunit allowing GTP to bind and

leading to disassociation of the  $\alpha$  subunit-effector enzyme and the  $\beta$ ,  $\gamma$  subunit from the agonist-receptor. G protein subunit isoform variation allows for association with specific effector enzymes. Upon activation of the receptor,  $G_{\alpha}$  coupled phospholipase- $C\beta$  is activated, hydrolyzing the membrane bound phospholipid, phosphatidylinositol 4,5 bisphosphate, to yield diacylglycerol (DAG) and inositol 1,4,5- triphosphate. DAG is the primary activator of most protein kinase C (PKC) isoforms. In DM, DAG synthesis is increased, in part via ROS-mediated activation of the DNA repair enzyme poly (ADP ribose) polymerase (PARP).<sup>28</sup> Thus both enhanced 7 transmembrane receptor activation and increased DAG synthesis contribute to PKC activation in DM.<sup>30</sup> In animal models of DM, increases in the myocardial activity of PKC isoforms  $\alpha$ ,  $\beta$ ,  $\epsilon$ , and  $\delta$  have been observed.<sup>65</sup>

A number of PKC isoforms are known to directly affect both myofilament function and calcium cycling.<sup>66,67</sup> At the myofilament level, PKC can phosphorylate troponin I, troponin

T, myosin binding protein C, myosin regulatory light chain, and titin. In animal models of HF and in human end-stage HF phosphorylation of troponins I and T directly modulates thin filament function leading to a depression in maximal contractile force, a process that is likely mediated by PKC.<sup>66,67</sup> In addition PKC activates protein phosphatase 1, which dephosphorylates phospholamban and inhibits SERCA-2 activity.<sup>68</sup> Sodium-calcium exchanger function may also be impaired by PKC.<sup>69</sup>

PKC also activates extracellular signal-related kinases 1 and 2 (ERK 1/2) of the mitogen-activated protein kinase (MAPK) family.<sup>64,70</sup> Activation of the ERK 1/2 pathway has been demonstrated to be an important mediator of the hypertrophic response in heart failure.<sup>71</sup> Current evidence suggests that the cascade is triggered by PKC-mediated activation of the “small” GTP binding protein, Ras. Ras activates Raf (a MAPK), which phosphorylates ERK 1/2, resulting in the activation of several transcription factors and inducing a hypertrophy gene program (see Figure 26-3). The ERK 1/2 pathway is also activated by several growth factors and mechanical stress-mediated signaling mechanisms.<sup>70</sup> Thus PKC signaling likely contributes to cardiac hypertrophy in DM (see later discussion).

#### Nonesterified Fatty Acids

As shown in Figure 26-2, nonesterified FA concentration and oxidation are characteristically increased in DM.<sup>22,24-26</sup> Triglycerides are also elevated and may be observed as lipid droplets in cardiac myocytes in animal models of type 2 DM.<sup>72</sup> The high concentration of FAs is itself a mechanism of the insulin resistance characteristic of type 2 DM.<sup>25,26</sup> This may be related to activation of PKC- $\theta$ , which interferes with the binding of insulin to insulin receptor-1.<sup>25</sup> Excessive FA oxidation in the cardiac myocyte results in accumulation of toxic, long chain FAs in the cytoplasm as the capacity of the mitochondria to process FAs is exceeded.<sup>24-26,72</sup> Lipotoxicity caused by increased cardiac myocyte FA and long chain FAs may directly impair cardiac contractility due to alterations in membrane-associated ion channel and pump function.<sup>73</sup> For example, excess FAs induce opening of the  $K_{ATP}$  channel resulting in shortening of the action potential duration.<sup>74</sup>

Accumulation of FAs also leads to increased use of alternative metabolic pathways that increase ceramide generation.<sup>24-26</sup> This may in part be mediated by peroxisome-proliferator-activated receptor- $\alpha$  induction.<sup>75</sup> Ceramide is an important activator of NF- $\kappa$ B and caspase 3, which in turn activate proapoptotic and proinflammatory signaling pathways. Increased ROS may also contribute to apoptotic signaling. Increased myocardial apoptosis has been demonstrated in animal DM models<sup>76</sup> and in patients with DM.<sup>77</sup> A recent study reported a markedly increased proportion of apoptotic cells in biopsy specimens from nonischemic cardiomyopathy patients with DM versus those without DM.<sup>78</sup>

#### Hyperinsulinemia

Hyperinsulinemia is present only in type 2 DM, and therefore does not contribute to cardiomyopathy in type 1 DM. Cardiac hypertrophy is perhaps the most important consequence of hyperinsulinemia.<sup>24,79,80</sup> Patients with DM have been shown to have increased cardiac mass independent of co-existent hypertension.<sup>79,80</sup> Multiple mechanisms are probably responsible for hypertrophy in DM.<sup>24</sup> PKC signaling is enhanced by hyperinsulinemia and, as mentioned earlier, can directly contribute to the hypertrophic response.<sup>70,71</sup> Insulin acutely augments glucose uptake via activation of a tyrosine kinase receptor-mediated Akt-1 pathway<sup>81</sup> (Figure 26-7). Akt-1 inactivates glycogen synthase kinase-3 $\beta$ , an inhibitor of nuclear factor in activated lymphocytes (NFAT-3), a key hypertrophy mediator. Hyperinsulinemia-mediated increased sympathetic activation may also function to augment Akt-1 activity.<sup>81</sup> The tyrosine kinase pathway also contributes to PKC activation (see Figure 26-7). Finally, insulin is an activator of the MAPK hypertrophic pathway.<sup>82</sup>

#### Diabetic Microvasculopathy

When the concept of diabetic cardiomyopathy was first proposed, “small vessel” disease (i.e., diabetic microvasculopathy) was offered as the likely mechanism. Subsequently, correlations between manifestations of microvascular disease (e.g., nephropathy, retinopathy) and the presence of HF or subclinical diastolic dysfunction have been reported.<sup>83-86</sup> However, a clear mechanistic link between diabetic

**FIGURE 26-7** Schema of insulin activation of a tyrosine kinase-mediated signaling pathway that contributes to cardiac hypertrophy and PKC activation (see text).

cardiomyopathy and microvasculopathy has not as yet been established.<sup>86</sup>

## Functional and Morphological Manifestations of Diabetic Cardiomyopathy

### Animal Models

Much of our understanding of the mechanisms and functional consequences of diabetic cardiomyopathy is derived from animal models. STZ, a direct pancreatic islet cell toxin, has been the most widely employed means to induce DM, most commonly in rats.<sup>24,26</sup> STZ mimics human type I DM with hyperglycemia and hypoinsulinemia. Alloxan<sup>87</sup> has been used mainly in larger animals to produce relatively mild type 1 DM. Type 2 insulin resistance models have also been widely employed, for example, leptin deficient db/db mice<sup>88</sup> and the Zucker fatty rat.<sup>89</sup> Depressed systolic function has been observed in virtually all of these models but tends to be more prominent in type 1 DM. In type 2 models, changes in diastolic function are generally more prominent, resembling human type 2 DM.<sup>90</sup> By echocardiography, these changes include increased isovolumic relaxation time and alterations in mitral inflow and pulmonary venous flow patterns.<sup>84,90-92</sup> Changes in systolic function are also common in type 2 models but typically include decreases in fiber shortening and ejection rates, with fractional shortening unchanged. Correspondingly, isolated heart preparations reveal slowed rates of pressure development and decline. Similar changes are observed in isolated cardiac myocytes.<sup>93</sup>

### Alterations in Calcium Cycling

In animal models of both type I and type II DM, alterations in calcium cycling are well documented.\* These include reductions in the rate of calcium release from the sarcoplasmic reticulum (SR), peak cytosolic systolic calcium concentration, the rate of SR calcium sequestration, and SERCA-2 activity. As noted earlier, ROS and AGEs may play a role via posttranslational modification of the proteins involved in calcium cycling. Thus in STZ rats, SERCA-2 and the ryanodine receptor have been shown to be glycated with both non-crosslinked and crosslinked AGEs.<sup>55,56</sup> As noted earlier, overexpression of the AGE receptor results in slowing of calcium dynamics,<sup>52</sup> further supporting a role for AGEs in the pathophysiology of diabetic cardiomyopathy in STZ rats.

These changes in calcium cycling proteins contribute to changes in cardiac function by reducing calcium available for activation of the myofilaments and decreasing late systolic calcium clearance, resulting in continued cross-bridge formation in early diastole and impaired and/or incomplete relaxation. Transgenic overexpression of SERCA-2 in an STZ mouse reversed the contractile and relaxation deficits, consistent with an important functional role for altered calcium cycling in this model.<sup>96</sup> Reduced calcium extrusion by the sarcolemmal sodium calcium exchanger may also contribute to abnormalities in relaxation, as may the increased expression of phospholamban, which binds to SERCA-2 and inhibits its function.<sup>26,34</sup>

In excitable strips dissected from human epicardial biopsies from patients at the time of coronary artery bypass grafting, the force frequency relation was found to be moderately depressed in patients with DM.<sup>97</sup> The force frequency relation is a key mechanism of adaptation to increased functional demands on the myocardium. It is profoundly depressed in end-stage, failing myocardium, and has been related to altered calcium cycling.<sup>98</sup> Thus force frequency relation

depression in DM patients could reflect the same underlying abnormality.

### Alterations in the Myofilament (see also Chapter 3)

Sarcomere shortening is the result of cyclic cross-bridge formation between the myosin “head” formed by the myosin heavy chain (MHC) and active sites on actin. The process is regulated by the thin filament associated proteins, troponin (Tn) C, I, and T, and tropomyosin. Ventricular myocardium is composed of two MHC isoforms,  $\alpha$  and  $\beta$ . Normal rodent myocardium is composed predominantly of  $\alpha$ -MHC while normal human myocardium is predominantly  $\beta$ -MHC.<sup>99</sup> Major increases in the proportion of the  $\beta$ -MHC isoform are observed in rodent models of HF and STZ DM.<sup>100,101</sup> Compared with  $\alpha$ -MHC,  $\beta$ -MHC exhibits slower kinetics as it interacts with actin. This myosin isoform shift likely contributes to the depressed contractile parameters observed in STZ DM. Since nonfailing human myocardium is composed of predominantly  $\beta$ -MHC, any myosin isoform shift toward the  $\beta$  isoform in *patients* with DM would be small and thus not likely to be functionally important.<sup>99</sup> In STZ rats, an increase in TnI phosphorylation has been reported, which may affect contractile protein function.<sup>102</sup> In humans, maximal myofilament contractile force and calcium sensitivity is decreased in detergent-treated (skinned) myocardial strips obtained from patients with DM.<sup>103</sup> These preparations are used to assess myofilament function independent of changes in calcium cycling. The changes in myofilament function in this human study were associated with an increase in TnI and TnT phosphorylation. TnI and TnT phosphorylation have complex effects on myofilament contractile function<sup>67</sup> and could also contribute to impaired ventricular contraction and relaxation. Finally, depressed optimal frequency of work production and power generation in skinned strips from female but not male coronary artery bypass patients with DM has been reported.<sup>104</sup> This could possibly help explain poorer outcomes in women with HF and DM.

As with calcium cycling proteins, posttranslational modification of myofilament proteins by ROS and AGEs may also contribute to myofilament dysfunction. In this regard, in addition to detecting AGEs in association with collagen fibrils, we have also identified AGEs in myofilament sections in biopsy specimens from patients with DM (see Figure 26-5, right panel).

### Ultrastructural Changes and Passive Myocardial Stiffness in Diabetes Mellitus (see also Chapter 5)

Myocardial collagen content is determined by the balance between synthetic pathways and degradation by matrix metalloproteinases (MMPs).<sup>105</sup> MMP activity is modulated by tissue inhibitors of MMPs (TIMPs). AGEs, renin-angiotensin-aldosterone system activation, and other elements of neurohormonal and proinflammatory signaling are key profibrotic modulators of this balance and play important roles in DM.<sup>106</sup>

Animal models of DM often demonstrate increased collagen content, but this is more consistent and prominent in human myocardium.<sup>106</sup> Factor et al quantified fibrosis in postmortem specimens from patients with DM, hypertension, and their combination.<sup>107,108</sup> In addition to increased collagen in DM patients, they noted a striking synergistic effect of the combination of DM and hypertension on collagen content. The apparent differences between animal models and patients may simply reflect differing duration of disease. van Heerebeek et al<sup>62</sup> recently published a report in which left ventricular (LV) endomyocardial biopsies from patients with DM and HF and either normal or reduced ejection fraction (EF) were compared. LV chamber stiffness was increased in both DM patient groups. Collagen volume fraction was greater in DM patients with reduced EF, but this study did not contain a group without DM for comparison. Despite evidence that myocardial collagen

References 26, 34, 52, 55, 56, 94, 95.

content is increased as well as abnormal noninvasively derived indexes of diastolic function in patients (see later discussion), there are no reports of direct measurements of myocardial passive stiffness in animal models or patients with DM.

Cardiac myocyte hypertrophy is the other main ultrastructural feature of diabetic cardiomyopathy, and has been discussed earlier.

## Clinical Features of Diabetic Cardiomyopathy

### *Role of Diabetic Cardiomyopathy as a Mechanism of Heart Failure Symptoms*

Although the increased risk of developing HF in patients with DM has been amply documented, in individual patients its precise contribution to the clinical presentation is rarely known. Thus in the case of a common disease such as nonischemic dilated cardiomyopathy (defined by the absence of significant coronary stenoses on angiography) it is impossible to know with confidence whether DM or some other cause is responsible. Patients with HF and normal or preserved EF (diastolic HF) typically have some other co-existing substrate for HF such as hypertension or CAD. The high incidence of HF following acute or chronic MI in patients with DM is likely accounted for to a significant extent by preexisting diabetic cardiomyopathy, but here again additional factors are usually present in individual patients. Recently, the association between obesity and other features of the metabolic syndrome and diastolic heart failure (often with a restrictive hemodynamic pattern) has been emphasized and related to the amount of epicardial fat.<sup>109</sup> Interestingly, on myocardial biopsy these patients have lipid droplets evident in cardiac myocytes, as has been reported previously in DM. In metabolic syndrome patients, once again, it is impossible to know how much underlying type 2 DM and/or insulin resistance contributes to HF versus other features of the metabolic syndrome.

### *Diabetic Cardiomyopathy and Diastolic Dysfunction*

Although the precise contribution of DM to the syndrome of HF is usually uncertain in individual cases, a large proportion, possibly in excess 30% to 40%, of patients with DM without hypertension, known CAD, or other overt evidence of cardiac disease, have evidence of diastolic dysfunction based on non-invasive assessments.<sup>85,110,111</sup> This has been documented in a number of echocardiographic-Doppler reports of abnormal mitral inflow profiles<sup>83,85,112</sup> and, more recently, abnormal tissue Doppler velocity patterns<sup>113,114</sup> indicative of diastolic dysfunction in DM patients with normal EF. These abnormalities have been correlated with HgbA<sub>1c</sub> levels, measures of insulin resistance, presence of microvascular complications of DM, and, most interestingly, plasma AGE levels.<sup>58</sup> Thus asymptomatic diastolic dysfunction appears to be the most common and earliest detectable manifestation of diabetic cardiomyopathy in patients. Once again, however, when symptoms of HF appear in patients other comorbidities are often present.

### *Increased Left Ventricular Mass*

As discussed earlier, LV mass is on average increased in DM patients. In the Multi-Ethnic Study of Atherosclerosis (MESA) cohort of subjects without clinical cardiovascular disease, in whom cardiac magnetic resonance imaging is being used to quantify cardiac structure and function, African Americans and Hispanics with DM had more prominent increases in LV mass than whites or Asians.<sup>115</sup>

## Management of Heart Failure in Patients with Diabetes

There is no current evidence that HF should be managed differently in patients with DM compared with nondiabetic patients, although few studies have addressed this topic.

Thus published American College of Cardiology/American Heart Association (ACC/AHA) guidelines<sup>116</sup> for medical management of ischemic and nonischemic systolic HF should be followed, with the usual cornerstones of  $\beta$ -adrenergic and renin-angiotensin-aldosterone system blockade. Until more definitive, evidence-based data are available, the management of diastolic HF remains empirical, but generally targeted at optimal management of contributing comorbid factors.

What little information that is available in regard to responses to medical therapy in HF patients with DM has been carefully reviewed by Masoudi and Inzucchi.<sup>22</sup> Thus a meta-analysis by Shekelle et al<sup>117</sup> revealed essentially identical outcome responses to angiotensin-converting enzyme (ACE) inhibitors in diabetic and nondiabetic patients with systolic HF. A community-based observational study by Masoudi et al<sup>118</sup> came to a similar conclusion. As pointed out by Masoudi and Inzucchi,<sup>22</sup> ACE inhibitors should be used especially cautiously in DM patients with type IV renal tubular acidosis and/or other aspects of diabetic nephropathy. There is virtually no information available about the use of angiotensin receptor blockers specific to patients with DM and systolic HF, although the same caution in regard to type IV renal tubular acidosis applies.

$\beta$ -blockers also appear to be equally efficacious and safe in diabetic and nondiabetic patients with dilated cardiomyopathy.<sup>119</sup> With respect to aldosterone antagonists, patients with DM were not reported separately in the Randomized Aldactone Evaluation Study (RALES) of spironolactone in systolic HF,<sup>120</sup> but in the Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) of eplerenone in patients with HF post-MI<sup>121</sup> improvement in outcomes were indistinguishable in patients with and without DM.

## Management of Diabetes in Patients with Heart Failure

### *The Question of Tight Glycemic Control*

In all patients the management of DM begins with diet, weight loss, and regular exercise. Blood glucose and HgbA<sub>1c</sub> levels should be monitored to ensure satisfactory glycemic control. The question of whether tight control of blood glucose is advantageous in the general management of DM has been a topic of debate for many years. The UK Prospective Diabetes Study (UKPDS)<sup>122</sup> provided strong evidence that tight control results in better microvascular outcomes. The evidence with respect to macrovascular complications such as MI and stroke is mixed, however. Nathan et al<sup>123</sup> reported marked improvement in macrovascular outcomes with tight control in patients with *type 1* DM. However, in the Action in Diabetes and Vascular disease: PreterAx and DiamicroN-MR Controlled Evaluation (ADVANCE) trial<sup>124</sup> of intensive control (HgbA<sub>1c</sub> of 6.5% or less) versus standard treatment (HgbA<sub>1c</sub> 7.0% to 7.9%) in *type 2* DM, intensive control resulted in significant reduction in nephropathy but no significant effects on macrovascular outcomes. Similarly, the recent Action to Control Cardiovascular Risk in Diabetes (ACCORD) study<sup>125</sup> concluded that tight control does not significantly reduce nonfatal MI or stroke. Moreover, tight control resulted in significantly *higher* mortality than standard treatment. Importantly, UKPDS, ADVANCE, and ACCORD did not demonstrate a reduction in incidence rates of HF. However, there are no prospective data about the effects of tight control in patients with established HF. An observational study by Eshagian et al<sup>126</sup> reported that patients with advanced systolic HF with HgbA<sub>1c</sub> greater than 7% actually had reduced mortality compared with patients with HgbA<sub>1c</sub> less than 7%. Although firm recommendations cannot be made at this time as to the role of tight control in patients with DM and HF, the available

evidence suggests that it need not be a specific therapeutic goal. However, in individual patients this must be tempered by the beneficial microvascular effects of tight control.

### Pharmacological Therapy

Many patients will of course require insulin to achieve satisfactory control. The effects of insulin on the course of HF and ventricular remodeling are controversial. The antiinflammatory effects of insulin and its salutary effects on cardiac myocyte energy metabolism would be expected to be useful in patients with HF. On the other hand, as discussed earlier, hyperinsulinemia may contribute to cardiac hypertrophy. Nichols et al<sup>127</sup> reviewed the Kaiser Permanente database and found that patients with DM receiving insulin had a greater chance of developing HF than those receiving oral hypoglycemics. Moreover, Smooke et al<sup>128</sup> retrospectively analyzed a cohort of patients with advanced systolic HF and found that insulin use was associated with increased mortality. While observational studies cannot distinguish between adverse effects of insulin versus the likelihood that insulin use simply identifies patients with both more severe DM and more severe underlying myocardial disease, these results point out the considerable uncertainties in this area. At present, one cannot argue strongly for or against insulin in situations where its use is optional.

For patients with DM receiving oral drugs for glycemic control, options have markedly increased over the last decade.<sup>22,129,130</sup> Currently available classes of drugs are summarized in Table 26-1. None of these drugs has been prospectively tested in sufficiently powered, long-term outcome trials in patients with established HF.

The sulfonylureas (glyburide, glipizide, glimepiride) have fallen somewhat out of favor in recent years because, at least in older studies, there was a suggestion of increased cardiovascular risk and their side effect profile is not as favorable as a number of other agents.<sup>22</sup>

The biguanide metformin, which continues to be widely used, had previously been considered contraindicated in HF because of early reports of lactic acidosis possibly caused by the drug. The latter resulted in an FDA-mandated package insert warning. Over the years, it became apparent that lactic acidosis is exceedingly rare and occurs only in the sickest HF patients.<sup>22</sup> Moreover, prospective studies<sup>22</sup> indicate that metformin reduces cardiovascular risk and a retrospective

analysis suggests improved survival in HF patients receiving metformin.<sup>131</sup> Accordingly, in 2006 the package insert warning was removed. Metformin is thus a very reasonable choice for many patients with DM and HF.

The peroxisome-proliferator-activated receptor  $\gamma$  agonist thiazolidinediones (TZDs) (pioglitazone, rosiglitazone) are highly effective for long-term glycemic control and exert a number of effects, including improvements in lipids, antiinflammatory properties, vasodilation, and blood pressure lowering that are attractive in patients with HF.<sup>132,133</sup> They are in general well tolerated,<sup>130</sup> do not have adverse effects on cardiac remodeling,<sup>134,135</sup> and, at least in animal models, may improve diastolic function.<sup>136</sup> There is also some evidence of improved long-term outcomes in patients with HF.<sup>131</sup> However, a large prospective study evaluating overall, long-term cardiovascular risk in patients receiving pioglitazone<sup>137</sup> had a negative result for its primary endpoint, although there was a significant but modest improvement in a secondary combined endpoint of mortality, MI, and stroke. More recently, a meta-analysis<sup>138</sup> revealed an increase in coronary events for rosiglitazone, but not pioglitazone. While the evidence for such an effect is at present inconclusive, this report has caused considerable concern.

Even though TZDs have properties that may be beneficial in patients with HF, it became apparent early on that they routinely cause weight gain and peripheral edema.<sup>129,132,133</sup> The mechanism is salt and water retention in the distal tubule of the kidney and possibly local effects on vascular permeability. Use of these drugs can precipitate HF in a small number of patients (<1%) without a prior HF history. In patients with known HF or those who are at high risk for HF, the incidence of exacerbation or precipitation is clearly further increased, although the precise magnitude of increased risk is difficult to quantify. Accordingly, current guidelines<sup>139</sup> recommend that TZDs not be used in patients with class III or IV HF and that they be used very cautiously in patients with less severe HF. Because of the current uncertainty with respect to the coronary event risk of rosiglitazone, it is prudent to avoid initiating therapy with this drug in patients with concomitant coronary artery disease until this issue is resolved. In patients already receiving the drug with excellent glycemic control, this decision should be individualized.

Certain of the newer oral agents may be particularly useful in HF patients. As indicated, however, little objective information is available as yet. The incretin mimetics include both injectable preparations (glucagon-like peptide-1 [GLP-1] analogues and mimetics) and the orally administered dipeptidyl peptidase IV inhibitors (sitagliptin, vildagliptin). In animal experiments, GLP-1 administration had salutary effects in HF.<sup>140</sup> In small clinical studies improvement in EF recovery after acute MI<sup>141</sup> and in EF and functional measures in chronic HF patients<sup>142</sup> were observed. The  $\alpha$ -glucosidase inhibitors (e.g., acarbose) act exclusively in the GI tract to block carbohydrate absorption. They have significant GI side effects but no systemic side effects such as salt and water retention. In the Study to Prevent Non-Insulin-Dependent Diabetes Mellitus (STOP-NIDDM)<sup>143</sup> in patients with insulin resistance without overt DM, acarbose markedly reduced the risk of MI.

The increased pharmacological options available for glycemic control allow considerable individualization in patients with co-existing HF. There are modest reasons to avoid sulfonylureas, and TZDs must be used with appropriate caution in patients with HF. Of the more commonly used agents, metformin appears to be an excellent choice in many patients.

### Selected Future Directions

Prevention of insulin resistance and type 2 diabetes and their complications, including cardiomyopathy, can be accomplished with straightforward measures such as weight loss

**TABLE 26-1** Classes and Mechanisms of Action of Drugs Used to Treat Diabetes

Class	Examples	Mechanism
Sulfonylureas	Glyburide	Increase insulin secretion by binding to sulfonylurea receptor
Meglitinides	Repaglinide	Same as sulfonylureas, shorter duration of action
Biguanides	Metformin	Decrease hepatic glucose production
$\alpha$ -Glucosidase	Acarbose	Reduces GI carbohydrate absorption inhibitors
Thiazolidinediones	Rosiglitazone Pioglitazone	PPAR $\gamma$ agonists that increase insulin sensitivity
Incretins	Exenatide	Increase glucose-dependent insulin production; decrease glucagon production by activating GLP-1 receptor
Dipeptidyl peptidase IV inhibitors	Sitagliptin	Inhibit degradation of GLP-1 receptors, potentiating incretin effects

and exercise. This is especially important in young people<sup>144</sup> and will certainly be a major focus going forward. With respect to treatment, one of the most promising future directions is development of anti-AGE agents. One crosslink breaker, alagebrium, has undergone limited clinical trials and other agents designed to reduce formation of AGEs and/or reduce RAGE signaling are in development.<sup>39,46,49</sup> Reduction of ROS formation and interference with PKC signaling are other promising therapeutic targets. Last, additional studies directed toward optimization of the management of DM in patients with HF are badly needed.

Cardiomyopathies are major causes of morbidity and mortality, and over the past 20 years, limited improvements in outcome have been reported.<sup>1</sup> However, improvement in the understanding of the major forms of cardiomyopathy has occurred over that time, in large part due to advances in genetics and genomics.<sup>2,3</sup> In addition, new forms of cardiomyopathy have been described and classified over that time frame, in large part due to our improved genetic-based understanding of heart muscle disease. Further, the improved understanding gained in heart muscle disease has led to understanding of similarities and differences in heart and skeletal muscle and their often overlapping clinical presentations.

A new classification scheme was recently developed for the cardiomyopathies in which five forms of disease were formally classified as distinct forms of cardiomyopathy.<sup>4</sup> These forms include dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM) (see Chapter 25), restrictive cardiomyopathy (RCM), arrhythmogenic right ventricular cardiomyopathy

(ARVC), and left ventricular noncompaction (LVNC). These were further classified into genetic/inherited forms and acquired/noninherited forms.<sup>4</sup> All of these forms of disease occur in childhood and adulthood, although ARVC is almost always identified in young adults. In all forms, heart failure may be conspicuous at the time of presentation or, in many cases, late in the course of the disease.

To understand the mechanisms responsible for the development of the clinical phenotypes of cardiomyopathies and resulting heart failure, an understanding of normal cardiac structure is necessary.

## NORMAL CARDIAC STRUCTURE

Cardiac muscle fibers consist of separate cellular units (myocytes) connected in series.<sup>5</sup> In contrast to skeletal muscle fibers, cardiac fibers do not assemble in parallel arrays but bifurcate and recombine to form a complex 3-dimensional network. Cardiac myocytes are joined at each end to adjacent myocytes at the intercalated disk, the specialized area of interdigitating cell membrane (Figure 27-1). The intercalated disk contains gap junctions (containing connexins), and mechanical junctions, consisting of adherens junctions (containing N-cadherin, catenins, and vinculin) and desmosomes (containing desmin, desmoplakin, desmocollin, desmoglein). Cardiac myocytes are surrounded by a thin membrane (sarcolemma) and the interior of each myocyte contains bundles of longitudinally arranged myofibrils. The myofibrils are formed by repeating sarcomeres, the basic contractile units of cardiac muscle consisting of interdigitating thin (actin) and thick (myosin) filaments (see Figure 27-1) that give the muscle its characteristic striated appearance.<sup>6,7</sup> The thick filaments are composed primarily of myosin but additionally contain myosin binding proteins C, H, and cardiac X. The thin filaments are composed of cardiac actin,  $\alpha$ -tropomyosin ( $\alpha$ -TM), and

cardiac troponins T, I, and C (cTnT, cTnI, cTnC). In addition, myofibrils contain a third filament formed by the giant filamentous protein, titin, which extends from the Z-disk to the M-line and acts as a molecular template for the layout of the sarcomere. The Z-disk at the borders of the sarcomere is formed by a lattice of interdigitating proteins that maintain myofilament organization by crosslinking antiparallel titin and thin filaments from adjacent sarcomeres (Figure 27-2). Other proteins in the Z-disk include  $\alpha$ -actinin, nebulin, telethonin/T-cap, capZ, MLP, myopalladin, myotilin, Cypher/Z-band alternatively spliced PDZ-motif protein (ZASP), filamin, and FATZ.<sup>6-8</sup>

Finally, the extrasarcomeric cytoskeleton, a complex network of proteins linking the sarcomere with the sarcolemma and the extracellular matrix (ECM), provides structural support for subcellular structures and transmits mechanical and chemical signals within and between cells. The extrasarcomeric cytoskeleton has intermyofibrillar and subsarcomeric components, with the intermyofibrillar cytoskeleton composed of intermediate filaments (IFs), microfilaments, and microtubules.<sup>9,10</sup> Desmin IFs form a three-dimensional scaffold throughout the extrasarcomeric cytoskeleton with desmin filaments surrounding the Z-disk, allowing for longitudinal connections to adjacent Z-disks and lateral connections to subsarcomeric costameres.<sup>10</sup> Microfilaments composed of nonsarcomeric actin (mainly  $\gamma$ -actin) also form complex networks linking the sarcomere (via  $\alpha$ -actinin) to various components of the costameres. Costameres are subsarcomeric domains located in a periodic, gridlike pattern, flanking the Z-disks and overlying the I bands along the cytoplasmic side of the sarcolemma. These costameres are sites of interconnection between various cytoskeletal networks linking sarcomere and sarcolemma and are thought to function as anchor sites for stabilization of the sarcolemma and for integration of pathways involved in mechanical force transduction. Costameres contain three principal components: the focal adhesion-type complex, the spectrin-based complex, and the dystrophin/dystrophin-associated protein complex (DAPC).<sup>11,12</sup> The focal adhesion-type complex, consisting of cytoplasmic

**FIGURE 27-1** Cardiac myocyte cytoarchitecture. Schematic of the interactions between dystrophin and the dystrophin-associated proteins in the sarcolemma and intracellular cytoplasm (dystroglycans, sarcoglycans, syntrophins, dystrobrevin, sarcospan) at the carboxy-terminal end of the dystrophin. The integral membrane proteins interact with the extracellular matrix via  $\alpha$ -dystroglycan-laminin  $\alpha_2$  connections. The amino-terminus of dystrophin binds actin and connects dystrophin with the sarcomere intracellularly, the sarcolemma, and extracellular matrix. Additional sarcolemmal proteins include ion channels, adrenergic receptors, integrins, and the Cocksackie and adenoviral receptor. Cell-cell junctions, including cadherins, the plakin, and other desmosomal family proteins are also notable. Also shown is the interaction between intermediate filament proteins (i.e., desmin) with the nucleus. MLP, muscle LIM protein;  $\beta_1$ ADR,  $\beta$ -1 adrenergic receptor; ZASP, Z-band alternatively spliced PDZ-motif protein.

**FIGURE 27-2** Z-disk architecture. The Z-disk of the sarcomere consists of multiple interacting proteins that anchor the sarcomere. (Reported with permission from Clark KA, McElhinny AS, Beckerle MC, et al. Striated muscle cytoarchitecture: an intricate web of form and function. *Annu Rev Cell Dev Biol* 2002;18:637-706.)

proteins (i.e., vinculin, talin, tensin, paxillin, zyxin), connect with cytoskeletal actin filaments and with the transmembrane proteins  $\alpha$ -,  $\beta$ -dystroglycan;  $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -sarcoglycans; dystrobrevin; and syntrophin. Several actin-associated proteins are located at sites of attachment of cytoskeletal actin filaments with costameric complexes, including  $\alpha$ -actinin and

the muscle LIM protein, MLP. The C-terminus of dystrophin binds  $\beta$ -dystroglycan (see Figure 27-1), which in turn interacts with  $\alpha$ -dystroglycan to link to the ECM (via  $\alpha$ -2-laminin). The N-terminus of dystrophin interacts with actin. Also notable, voltage gated sodium channels colocalize with dystrophin,  $\beta$ -spectrin, ankyrin, and syntrophins while potassium

channels interact with the sarcomeric Z-disk and intercalated disks.<sup>13,14</sup> Since arrhythmias and conduction system diseases are common in children and adults with DCM, this could play an important role. Hence, disruption of the links from the sarcolemma to ECM at the dystrophin C-terminus and of those to the sarcomere and nucleus via N-terminal dystrophin interactions could lead to a “domino effect” disruption of systolic function and development of arrhythmias.

## DILATED CARDIOMYOPATHY

Dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy (see also Chapter 24). It is characterized primarily by left ventricular (LV) dilation and systolic dysfunction (Figure 27-3) with associated right ventricular (RV) dysfunction and diastolic abnormalities. In children, the annual incidence of DCM is 0.57 cases per 100,000 per year overall, but is higher in boys than in girls (0.66 vs. 0.47 cases per 100,000;  $P < .001$ ), in blacks than in whites (0.98 vs. 0.46 cases per 100,000;  $P < .001$ ), and in infants (<1 year) than in children (4.40 vs. 0.34 cases per 100,000;  $P < .001$ ). The majority of children (66%) are thought to have idiopathic disease.<sup>15</sup> The mortality rate in the United States due to cardiomyopathy is greater than 10,000 deaths per annum, with DCM being the major contributor.<sup>1</sup> The total cost of health care in the United States focused on cardiomyopathies is in the billions of dollars and only limited success has been achieved. To achieve improved care and outcomes in children and adults, understanding of the causes of these disorders has been sought.

Dilated cardiomyopathy has become a popular target of research over the past 10 to 15 years, with multiple genes identified during that time period. These genes appear to encode two major subgroups of proteins, cytoskeletal and sarcomeric proteins.<sup>2</sup> The cytoskeletal proteins identified to date include dystrophin, desmin, lamin A/C,  $\delta$ -sarcoglycan,  $\beta$ -sarcoglycan, and metavinculin. In the case of sarcomere-encoding genes, the same genes identified for HCM appear to be culprits, and include  $\beta$ -myosin heavy chain, myosin binding protein C, actin,  $\alpha$ -tropomyosin, and cardiac troponin T. A new group of sarcomeric genes, those encoding Z-disk proteins, have also been identified and include cypher/ZASP, muscle LIM protein, and  $\alpha$ -actinin-2.<sup>2,3</sup> In addition, phospholamban and G4.5/Tafazzin have also been reported. Another form of DCM, the acquired disorder viral myocarditis, has the same clinical features as DCM including heart failure, arrhythmias, and conduction block.<sup>3</sup> The most common causes of myocarditis are viral, including the enteroviruses (coxsackieviruses and echovirus), adenoviruses, and parvovirus B19, among other cardiotropic viruses. Evidence exists that suggests that viral myocarditis and DCM (genetic) have similar mechanisms of disease based on the proteins targeted.

## Clinical Genetics of Dilated Cardiomyopathy

Dilated cardiomyopathy was initially believed to be inherited in a small percentage of cases until Michels et al showed that approximately 20% of probands had family members with echocardiographic evidence of DCM when family screening was performed.<sup>16</sup> More recently, inherited, familial DCM (FDCM) has been shown to occur in 30% to 40% of cases with autosomal dominant inheritance being the predominant pattern of transmission; X-linked, autosomal recessive, and mitochondrial inheritance is less common.<sup>2</sup>

## Molecular Genetics of Dilated Cardiomyopathy

Over the past decade, progress has been made in the understanding of the genetic cause of FDCM (Table 27-1). Initial progress was made studying families with X-linked forms of

**FIGURE 27-3** Echocardiography in dilated cardiomyopathy. Apical four-chamber view demonstrating a dilated left ventricle. In real-time, the systolic function is depressed.

DCM, with the autosomal dominant forms of DCM beginning to unravel over the past few years. In the case of X-linked forms of DCM, two disorders have been well characterized, X-linked cardiomyopathy (XLCM), which presents in adolescence and young adults, and Barth syndrome, which is most frequently identified in infancy.<sup>17,18</sup>

## X-LINKED CARDIOMYOPATHIES

### X-Linked Dilated Cardiomyopathy (XLCM)

First described in 1987 by Berko and Swift as DCM occurring in males in the teen years and early 20s with rapid progression from CHF to death due to ventricular tachycardia/

ventricular fibrillation (VT/VF) or transplantation, these patients are distinguished by elevated serum creatine kinase muscle isoforms (CK-MM).<sup>17</sup> Female carriers tend to develop mild to moderate DCM in the fifth decade and the disease is slowly progressive. Towbin et al were the first to identify the disease-causing gene and characterize the functional defect.<sup>19</sup> In this report, the dystrophin gene was shown to be responsible for the clinical abnormalities and protein analysis by immuno-blotting demonstrated severe reduction or absence of dystrophin protein in the heart of these patients. These findings were later confirmed by Muntoni et al when a mutation in the muscle promoter and exon 1 of dystrophin was identified in another family with XLCM.<sup>20</sup> Subsequently, multiple mutations have been identified in dystrophin in patients with XLCM.

Dystrophin is a cytoskeletal protein that provides structural support to the myocyte by creating a latticelike network to the sarcolemma. In addition, dystrophin plays a major role in linking the sarcomeric contractile apparatus to the sarcolemma and extracellular matrix.<sup>21,22</sup> Furthermore, dystrophin is involved in cell signaling, particularly through its interactions with nitric oxide synthase. The dystrophin gene is responsible for Duchenne and Becker muscular dystrophy (DMD/BMD) when mutated as well.<sup>23</sup> These skeletal myopathies present early in life (DMD is diagnosed before age 12 years while BMD is seen in teenage males older than 16 years of age) and the vast majority of patients develop DCM before their twenty-fifth birthday. In most patients, CK-MM is elevated similar to that seen in XLCM; in addition, manifesting female carriers develop disease late in life, similar to XLCM. Furthermore, immunohistochemical analysis demonstrates reduced levels (or absence) of dystrophin, similar to that seen in the hearts of patients with XLCM.

Murine models of dystrophin deficiency demonstrate abnormalities of muscle physiology based on membrane structural support abnormalities.<sup>24</sup> In addition to the dysfunction of dystrophin, mutations in dystrophin secondarily affect proteins that interact with dystrophin. At the amino-terminus (N-terminus), dystrophin binds to the sarcomeric protein actin, a member of the thin filament of the contractile apparatus. At the carboxy-terminus (C-terminus), dystrophin interacts with  $\alpha$ -dystroglycan, a dystrophin-associated membrane-bound protein, which is involved in the function of the dystrophin-associated protein complex (DAPC), which includes  $\beta$ -dystroglycan, the sarcoglycan subcomplex ( $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -, and  $\epsilon$ -sarcoglycan), syntrophins, and dystrobrevins (see Figure 27-1).<sup>25</sup> In turn, this complex interacts with  $\alpha_2$ -laminin and the extracellular matrix.<sup>26</sup> Like dystrophin, mutations in these genes lead to muscular dystrophies with or without cardiomyopathy, supporting the contention that this group of proteins are important to the normal function of the myocytes of the heart and skeletal muscles.<sup>26</sup> In both cases, mechanical stress appears to play a significant role in the age-onset dependent dysfunction of these muscles.<sup>24</sup> The information gained from the studies on XLCM, DMD, and BMD, led us to hypothesize that DCM is a disease of the cytoskeleton/sarcolemma, which affects the sarcomere, a “final common pathway” of DCM.<sup>27,28</sup> We also have suggested that dystrophin mutations play a role in idiopathic DCM in males. This is supported when we showed that 3 of 22 boys with DCM had dystrophin mutations and all were later found to have elevated CK-MM as well.<sup>29</sup> In addition, eight families with DCM and possible X-linked inheritance were also screened, and in three of eight families, dystrophin mutations were noted. Again, CK-MM was elevated in all subjects carrying mutations.<sup>30</sup>

### Barth Syndrome

Initially described as X-linked cardioskeletal myopathy with abnormal mitochondria and neutropenia by Neustein et al and Barth et al, this disorder typically presents in male

infants as CHF associated with neutropenia (cyclic) and 3-methylglutaconic aciduria.<sup>31,32</sup> Mitochondrial dysfunction is noted on EM and electron transport chain biochemical analysis. Recently, abnormalities in cardiolipin have been noted.<sup>33</sup> Echocardiographically these infants typically have LV dysfunction with LV dilation, endocardial fibroelastosis, or a dilated hypertrophic left ventricle. In some cases these infants succumb due to CHF/sudden death VT/VF, or sepsis due to leukocyte dysfunction. The majority of these children survive infancy and do well clinically, although DCM usually persists. In some cases, cardiac transplantation has been performed. Histopathological evaluation typically demonstrates the features of DCM, although endocardial fibroelastosis may be prominent and the mitochondria are abnormal in shape and abundance.

The genetic basis of Barth syndrome was first described by Bione et al who cloned the disease-causing gene, *G4.5*.<sup>34</sup> This gene encodes a novel protein called tafazzin, whose gene product is an acyltransferase and results in cardiolipin abnormalities.<sup>33</sup> Mutations in *G4.5* result in a wide clinical spectrum, which includes apparent classic DCM, hypertrophic DCM, endocardial fibroelastosis (EFE), or LVNC.<sup>2,35</sup>

### Autosomal Dominant Dilated Cardiomyopathy

The most common form of inherited DCM is the autosomal dominant form of disease.<sup>3</sup> These patients present as classic “pure” DCM or DCM associated with conduction system disease (CDDC). In the latter case, patients usually present in the third decade of life with mild conduction system disease, which can progress to complete heart block over decades. DCM usually presents late in the course but is out-of-proportion to the degree of conduction system disease.<sup>36</sup> The echocardiographic and histological findings in both subgroups are classic for DCM, although the conduction system may be fibrotic in patients with CDDC. In both groups of DCM patients, VT, VF, and TdP occur and may result in sudden death.

Genetic heterogeneity exists for autosomal dominant DCM with more than 15 loci mapped for pure DCM and five loci for CDDC. In the case of pure DCM, 10 genes have been identified to date, including three by our group ( $\delta$ -sarcoglycan,  $\alpha$ -actinin-2, ZASP), and actin, desmin, troponin T,  $\beta$ -myosin heavy chain, titin, metavinculin, myosin binding protein C,  $\alpha$ -tropomyosin, muscle LIM protein (MLP),  $\beta$ -sarcoglycan, and phospholamban (see Table 27-1).<sup>2,37-39</sup>

The majority of genes identified to date encode either cytoskeletal or sarcomeric proteins. In the case of cytoskeletal proteins (desmin,  $\delta$ -sarcoglycan, metavinculin, MLP), defects of force transmission are considered to result in the DCM phenotype, while defects of force generation have been speculated to cause sarcomeric protein-induced DCM.<sup>27</sup>

Cardiac actin is a sarcomeric protein that is a member of the sarcomeric thin filament interacting with tropomyosin and the troponin complex. As previously noted, actin plays a significant role in linking the sarcomere to the sarcolemma via its binding to the N-terminus of dystrophin and the mutations in actin, which resulted in DCM as described by Olson et al appear to be directly involved in the binding of dystrophin.<sup>40</sup> The DCM-causing mutations are believed to result by causing force transmission abnormalities. Further, actin interacts in the sarcomere with TnT and  $\beta$ -MHC, two other genes resulting in either DCM or HCM depending on the position of the mutation.<sup>41</sup> In the case of TnT and  $\beta$ -MHC, force generation abnormalities have been speculated as the responsible mechanism.

Desmin is a cytoskeletal protein that forms intermediate filaments specific for muscle.<sup>10</sup> This muscle-specific 53 kDa subunit of class III intermediate filaments forms connections between the nuclear and plasma membranes of cardiac, skeletal, and smooth muscle. Desmin is found at the Z lines and the intercalated disks of muscle and its role in muscle

function appears to involve attachment or stabilization of the sarcomere. Mutations in this gene appear to cause abnormalities of force and signal transmission similar to that believed to occur with actin mutations.<sup>42</sup>

Another DCM-causing gene,  $\delta$ -sarcoglycan, is a member of the sarcoglycan subcomplex of the DAPC.<sup>37</sup> This gene encodes for a protein involved in stabilization of the myocyte sarcolemma and signal transduction. Mutations identified in familial and sporadic cases resulted in reduction of the protein within the myocardium. In the absence of  $\delta$ -sarcoglycan, the remaining sarcoglycans ( $\delta$ ,  $\beta$ ,  $\gamma$ ,  $\Sigma$ ) cannot assemble properly in the endoplasmic reticulum.<sup>43</sup> Mouse models of  $\delta$ -sarcoglycan deficiency demonstrate dilated, hypertrophic cardiomyopathy, sarcolemmal fragility, and disrupted vascular smooth muscle, which leads to vascular spasm, including coronary spasm.<sup>44</sup> Other human mutations in  $\delta$ -sarcoglycan cause a form of autosomal recessive limb girdle muscular dystrophy (LGMD2F), which rarely is associated with heart disease.

The final cytoskeletal protein-encoding gene, metavinculin, encodes vinculin and its splice variant metavinculin. Vinculin is ubiquitously expressed and metavinculin is coexpressed with vinculin in heart, skeletal, and smooth muscle, with this protein complex localized to subsarcolemmal costameres in the heart where they are localized to subsarcolemmal costameres in the heart where they interact with  $\alpha$ -actinin, talin, and  $\gamma$ -actin to form a microfilamentous network linking the cytoskeleton and the sarcolemma. In addition, these proteins are present in adherens junctions in intercalated disks and participate in cell-cell adhesion. Mutations in metavinculin has been shown to disrupt the intercalated disks and alter actin filament cross-linking.<sup>45,46</sup>

Mutations in the sarcomere may produce hypertrophic cardiomyopathy or dilated cardiomyopathy. In the latter case, abnormalities in force generation or transmission are thought to contribute to the development of this phenotype.<sup>41</sup> In addition to mutations in the thin filament protein actin, mutations in the thick filament protein-encoding gene  $\beta$ -myosin heavy chain has been shown to cause DCM with associated sudden death in at least one infant, and DCM in older children and adults.<sup>41,47</sup> Mutations in this gene are thought to perturb the actin-myosin interaction and force generation or alter cross-bridge movement during contraction. Mutations in cardiac troponin T, a thin filament protein, have been speculated to disrupt calcium-sensitive troponin C binding.<sup>47</sup> Mutations in phospholamban have also been identified, which further support calcium handling as a potentially important mechanism in the development of DCM.<sup>48,49</sup> Interestingly, Haghihi et al identified homozygous mutations causing dilated cardiomyopathy and heart failure, while heterozygotes had cardiac hypertrophy.<sup>49</sup> Recessive mutation in troponin I is thought to impair the interaction with troponin T, while  $\alpha$ -tropomyosin mutations have also been identified and were predicted to alter the surface charge of the protein leading to impaired interaction with actin.<sup>50</sup>

A recent area of interest for evaluation at the molecular level is the Z disk.<sup>51</sup> Knoll et al identified mutations in muscle LIM protein (MLP) and demonstrated that this results in defects in the interaction with telethonin.<sup>52</sup> Using mouse models, they also demonstrated that MLP acts as a stretch sensor and that mutant MLP causes defects in this activity. More recently, mutations in MLP in families and sporadic cases were described and, in addition, abnormalities in the T-tubule system and Z disk architecture by electron microscopy was identified, which correlates with the histopathology seen in MLP-knockout mice.<sup>53</sup> This was further supported by the finding of reduced expression of MLP in chronic human heart failure.<sup>54</sup> In addition, mutations in  $\alpha$ -actinin-2, which is involved in cross-linking actin filaments and shares a common actin binding domain with dystrophin, were also identified in familial DCM, which disrupts its binding to MLP.<sup>3</sup> Vatta et al identified mutations in the Z-band alternatively spliced PDZ-motif protein ZASP, the

human homolog of the mouse cypher gene, which when disrupted leads to DCM.<sup>55</sup> Multiple mutations in this gene were identified in families and sporadic cases of DCM and with LV noncompaction. This protein, which interacts with  $\alpha$ -actinin-2, disrupts the actin cytoskeleton when mutated. Another gene, titin, which encodes the giant sarcomeric cytoskeletal protein titin that contributes to the maintenance of the sarcomere organization and myofibrillar elasticity, interacts with these proteins at the Z disk/I band transition zone.<sup>56</sup> Mutations have been identified in familial DCM as well.<sup>57</sup>

As seen in pure autosomal dominant DCM, genetic heterogeneity also exists for CDDC. To date, CDDC genes have been mapped to chromosomes 1p1-1q1, 2q14-21, 3p25-22, and 6q23. The only gene thus far identified was reported to be lamin A/C on chromosome 1q21, which encodes a nuclear envelope intermediate filament protein.<sup>58,59</sup>

### Lamin A/C

The lamins are located in the nuclear lamina at the nucleoplasmic side of the inner nuclear membrane, and lamin A and C are expressed in heart and skeletal muscle.<sup>60</sup> Mutations in this gene were initially reported to cause the autosomal dominant form of Emery-Dreifuss muscular dystrophy, which has skeletal myopathy associated with DCM and conduction system disease.<sup>61,62</sup> It has also been found to cause a form of autosomal dominant limb girdle muscular dystrophy (LGMD1B), which is also associated with conduction system disease.<sup>63</sup> Multiple mutations have been identified in patients with DCM and conduction system disease which, in some cases, had mildly elevated CK. This gene defect appears to be relatively common in patients with CDDC. The mechanism(s) responsible for the development of DCM and conduction system abnormalities and skeletal myopathy are being determined.<sup>64</sup> Comprehending may be aided by understanding how other genes that encode interacting proteins result in disease, such as thymopoietin.<sup>65</sup>

## Muscle Is Muscle: Cardiomyopathy and Skeletal Myopathy Genes Overlap

Interestingly, nearly all of the genes identified for inherited DCM are also known to cause skeletal myopathy in humans and/or mouse models. In the case of dystrophin, mutations cause Duchenne and Becker muscular dystrophy while  $\delta$ -sarcoglycan mutations cause limb girdle muscular dystrophy (LGMD2F). Lamin A/C has been shown to cause autosomal dominant Emery-Dreifuss muscular dystrophy (EDMD) and LGMD1B, whereas actin mutations are associated with nemaline myopathy. Desmin, G4.5,  $\alpha$ -dystrobrevin, Cypher/ZASP, MLP,  $\alpha$ -actinin-2, titin,  $\beta$ -sarcoglycan mutations also have associated skeletal myopathy suggesting that cardiac and skeletal muscle function is interrelated and that possibly the skeletal muscle fatigue seen in patients with DCM with and without CHF may be due to primary skeletal muscle disease and not only related to the cardiac dysfunction. It also suggests that the function of these muscles has a "final common pathway" and that both cardiologists and neurologists should consider evaluation of both sets of muscles.

Further support for this concept comes from studies of animal models. Mutations in  $\delta$ -sarcoglycan in hamsters results in cardiomyopathy while mutations in all sarcoglycan subcomplex genes in mice cause skeletal and cardiac muscle disease. Mutations in other DAPC genes and dystrophin in murine models also consistently demonstrate abnormalities of skeletal and cardiac muscle function. Arber et al also produced a mouse deficient in muscle LIM protein (MLP), a structural protein that links the actin cytoskeleton to the contractile apparatus.<sup>53</sup> The resultant mice develop severe DCM, CHF, and disruption of cardiac myocyte cytoskeletal architecture. Murine mutations in titin, cypher,  $\alpha$ -dystrobrevin, desmin,

and other all demonstrate cardiac and skeletal muscle disease. Finally, Badorff et al has shown that the DCM that develops after viral myocarditis has a mechanism similar to the inherited forms.<sup>66</sup> Using coxsackievirus B3 (CVB3) infection of mice, the authors showed that the CVB3 genome encodes for a protease (enteroviral protease 2A), which cleaves dystrophin at the third hinge region of dystrophin, resulting in force transmission abnormalities and DCM. In addition, Xiong et al showed that abnormal dystrophin increases susceptibility to viral infection and resultant myocarditis.<sup>67</sup> Interestingly, a similar dystrophin mutation, which affects the first hinge region of dystrophin in patients with XLCM, was previously reported by our laboratory, demonstrating a consistent mechanism of DCM development, abnormalities of the cytoskeleton/sarcolemma, and sarcomere. In addition, we have shown that N-terminal dystrophin is reduced or absent in hearts of patients with all forms of DCM (ischemic, acquired, genetic, idiopathic) and that reduction of mechanical stress by use of left ventricular assist devices (LVADs) results in reverse remodeling of dystrophin and of the heart itself.<sup>68</sup>

## HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is characterized by ventricular hypertrophy predominantly affecting the left ventricle. Most commonly, the clinical phenotype includes asymmetrical septal hypertrophy and hypercontractile systolic function in the face of diastolic dysfunction. This “stiff” appearing heart occasionally develops dilated atria due to restrictive physiology. In some patients, the left ventricle has concentric hypertrophy. Left ventricular outflow tract obstruction (LVOTO) and arrhythmias are variable findings. While heart failure due to diastolic dysfunction or to a “burned out” form in which systolic dysfunction develops, the most well-known clinical feature of HCM is its propensity for sudden cardiac death.

The genetics of HCM is most commonly associated with autosomal dominant inheritance and approximately 70% of subjects can be found to have mutations in sarcomere-encoding genes. This is covered in detail in Chapter 25. Other forms of inheritance, such as X-linked, mitochondrial, or autosomal recessive are also seen, most commonly in childhood and the causes differ from the classic form of sarcomeric disease. Some of these other forms of “inappropriate” LV hypertrophy are described later.

### Infiltrative Forms of Hypertrophic Cardiomyopathy

A variety of disorders that have apparent LV hypertrophy and features of hypertrophic cardiomyopathy occur due to infiltrative disorders. The classic form of infiltrative disease in this category is Pompe disease, a disorder typically presenting in the first weeks of life.<sup>69</sup> More recently, other forms of infiltrative disease have been identified with later onset disease, such as Fabry disease, Danon disease, and LV hypertrophy due to mutations in AMP-activated protein kinase (AMP-K) encoded by the PRKAG2 gene.<sup>70-73</sup> These disorders, along with those caused by mitochondrial abnormalities and genetic dysmorphism syndromes, such as Noonan syndrome and LEOPARD syndrome, are caused by abnormalities not primarily affecting the sarcomere.<sup>93</sup> Therapy is similar to the sarcomeric form of the disease, unless systolic dysfunction occurs. In this case, heart failure therapy should be instituted.

#### Pompe Disease (Type II Glycogen Storage Disease)

Genetic deficiency of acid  $\alpha$ -1,4 glucosidase, an enzyme involved in the breakdown of glycogen to glucose, results in a wide clinical spectrum ranging from the rapidly fatal infantile

onset of type II glycogen storage disease (GSD) to a slowly progressive adult-onset myopathy. The infantile-onset form (Pompe disease) typically manifests during the first 5 months of life, and patients usually die before their second year.<sup>69</sup> This rare inborn error of glycogen metabolism occurs in less than 1 per 100,000 births. Massive glycogen accumulation occurs, leading to the clinical findings of enlarged tongue, striking hepatomegaly, hypotonia with decreased deep tendon reflexes, and cardiomyopathy (usually HCM) with congestive heart failure. The glycogen accumulation can be noted histologically in the skeletal muscles, liver, and heart. Children usually succumb in the first 2 years of life. The diagnosis may be predicted from the pathognomonic electrocardiogram (ECG).<sup>19</sup> The disease has autosomal recessive inheritance; the gene coding for the lysosomal enzyme was originally mapped to chromosome 17 at subband 17q23-q25.<sup>74</sup>

Allelic variation at the acid  $\alpha$ -glucosidase locus is presumed to be the most important factor in diversity of type II GSD.<sup>75</sup> It has been shown that various combinations of homoallelic and heteroallelic mutant genotypes are the basis for this clinical heterogeneity. Zhong et al identified a missense mutation in one allele of a patient with Pompe disease.<sup>76</sup> This base pair substitution resulted in a loss of restriction endonuclease sites, which allowed them to demonstrate mRNA expression deficiency from the second allele using polymerase chain reaction (PCR)-amplified RNA. This was the first evidence of single base pair missense mutations in patients with this disease. In addition to molecular analysis, the diagnosis can be made biochemically by analysis of  $\alpha$ -glucosidase in blood lymphocytes or skin fibroblasts. Prenatal diagnosis is possible by amniocentesis or chorionic villus sampling by assay of  $\alpha$ -glucosidase. Enzyme therapy is now possible and appears to reverse the cardiac phenotype.<sup>77</sup>

#### Fabry Disease

An X-linked recessive disorder with mild expression occasionally seen in carrier females, this entity is caused by deficiency of the enzyme  $\alpha$ -galactosidase ( $\alpha$ -Gal) and is found in 1 of 40,000 people. Young adults may be prone to renal failure and myocardial infarctions. Fabry disease usually has its onset in adolescence and usually manifests with sensations of burning pain in the hands and feet.<sup>78</sup> These sensations tend to be associated with fever, heart, cold, and exercise. With increasing age, multiple angiokeratoma become noticeable, especially around the umbilicus and genitalia. Corneal opacities are often noted. Progressive renal failure develops with age. CNS manifestations include seizures and headaches, and hemiplegia associated with an increased risk of stroke. Primary cardiac manifestations in affected males are hypertrophic cardiomyopathy and mitral insufficiency and the diagnosis depends on echocardiography.<sup>79</sup> The LV myocardium and mitral valve tend to be areas of greatest storage of lipid material. On electrocardiogram, the PR interval is usually short. Deposition of sphingolipids in the coronary arteries leads to myocardial ischemia and infarction.<sup>80</sup>

The disease-causing gene was originally localized to the long arm of the X chromosome in the Xq22 region, and the full-length cDNA was isolated and sequenced, demonstrating a 1393-bp cDNA with a 60-nucleotide 5' untranslated region, and encoding a precursor peptide of 429 amino acids.<sup>81</sup> The gene was found to contain seven exons; mutations and phenotypic correlation have been described.<sup>82</sup>

Nakao et al studied 1603 men by echocardiography and demonstrated significant LVH in 230 subjects (14%) of which 7 (3%) had proven  $\alpha$ -Gal deficiency.<sup>83</sup> These patients had concentric LVH. More recently, Sachdev et al identified five patients with HCM diagnosed after age 40 years and one with earlier-onset (younger than 40 years) HCM, all with low  $\alpha$ -Gal activity.<sup>84</sup> In five of the six patients, the hypertrophy was concentric, while one had asymmetrical hypertrophy. In one

case, LV outflow tract obstruction was noted. Nonsustained ventricular tachycardia occurred in two patients and another patient had 2-degree AV block initially and then atrial fibrillation. Therefore, it appears that these abnormalities in  $\alpha$ -Gal activity result in some cases of HCM or “unexplained” LVH. Enzyme replacement therapy may have a role in the treatment of Fabry disease with optimal results being seen with institution of therapy before evidence of myocardial fibrosis.<sup>85</sup>

### Danon Disease

Danon disease is an X-linked dominant disorder characterized by intracytoplasmic vacuoles containing autophagic material and glycogen in cardiac and skeletal muscle cells, cardiomyopathy, and skeletal myopathy, with or without conduction defect, Wolff-Parkinson-White syndrome, or mental retardation.<sup>86</sup> The underlying abnormality affects lysosomal function and is due to mutations in the lysosomal associated membrane protein 2 (LAMP2) and the biopsy demonstrates vacuolization (Figure 27-4).<sup>87</sup> The clinical phenotypic expression of Danon disease is variable. Charron et al screened 50 cases of HCM for LAMP2 mutations and identified mutations in two patients with HCM and skeletal myopathy.<sup>88</sup> Both of these individuals presented during their teenage years and other younger affected individuals in the family were also identified as young as 7 years of age. Wolff-Parkinson-White syndrome and high voltage QRS complexes on electrocardiogram were notable along with high creatine kinase plasma levels. In addition, late LV dilation and dysfunction occurred with symptoms of heart failure. Atrial and ventricular arrhythmias and conduction disease was notable along with death during their 20s. Visual acuity abnormality was also common because of choriocapillary ocular atrophy. This disease appears to be underrecognized and may play a significant role in pediatric heart failure.

### AMP-Activated Protein Kinase (AMP-K)

AMP-activated protein kinase (AMP-K), encoded by the  $\gamma$ -2 regulatory subunit of the *PRKAG2* gene on chromosome 7q31, is an enzyme that modulates glucose uptake and glycolysis.<sup>89</sup> Dominant mutations in this gene were first identified by Gollob et al and Blair et al in 2001 in subjects with hypertrophic cardiomyopathy, Wolff-Parkinson-White (WPW) preexcitation, and atrioventricular block.<sup>90,91</sup> The genetic locus on chromosome 7q3 was first described by MacRae et al in 1995 in families with HCM and WPW and was felt to be clinically

different than the patients with other forms of adult HCM.<sup>101</sup> Blair et al<sup>113</sup> made the case that mutations in AMP-K resulted in HCM due to compromise of energy production and use, but Arad et al provided evidence that this disorder is a form of glycogen-storage disease.<sup>73</sup> Cardiac pathology differed from other forms of HCM, with no myocyte and myofibrillar disarray seen but instead pronounced formation of vacuoles, which were filled with glycogen-associated granules. The myocytes were enlarged and interstitial fibrosis was minimal. Using a yeast system in which a similar enzyme is functional, Arad et al introduced the same mutations found in the patients and showed that the enzyme activity is persistent (i.e., does not turn off), leading to glycogen accumulation. The authors confirmed these findings by developing a murine model that mimics the human disorder.<sup>92</sup>

## ENERGY-DEPENDENT FORMS OF HYPERTROPHIC CARDIOMYOPATHY

### Mitochondrial Cardiomyopathies

The human mitochondrial genome is a small, circular DNA molecule that is maternally inherited.<sup>93</sup> Mitochondrial DNA (mtDNA) encodes 13 of the 69 proteins required for oxidative metabolism, 22 transfer RNAs (tRNAs) and 2 ribosomal RNAs (rRNAs) required for their translation (Figure 27-5). Because mtDNA has much less redundancy than the nuclear genome (in which essentially identical information is received from both parents), and tRNAs and rRNAs are present in multiple copies, the mitochondrial genome is an excellent target for mutations giving rise to human disease.<sup>94</sup> Mitochondria enjoy a symbiotic relationship with the cell. These subcellular organelles are dependent on nucleocytoplasmic mechanisms for most structural components, but do contribute vital peptides that are central to cellular respiration. Mitochondria contain a permeable outer membrane and a highly restrictive inner membrane that guards the chemical microenvironment of the matrix compartment. Adaptive mechanisms exist for the passage of large and small molecules across the inner membrane. Translocases shuttle monocarboxylic acids, amino acids, acyl-carnitine conjugates, small ions, and other metabolites in and out of the mitochondrial matrix. Energy is required for importation of proteins into the mitochondria because the nuclear gene-synthesized mitochondrial proteins are precursor molecules that require presequence cleavage. The 13 mtDNA genes

**FIGURE 27-5** Mitochondrial (mtDNA) genome. Circular mtDNA encoding proteins of the mitochondria, including a portion of the proteins of the electron transport chain.

### Kearns-Sayre Syndrome

Channer et al reported a case of rapidly developing progressive congestive heart failure and DCM requiring transplantation in a patient with Kearns-Sayre syndrome.<sup>100</sup> Approximately 20% of Kearns-Sayre syndrome patients have cardiac involvement and the majority usually have conduction defects causing progressive heart block. These patients generally have large, heterogeneous deletions in the mitochondrial chromosome. Poulton et al showed germ line deletions of mtDNA in a family with Kearns-Sayre syndrome using polymerase chain reaction (PCR) to amplify across the deletion, with primers flanking these deletions.<sup>101</sup> The patient was shown to have a deletion in muscle mtDNA and at low levels in blood that was identical to that found in the mother and sister. The probands, however, had more deleted DNA, correlating with more severe symptomatology. Other mutations have also been described.<sup>102</sup>

This syndrome is characterized by myoclonic epilepsy with ragged red muscle fibers (MERRF) and is caused by a single nucleotide substitution in tRNA LYS that apparently interferes with mitochondrial translation.<sup>103</sup> Shoffner et al showed an A to G transition mutation as the cause of the disease associated with defects in complexes I and IV.<sup>104</sup> This abnormality causes decline in ATP-generating capacity, with onset of disease that includes cardiomyopathy. Other reports outline various disease-causing mutations.<sup>105</sup>

## Left Ventricular Noncompaction

This disorder has previously been considered to be a rare disease and has been identified by a variety of names including spongy myocardium, fetal myocardium, and noncompaction of the LV myocardium.<sup>106,107</sup> The abnormality is believed to represent an arrest in the normal process of myocardial compaction, the final stage of myocardial morphogenesis, resulting in persistence of multiple prominent ventricular trabeculations and deep intertrabecular recesses (Figure 27-7).

**FIGURE 27-7** Illustration of LV noncompaction. Note the spongy appearance of the ventricular myocardium and the relative wall thickness. (Modified from Towbin JA, Bowles NE. The failing heart. *Nature* 2002;415:227-233.)

The myocardium typically demonstrates trabeculations and deep intertrabecular recesses at the apex (Figure 27-8) and the echocardiographic findings include trabeculations and deep intertrabecular recesses (Figure 27-9) and color Doppler suggestion of blood traversing the recesses (Figure 27-10). This cardiomyopathy is somewhat difficult to diagnose unless the physician has a high level of suspicion during echocardiographic evaluation. In fact, on careful review of echocardiograms and other clinical data, it appears that LV noncompaction is relatively common in children and is also seen in adults.<sup>107,108</sup> In the most recent American Heart Association/American College of Cardiology (AHA/ACC) Cardiomyopathy Classification, LVNC for the first time was recognized as a formal form of classified cardiomyopathy.

Two forms of LV noncompaction occur: (1) isolated noncompaction and (2) noncompaction associated with congenital heart disease such as septal defects (ventricular and/or atrial septal defect), pulmonic stenosis, and hypoplastic left heart syndrome, among others.<sup>109,110</sup> In the isolated form and the form associated with congenital heart disease, metabolic derangements may be notable.<sup>111</sup>

#### Clinical Features

Left ventricular noncompaction most commonly presents in infancy with signs and symptoms of heart failure but some patients are identified during later childhood, adolescence, or adulthood. Pignatelli et al recently reported the findings on 36 children identified over a 5-year period, with the median age at presentation being 90 days (range 1 day to 17 years).<sup>108</sup> In this study, 40% of the children had low cardiac output or congestive heart failure and only one child (3%) had syncope. The most common presenting symptom other than heart failure was asymptomatic electrocardiographic or radiographic abnormalities, with 42% being asymptomatic. In addition, 14% of children had associated dysmorphic features while 19% of affected children had first-degree relatives with cardiomyopathy. The children with dysmorphic features were diagnosed with DiGeorge syndrome in one child and one child had congenital adrenal hyperplasia.

#### Genetics

When LV noncompaction is inherited, it can be transmitted as an X-linked, mitochondrial, autosomal recessive or autosomal dominant trait.<sup>112</sup> In approximately 20% to 30% of cases, familial inheritance has been identified. The X-linked form usually is associated with isolated noncompaction and a mutation in the *G4.5* (tafazzin) gene located on chromosome Xq28.<sup>110</sup> This gene has also been identified in patients with Barth syndrome.

In autosomal dominant inherited cases, mutations in the Z-line protein encoding ZASP, located on chromosome 10q22, have been identified in isolated noncompaction, while

**FIGURE 27-8** Anatomical specimen with LV noncompaction. LV trabeculations (black arrow) and intertrabecular recesses (white arrow) are notable at the apex of this heart of a child with LVNC.

**FIGURE 27-9** Echocardiographic features of LV noncompaction. Apical four-chamber view of LVNC with apical and free wall trabeculations and ventricular hypertrophy.

mutations in the gene encoding  $\alpha$ -dystrobrevin, a cytoskeletal protein located on chromosome 1, have been identified in patients with noncompaction associated with congenital heart disease.<sup>55,110</sup> No genes have been identified thus far for autosomal recessive-inherited noncompaction while mutations in mitochondrial DNA have been seen in patients with noncompaction.<sup>109,111</sup>

#### Therapy and Outcome

The specific therapy depends on the clinical and echocardiographic findings. In patients with systolic dysfunction and heart failure, anticongestive therapy identical to those used in patients with dilated cardiomyopathy is appropriate. In particular, angiotensin-converting enzyme (ACE) inhibitors such as captopril and enalapril, and  $\beta$ -adrenergic blocking agents such as metoprolol or carvedilol are useful. Diuretics may also be needed. However, in those patients exhibiting findings more consistent with a hypertrophic cardiomyopathy or

**FIGURE 27-10** Echocardiographic features of LV noncompaction. A parasternal short-axis view with color Doppler demonstrates hypertrophy of the LV apex with deep trabeculations filled with blood (red flow).

a diastolic dysfunction physiological phenotype,  $\beta$ -blocker therapy alone with propranolol or atenolol is more appropriate. In patients with either of these forms of noncompaction with associated mitochondrial or metabolic dysfunction, some investigators add a “vitamin cocktail” to the cardiac therapy with coenzyme Q10, carnitine, riboflavin, and thiamine commonly used alone or in combination.

In patients having associated congenital heart disease, appropriate therapeutic approaches may include simple pharmacological therapy with diuretics for volume overload associated with left to right shunts, more complex pharmacological therapy for patients with restrictive physiology and pulmonary hypertension, or invasive therapy with catheter intervention or surgical repairs, depending on the lesions. Intimate understanding of the cardiac function abnormalities, evidence of thrombi (which should be treated with anticoagulation), and the metabolic status of the patient must be attended to by the interventional cardiologist, cardiac anesthesiologist, and surgeon in approaching these patients invasively. In addition, cardiac rhythm disturbances need to be identified and therapies such as pacemakers, implantable defibrillators, and intracardiac ablations considered.

The clinical outcome of patients with noncompaction has been reported to be poor with death occurring due to heart failure or sudden death presumably arrhythmia-related or stroke-related due to embolization of LV thrombi.<sup>106,110</sup> However, Pignatelli et al demonstrated a 5-year survival rate of 86%; when transplanted patients were added, the 5-year survival rate (free at transplantation) was 75%.<sup>108</sup>

## Restrictive Cardiomyopathy

Restrictive cardiomyopathy (RCM), the rarest of the cardiomyopathies, is a diastolic disorder in which the atria are dilated in the face of normal ventricular size, thickness, and systolic function (Figure 27-11). In some cases, ventricular hypertrophy may coexist and, in this case, is commonly described as HCM with restrictive physiology instead of RCM function (Figure 27-12).<sup>113</sup> Sudden death is common although diastolic heart failure occurs in some cases. RCM may be associated with skeletal myopathy, conduction system disease, or can occur as an isolated disorder. In childhood, this disorder has a rapidly progressive course with sudden death occurring within 2 years of clinical presentation. These patients most

**FIGURE 27-11** Restrictive cardiomyopathy. A parasternal long-axis view demonstrates a moderately dilated left atrium with normal LV size, thickness, and systolic function and no mitral regurgitation or shunt lesions.

**FIGURE 27-12** Restrictive cardiomyopathy. Apical four-chamber view with biatrial enlargement and mild interventricular septal hypertrophy.

typically have syncope without prior symptoms. In some patients, chest pain, atrial or ventricular arrhythmias, or a family history of RCM or sudden death leads to the diagnosis.

### Genetic Basis of Restrictive Cardiomyopathy

The disease, when inherited, is most commonly an autosomal dominant trait.<sup>112</sup> In the past, complex forms of RCM were studied and genes identified as causative. For instance, patients with RCM associated with conduction system disease and/or skeletal myopathy were found to result from mutations in desmin. Further, infiltrative forms of disease caused by amyloid or sarcoid, were also identified. More recently, studies of families and sporadic cases have been successful in defining RCM as a result of mutations in sarcomere-encoding genes. The most common of these genes appears to be troponin I, although mutations in the  $\beta$ -myosin heavy chain gene ( $\beta$ -MyHC) have also been reported.<sup>113</sup> More studies are required to further pinpoint the causes of RCM and

to determine the mechanism(s) differentiating the severity of diastolic dysfunction that separates RCM and HCM as clinical disorders.

## Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is characterized by replacement of RV myocardium with adipose or fibrofatty tissue that occasionally extends to the left ventricle.<sup>114</sup> Clinically the disease manifests as rhythm disturbances of RV origin, ranging from innocuous ventricular ectopy to potentially life-threatening ventricular tachycardia and fibrillation resulting in syncope or sudden death. In fact, ARVC represents a significant cause of sudden death, particularly in young athletes. ARVC exhibits wide phenotypic variability with onset of symptoms typically in the second to fourth decades of life, although some patients present in their early teen years. In some affected patients, heart failure occurs. The lack of standardized diagnostic criteria led to the formulation of major and minor criteria by the European Society of Cardiology/International Federation of Cardiology task force in 1994. An updated “Task Force” set of diagnostic criteria for ARVC are currently being devised. Unfortunately, limitations persist in disease identification due in part to the constellation of structural and functional abnormalities and the reliance on multiple diagnostic modalities that have potentially low sensitivity and/or specificity.<sup>114</sup> Echocardiographic findings typically include RV dilation, focal aneurysms, and wall motion abnormalities. Electrocardiograms (ECGs) may reveal T wave inversions in the right precordial leads, premature ventricular contractions, ventricular tachycardia with left bundle branch pattern, or  $\epsilon$  waves that correspond to late potentials seen on signal-averaged electrocardiogram (SAECG).<sup>115</sup> Endomyocardial biopsy will often identify the histopathological changes characteristic of ARVC, including replacement of the myocardium with fibrous tissue and fat (Figure 27-13). A recent study by Asimaki et al suggests that a high sensitivity and specificity for diagnosis may be possible with immunohistochemical analysis.<sup>116</sup> Cardiac magnetic resonance (CMR) imaging has provided another adjunctive test in recent years but it too has similar limitations.<sup>117</sup> Molecular genetics perhaps offers the greatest promise for future inroads into improved diagnostic accuracy and guiding future treatment strategies.<sup>114</sup> Recent genetic studies have helped to define the underlying “final common pathway” involved in the development of the clinical disorder.

### Clinical Genetics of Arrhythmogenic Right Ventricular Cardiomyopathy

The exact prevalence of the disease is unknown; however, limited studies suggest there are roughly 6 in 10,000 affected individuals in the general population with significantly higher rates observed in geographic regions such as north-east Italy. Approximately 30% of ARVC is familial, most often exhibiting autosomal dominant inheritance. Less common autosomal recessive forms, Naxos disease and Carvajal syndrome, have been associated with palmoplantar keratoderma and woolly hair. In many affected individuals, particularly those with Carvajal syndrome, a primary LV form of the disease occurs. ARVC displays incomplete penetrance with variable phenotypic expression.

### Genetic Basis of Arrhythmogenic Right Ventricular Cardiomyopathy

As with the other forms of cardiomyopathy and arrhythmia disorders, the genes responsible for ARVC encode proteins of a “final common pathway,” in this case cell-cell junctions.<sup>118</sup> To date, eight genes for autosomal dominant inherited ARVC and two genes for autosomal recessive ARVC have been identified. In all cases to date, the causative gene encodes a desmosomal protein or a protein that interacts with and modulates

**FIGURE 27-13** Histopathology of arrhythmogenic RV cardiomyopathy. Myocardial histopathology demonstrating myocardium (muscle) surrounded by fibrous tissue (scar) and fat (adipose tissue).

or modifies the function of a desmosomal protein. The genes responsible for the dominant form of ARVC include desmoplakin (*DSP*), plakophilin-2 (*PKP2*), desmoglein-2 (*DSG2*), desmocollin-2 (*DSC2*), plakoglobin (*JUP*), transforming growth factor  $\beta$ -3 (*TGF $\beta$ 3*), and, most recently, transmembrane protein 43 (*TMEM43*). The ryanodine receptor (*RyR2*) has also been reported but doubt regarding its authenticity as an ARVC-causing gene has been raised. Gerull et al have suggested that *PKP2* mutations are the most common cause of this form of disease, responsible for approximately 25% of all cases (Table 27-2). However, we have found that a high percentage of subjects and families with ARVC and *PKP2* mutations have reduced penetrance and, in fact, the disease is caused by either second mutations in *PKP2* (compound heterozygosity) or mutations in a second desmosome-encoding gene (digenic heterozygosity).

In the case of the autosomal recessive forms of ARVC, Naxos disease is caused by homozygous mutations in *JUP*, while Carvajal syndrome occurs due to homozygous mutations in *DSP*.<sup>119</sup>

### Animal Models of Arrhythmogenic Right Ventricular Cardiomyopathy

Animal models have demonstrated that the intercalated disks of cardiomyocytes are “pulled apart” and, in many cases, total loss of the desmosomes of the intercalated disk occurs. In addition, in the case of *DSP* mutants, lipid infiltration appears to be caused by disturbance of the *wnt* signaling pathway. To date, animal models for desmoplakin, *RyR2*, and plakophilin-2 (*PKP2*) have been reported.

**Ryanodine Receptor Mutant Murine Models.** Based on the original report by Tiso et al outlining mutations in *RyR2* (located on chromosome 1q42-q43) in subjects reported to have ARVC type 2 (ARVC2), animal modeling studies were initiated.<sup>120</sup> Using homologous recombination in embryonic stem cells, a point mutation in exon 8 of the *RyR2* gene (*R176Q*) was engineered in C57Black/6 (C57BL/6) mice using a knock-in strategy by Kannankeril et al.<sup>121</sup> This mutation, which was previously shown to cosegregate with ARVD in humans leading to the effort-induced polymorphic VT and mild ARVD histologically characteristic of the ARVD2 form of disease, demonstrated germ line transmission in these mice and once grown were studied clinically and by use of pathological analysis. Histological analysis of hearts from mutant (*RyR2*<sup>R176Q/+</sup>) and wild-type (WT) mice revealed no evidence of structural abnormalities or fibrofatty infiltration. Noninvasive imaging demonstrated mild systolic dysfunction, and electrocardiographic evaluation identified no spontaneous

**TABLE 27-2 Arrhythmogenic RV Cardiomyopathy (ARVC) Genetics**

Locus Name	Inheritance	Map Position	Gene
ARVD1	AD	14q23	<i>TGFβ3</i>
ARVD2	AD	1q42-q43	<i>RyR2</i>
ARVD3	AD	14q12	?
ARVD4	AD	2q32	?

Naxos	AR	17q21	<i>Plakoglobin</i>
Carvajal	AR	6p24	<i>Desmoplakin</i>

arrhythmias in telemetered animals. However, intracardiac electrophysiological studies using programmed stimulation elicited differences in inducibility of VT in the mutant mice versus the WT animals. The aggressive stimulation protocol induced multiple short episodes of VT <0.5 seconds in length in both groups. Using isoproterenol infusion, however, the authors demonstrated an increased number and duration of VT episodes in the mutant mice. In addition, spontaneous ventricular ectopy was induced in the mutant animals but not in the WT mice. This model was inconclusive regarding the phenotype but appeared more consistent with a CPVT phenotype than that of a classic form of ARVC.

**Plakophilin-2 Mutant Murine Models.** Plakophilins are proteins of the armadillo family of proteins that function in embryonic development and in the adult. Proteins of the armadillo family are characterized by domains composed of variable numbers of repeats of the *arm* motif, 42 amino acids in length, and this family includes  $\beta$ -catenin, plakoglobin ( $\gamma$ -catenin), and plakophilins. Arm repeat proteins bind to the cytoplasmic end of glycoproteins of the cadherin family of cell adhesion molecules, thus forming plaques to which bundles of cytoskeletal filaments are tethered. The plakophilin subfamily of *arm* repeat proteins include four members (PKP1-4), juxtamembranous components of plaques of desmosomes that tightly associate with other arm proteins, cadherins, and desmoplakin, and participate in intermediate filament anchorage. In addition, plakophilins translocate to the nucleus.

Grossmann et al created a null mutation of the plakophilin-2 (*PKP2*) gene by homologous recombination in embryonic stem cells whereby an early stop of *PKP2* translation after exon 1 (43 amino acids) was engineered.<sup>122</sup> Generation of homozygous mutants led to no live offspring, consistent with embryonic lethality. Normal development occurred until embryonic day 10.75 (E10.75), at which time blood accumulation in the pericardial and peritoneal cavities was noted. At E11.5, the number of viable embryos declined significantly. In addition, reduced trabeculations within the ventricles and atrial wall thinning was observed. Confocal microscopy demonstrated lack of the normal colocalization of desmoplakin to the junctions and intercalated disks, instead being dispersed over the cytoplasm, mostly distant from the intercalated disks. In addition, PKP2 was absent and desmoglein-2, another desmosomal cadherin protein, could not be localized in significant levels in these mutant hearts. Electron microscopy confirmed these findings and abnormalities of cytoskeletal organization. In the latter case, intermediate filament arrays appearing as

extensive swirls of disordered filaments around dense desmoplakin aggregates were seen. Hence, these findings were consistent with the concept that abnormalities of PKP2 lead to cardiac abnormalities with an unusual form of cardiomyopathy due to desmosomal destabilization. These findings are supportive of the human mutations in PKP2 that are believed to cause ARVC.

**Junctional Plakoglobin Mutant Murine Models.** Junctional plakoglobin (JUP), also known as Gamma-catenin, was the first member of the armadillo family of proteins discovered. It is a constituent of the cytoplasmic plaque of desmosomes and other cell adherens junctions and is involved in anchorage of cytoskeletal filaments to specific cadherins and consists of 13 arm repeats flanked by unique N-terminal and C-terminal sequences. JUP associates with the desmosomal cadherin proteins desmoglein 1-3 and desmocollin 1-3 to form plaques, which also contain desmoplakin and PKP2.

Using homologous recombination in which mutation in the junction between exons 3 and 4 of the plakoglobin gene was engineered in embryonic stem cells and injected into C57Black/6 (C57BL/6) mice, Ruiz et al generated null JUP mice.<sup>123</sup> Homozygous mutants (JUP<sup>-/-</sup>) were found to be embryonic lethal between days 12 to 16 of embryogenesis (E12-E16) while heterozygous mutants (JUP<sup>+/-</sup>) and WT animals were born with normal development. Evaluation of homozygous embryos between days E10-E16 of gestation demonstrated mild growth retardation at E12 and reduced blood supply, especially to the liver and placenta. The pericardial cavity was swollen and filled with blood and the hearts of these embryos was frequently ruptured within the ventricular walls. Heart rates were increased in these mutants and ventricular contraction was reduced in E11.5 embryos, consistent with systolic dysfunction. Immunofluorescence microscopy showed extensive expression of JUP at E10.5 in WT animals but expression was absent in homozygous mutants. The morphology of the intercalated disks was grossly altered as well. Desmoplakin was found to colocalize in many places with  $\beta$ -catenin but desmoglein was absent in these junctions. Hence, the homozygous mutant animals lack desmosomes, which are replaced by extended adherens, junctions that contain desmosomal proteins such as desmoplakin but have impaired architectural stability and function. Interestingly, the skin of these animals was unaffected.

The findings in this animal model support the concept that mutant JUP results in a form of cardiomyopathy. In humans, homozygous mutations in JUP, located on human chromosome 17q21, result in the cardiocutaneous disorder called Naxos disease in which ARVC is a major component.<sup>124</sup> Although the animal model described here is not a perfect re-creation of the human condition, it serves to be a proof of concept.

**Desmoplakin Mutant Murine Models.** Desmoplakin (DSP), localized to chromosome 6p24, was initially identified as the mutant gene causing autosomal recessive Carvajal syndrome. It was later shown to cause autosomal dominant ARVC8 and is a major component of desmosomes, complex intercellular junctions assembled through cooperative interactions between multiple proteins.<sup>125</sup> The majority of patients with DSP have the classic form of ARVC, although a substantial number of affected individuals have associated LV disease.

Using the Cre-LoxP system, a cardiac-restricted exon 2 deletion in DSP was created in mice. These animals were engineered by crossing mice in which the second exon of the murine desmoplakin gene (*Dsp*) is flanked by LoxP sequence (floxed DP mice; 129/SvJ strain) with mice expressing Cre recombinase under the control of the  $\alpha$ -MHC promoter ( $\alpha$ -MHC-Cre mice; FVB/N strain). Homozygous (DP<sup>-/-</sup>) mutant mice had a high rate of embryonic lethality. These

homozygous mutant mouse embryos exhibited growth arrest at embryonic stage E10-E12, appeared pale, had no circulating red blood cells in their organs, and were growth retarded. Histopathological evaluation revealed poorly formed hearts with no chamber specification and unorganized cardiac myocytes. In addition, red blood cells were localized to the pericardial sac instead of within the cardiac chambers. Furthermore, an excess number of cells resembling adipocytes, dispersed between myocytes and localized to adjacent areas, were also detected. In comparison, their cardiac phenotype was normal in DP<sup>+/+</sup> and DP<sup>+/-</sup> embryos, with and without the  $\alpha$ -MHC-Cre transgene. Those DP<sup>-/-</sup> mice surviving the embryonic period (approximately 5% of the litter) died typically within the first 2 weeks postnatally. On the other hand, DP<sup>+/-</sup> mice were born with normal development but had age-dependent penetrance of heart involvement, including a 20% incidence of SCD by 6 months of life. Gross pathological analysis of both DP<sup>+/-</sup> and DP<sup>-/-</sup> animals demonstrated grossly enlarged cardiac chambers and increased heart weight with an increased heart weight-to-body ratio being highest in the homozygous mutants and lowest in the WT animals. Both right ventricle and left ventricle were enlarged equally and this enlargement occurred at approximately the same age. The gross anatomical findings were further supported by echocardiographic measurements, which revealed thin ventricular walls, increased LV end-diastolic and end-systolic dimensions, and depressed systolic function with reduced ejection fraction. Furthermore, baseline resting electrocardiographic evaluation identified spontaneous ventricular ectopy, including premature ventricular contractions, ventricular couplets, and short runs of VT in heterozygous mutants but no ventricular arrhythmias in WT mice. Histological examination revealed poorly organized myocytes with large areas of patchy fibrosis; in the DP<sup>-/-</sup> animals, fibrosis was seen in up to 30% to 40% of the myocardium. Excess accumulation of fat droplets was notable in both DP<sup>-/-</sup> and DP<sup>+/-</sup> mutant mice using oil red O staining, and was seen predominantly at the site of fibrosis.

In addition to these pathological abnormalities, the authors showed that junctional plakoglobin, a member of the armadillo repeat protein family that plays a role in regulation of gene expression, interacts and competes with  $\beta$ -catenin, the effector of the canonical Wnt signaling, having a negative effect on this pathway. They were able to show that plakoglobin was translocated to the nucleus in cardiac-restricted DP-deficient mice and that expression levels of gene targets of the canonical Wnt/ $\beta$ -catenin pathway (*c-myc* and *cyclin D1*) were reduced. Expression of adipogenic genes were increased, as was TUNEL-positive cells, but in the absence of DNA laddering consistent with low levels of apoptosis.

Another animal model of mutant desmoplakin was recently described by our group. This model, a transgenic mouse with cardiac-restricted overexpression of a C-terminal DSP mutant (R2834H), demonstrated histological evidence of increased cardiomyocyte apoptosis, cardiac fibrosis, and neutral lipid accumulation (Figure 27-14). Echocardiography and CMR imaging revealed ventricular enlargement and cardiac dysfunction of both ventricles (see Figure 27-14), which was confirmed on necropsy. RV wall thickness was also reduced. The mutant mice also displayed interruption of the DSP-desmin interaction at intercalated disks and marked ultrastructural abnormalities of the intercalated disks. The intercalated disks were irregularly shaped with markedly widened gaps between adjacent anchoring sarcomeres, affecting both the adherens junctions and desmosomes. In addition, changes in other desmosomal and junctional components were notable, including increased expression and redistribution of JUP, PKP2, and  $\beta$ -catenin, and changes in gap junction components including redistribution of connexin 43.

**FIGURE 27-14** Desmoplakin transgenic mouse model (DSP) of arrhythmogenic RV cardiomyopathy. The leftward panels demonstrate findings in the DSP mutant mouse while the rightward panels demonstrate findings in the nontransgenic (NTG) mice. From top to bottom, the DSP mutants show fibrosis (blue stain), lipid infiltration (oil red O stain), disrupted intercalated disk appearing to be “pulled apart,” dilated thin-walled right ventricle on gross anatomy, and biventricular dilation by cardiac magnetic resonance imaging compared with the NTG counterparts.

#### Mechanisms of Arrhythmogenic Right Ventricular Cardiomyopathy

ARVC is a disease of desmosomal dysfunction as demonstrated by the human genetics and animal models. In addition to dysfunction of the key desmosomal proteins (Figure 27-15) and disruption of protein-protein interactions of the desmosomal proteins, mechanical stress forces complete the phenotypic presentation with disruption of the intercalated disks, leading to dilation and dysfunction of the ventricles. Arrhythmias occur and sudden death is thought to result from ventricular tachyarrhythmias. Signaling pathway function, particularly the wnt pathway, also appears to play a key role.

## CONCLUSIONS AND FUTURE DIRECTIONS

Heart failure, when caused by cardiomyopathies, appears to occur due to disruption of “final common pathways” and the resultant physiological disturbances that ensue. These disruptions may be due to purely genetic causes, such as mutations

**FIGURE 27-15** Desmosome proteins and structure. Illustration of the desmosome, the proteins comprising the desmosome, and the cell-cell contacts between myocytes. Key proteins, including plakoglobin, plakophilin, and desmoplakin are shown, with the link of desmoplakin to the intermediate filaments (desmin) also seen. Disruption of protein structure plus mechanical stress leads to disrupted protein-protein binding and the “pulling apart” of cell-cell contacts seen in these patients and animal models.

in a single gene that results in a dysfunctional protein, which leads to a domino effect of downstream protein interaction abnormalities and ultimately a phenotype. In other situations, multiple mutations in the same gene (compound heterozygosity) or in different genes (digenic heterozygosity) may lead to a phenotype that may be classic, more severe, or even overlapping with other disease forms. In some cases, different intersecting pathways may become disturbed, resulting in complex phenotypes. Further, acquired causes may play a role by causing disruption of these functional pathways. For instance, dilated cardiomyopathy results from disruption in the “final common pathway” linking the sarcomere and sarcolemma and mutations in the affected genes are responsible for cardiac and skeletal muscle dysfunction. The mechanisms of disease, which include disruption of the linkage due to protein-protein interaction abnormalities that occur from dysfunctional proteins, and the interplay of other factors such as mechanical stress and stretch, are being elucidated in detail with the development of animal models of the human disease. Many of the genes identified are now clinically available in fee-for-service laboratories. Novel therapies have resulted from the improved understanding of this clinical phenotype, as noted previously. Similarly, the genetic basis and mechanistic understanding of HCM as a disturbance of sarcomeric function has occurred over the past 2 decades and genetic tests are clinically available. The development of novel targeted therapies has been somewhat slow in coming but is expected to develop in the near future. In the case of LVNC, the “new kid on the block,” genetic understanding is in the early phases. The future of cardiomyopathy care is poised to shift in the next decade due to these new developments, and the growing science of stem cell therapy. Since children have “pure” disease states, unfettered by comorbidities, the dream of “cures” of muscle disease (cardiac, skeletal muscle) will likely be realized more fully in this population. We must move toward that goal.

# Heart Failure as a Consequence of Hypertension

Thomas D. Giles and Gary E. Sander

Hypertension, if defined simply by JNC (Joint National Committee) criteria as a systemic arterial blood pressure (BP) greater than 140/90 mm Hg, is present in at least one third of the U.S. population. Ninety-one percent of cases of heart failure are preceded by hypertension when a BP level of 140/90 mm Hg is used as the sole diagnostic criterion. Hypertension is thus the most important modifiable risk factor for heart failure.<sup>1,2,3</sup> However, it is now evident that the optimal BP of adults over 40 years of age is less than 115/75 mm Hg and furthermore that the increase in cardiovascular risk rises sharply above that number.<sup>4</sup> Simply stated, there is no threshold BP pressure that identifies those with hypertension from those without the disease; hence BP is best understood as a biomarker of hypertension as a disease. In fact, a definition of hypertension independent of BP thresholds was proposed by a Writing Group of the American Society of Hypertension.<sup>5</sup> Throughout this review, unless otherwise specified, the term hypertension will be used to refer to the disease state rather than as simply an elevation of BP greater than 140/90 mm Hg.

*Hypertension* is a disease of the cardiovascular system that primarily manifests itself as an increase in systemic arterial blood pressure and may be associated with the development of myocardial disease (i.e., cardiomyopathy). There are numerous causes of increased blood pressure involving genetic and environmental factors. *Heart failure* is not a disease, but rather a clinical syndrome that manifests itself late in the course of a cardiomyopathy. Hypertensive cardiomyopathy is a pathophysiological process that may lead to the development of heart failure. The importance of heart failure as a complication of hypertension is seen when viewing the untreated natural history.<sup>6</sup>

The presence of a resting arterial blood pressure chronically greater than 140/90 mm Hg has been defined as hypertension by the JNC VI report.<sup>7</sup> However, it has become increasingly apparent that sustained BP that exceeds the optimal level for an individual does damage target organs, including the heart. The threshold for departure from optimal BP has not yet been identified, but cardiovascular abnormalities, including increased left ventricular mass and reduced vasodilator capacity, have been demonstrated in the normotensive offspring of subjects with hypertension, with more prominent abnormalities in those with two hypertensive parents.<sup>8</sup> Hypertensive heart disease, perhaps better identified as hypertensive cardiomyopathy—the ultimate cause of heart failure associated with hypertension—in its simplest form results from the increased workload of the heart, a true *hyperergopathic cardiomyopathy*.<sup>9</sup>

Hypertension seldom exists for a prolonged time without association with other factors that modify the response of the myocardium. These factors include genotype, gender and body size, and comorbid conditions such as coronary artery disease, diabetes mellitus, obesity, excessive alcohol intake, neurohumoral factor [renin-angiotensin-aldosterone system (RAAS), sympathetic nervous system (SNS)] activation, and many others. Hypertension thus becomes an important factor in the production of a *pluricausal* cardiomyopathy (cardiomyopathy resulting from more than one cause) and resultant heart failure; in fact, most heart failure is the result of *pluricausal* cardiomyopathy. Therefore, hypertension alone may produce cardiomyopathy and heart failure, but may also interact with other factors that are important in increasing the risk of developing myocardial disease and dysfunction.

of heart failure, especially in the 30- to 62-year age group, occurring six times more frequently relative to individuals identified as normotensive.<sup>2</sup> In 1996, the progression from elevated BP alone to hypertension with congestive heart failure was reported in participants in the Original Framingham Heart Study and Framingham Offspring Study, which had been initiated on January 1, 1970.<sup>10</sup> During this interval a total of 5,143 subjects were observed with a mean follow-up 14.1 years. Elevated BP preceded the development of heart failure in 91% of the 392 new cases (Figure 28-1). The hazard for developing heart failure in hypertensive, compared with normotensive, subjects was approximately twofold in men and threefold in women after adjustment for age and heart failure risk factors in proportional hazards regression models. The 5-year survival rate for hypertensive heart failure was 24% for men and 31% for women.

Although much attention has been devoted to diastolic BP, the role of an elevated systolic BP is perhaps more important in the development of hypertensive heart disease. Heart failure is often preceded by isolated systolic hypertension as defined by a systolic BP greater than 160 mm Hg with a diastolic BP less than 90 mm Hg.<sup>11</sup> The importance of systolic BP in the production of hypertensive cardiomyopathy is supported by the finding that systolic pressure is a stronger determinant on left ventricular geometry and function than is diastolic pressure.<sup>12</sup>

The role of hypertension in the development of heart failure is of particular importance in the older patient population (see Chapter 49). More than 75% of heart failure patients in the United States are older than 65 years of age; heart failure is the leading cause of hospitalization in older adults.<sup>13</sup> Elevated BP is prevalent in older patients; heart failure in this group is often associated with preserved left ventricular systolic function and is perhaps due to diastolic dysfunction. Heart failure with preserved systolic function accounts for up to 50% of all cases of congestive heart failure in adults more than 65 years of age. In the Helsinki Aging Study, 8.2% of the cohort of subjects born in 1904, 1909, and 1914 developed heart failure; of these, 72% had normal left

## EPIDEMIOLOGY

Much of what is known concerning the epidemiology of hypertension and heart failure has come from the Framingham study (see Chapter 22). As early as 1972, elevated BP (>140/90 mm Hg) was identified as the most frequent cause

**FIGURE 28-1** The epidemiology of heart failure. The prominent role played by hypertension in the development of heart failure is shown by data from the Framingham study. (From Levy D, Larson MG, Vasan RS, et al. The progression from hypertension to congestive heart failure. *JAMA* 1996;275:1557-1562.) Copyright © (2011) American Medical Association. All rights reserved.

ventricular function determined by echocardiography.<sup>14</sup> Diastolic heart failure was found in 51% of patients and hypertension was the underlying cause in 54% of these subjects. Black patients with elevated BP are at increased risk for the development of heart failure (see Chapter 49). In a study of 301 black patients with congestive heart failure, systemic hypertension was the most common cause and was the primary cause in 61%.<sup>15</sup>

Some common comorbid conditions that contribute, along with hypertension, to the development of pluricausal cardiomyopathy and heart failure are coronary atherosclerosis, diabetes mellitus, and alcohol consumption. Among hypertensive subjects in the Framingham study, myocardial infarction, diabetes, left ventricular hypertrophy, and valvular heart disease were further predictive of increased risk for heart failure in both men and women.<sup>10</sup> Cardiovascular morbidity and mortality are increased 4.4 fold in type 2 diabetic patients in comparison with nondiabetic subjects even in the absence of classical risk factors including hypertension.<sup>16</sup> The coexistence of diabetes with elevated BP results in cardiomyopathy and heart failure in excess of that which would be expected from either one alone.<sup>17-19</sup> Increased alcohol consumption may also play a role in the development of heart failure in hypertensive individuals.<sup>20</sup>

#### Pathophysiology of Hypertensive Cardiomyopathy

The characteristic change that occurs in the heart secondary to a chronic increase in systemic arterial BP is left ventricular hypertrophy (LVH). At some point the hypertrophy ceases to be “physiological” in nature and becomes “pathological.”<sup>21</sup> Although the characteristics of LVH are dependent on numerous factors that include age, sex, genotype, endocrine, autocrine, and paracrine influences, what is central to the development of

ventricular hypertrophy is the reaction of the myocardium to increased wall stress secondary to increased pressures.

**Mechanical Effects of Hypertension on the Left Ventricle.** In individuals with normal blood pressure, factors that have been shown to influence left ventricular mass are genotype, gender, and body size.<sup>22</sup> The genetic influence on LV mass has been demonstrated in studies of monozygotic and dizygotic twins and population studies. Left ventricular mass index is increased in the offspring of parents with hypertension before increased systemic arterial pressure was present either at rest, or with exercise.<sup>8</sup> The influence of gender on LV mass becomes apparent at puberty and then persists throughout adulthood. Body size is important in determining LV mass, particularly lean body mass (75% of the variance). All of the previous determinants of LV mass influence the loading conditions of the ventricle and are, therefore, hemodynamic stimuli to the production of LVH. Thus in the normal individual, cardiac work (i.e., stroke volume times mean systolic pressure) is closely related to LV mass. Since stroke work is determined by the force required to overcome vascular impedance, it is interesting that the development of heart failure is related more to pulse pressure (an indirect assessment of vascular compliance) than to mean arterial pressure or previous myocardial infarction.<sup>23</sup> This reflects a loss of proximal arterial elastance associated with a decrease in elastin and an increase in type 4 collagen. Also important is the influence of heart rate, which determines the amount of work performed over time.

It has been suggested that a gender-specific LV mass can be determined and that theoretically, every value of observed LV mass that exceeds 100% of the predicted value may be considered as abnormally elevated. Thus by extension, a BP that is greater than “optimal” may, by increasing cardiac work, be associated with an abnormal increase in LV mass that may not, by current criteria, reach the threshold of “clinical hypertrophy.”

The adaptive response of the left ventricle to an increased workload is primarily aimed at maintaining normal wall tension (see Chapter 15). Assuming the ventricle to be a sphere or ellipsoid, the average meridional wall stress is defined as force per unit area acting at the midplane of the heart in the direction of apex to base. Meridional or longitudinal wall stress ( $\sigma_m$ ) is a function of the intracavitary pressure (P), the internal radius of the ventricle (R), and wall thickness (h): ( $\sigma_m = PR/2h$ ). During normal ventricular systole, increases in LV pressure are matched by increases in wall thickness resulting from the thickening of the normal ventricular wall, thereby maintaining normal wall tension. However, when there is exposure to a chronic increase in ventricular pressure, as with elevated BP, the increase in wall thickness and muscle mass represents a structural change. The increase in thickness of the LV wall tends to maintain systolic wall stress ( $\sigma_m$ ) within a narrow range despite variations in ventricular size or systolic pressure. There is an inverse relationship between LV systolic pressure and the radius/thickness (R/2h) or end-diastolic volume/mass ratio.

The concept of wall stress provides a means of interpretation for the patterns of hypertrophy apparent at the gross anatomical level. These patterns are concentric remodeling, concentric hypertrophy, and eccentric hypertrophy (see Chapter 15). Concentric remodeling is the first step in the restructuring of the heart and consists of an increase in wall thickness relative to LV end-diastolic dimensions without an increase in myocardial mass; this pattern is particularly apparent in the left ventricle. Remodeling is accomplished by a rearrangement of the cells of the myocardium so that the left ventricular cavity is reduced in its internal dimension. This concentric remodeling, by increasing LV wall thickness and reducing LV chamber diameter, maintains normal wall tension despite the increased systemic arterial pressure.

Concentric hypertrophy occurs when there is an increased myocardial mass with normal or reduced ventricular internal dimensions. Eccentric hypertrophy occurs when the ventricle becomes dilated; calculated myocardial mass is increased. When this occurs, the ventricle loses its mechanical advantage<sup>24,25</sup> and LV dilation increases the risk of heart failure.<sup>26</sup>

**Cellular Biochemical and Molecular Aspects of Hypertensive Cardiomyopathy.** All components of the myocardium—myocytes, interstitial cells, and the microcirculation—are involved in the myocardial remodeling process of hypertensive cardiomyopathy; formed elements of the blood, including monocytes and macrophages, may also play a role in the development of cardiomyopathy (see Chapter 11). Myocytes account for approximately 25% of all of the cells in the myocardium, but represent 70% of the myocardial mass. The number of cardiac myocytes is genetically determined and reaches a final amount within the first year after birth, when mitotic activity ceases.<sup>26</sup> Hypertrophy of myocytes occurs in response to the chronic increase in systolic wall tension produced by increased systemic arterial blood pressure. Thus the mechanical forces imposed by increased myocardial work provides a basis for the progression of myocardial disease in hypertension from progressive cardiomyopathy to the appearance of heart failure.<sup>21,27–29</sup> Initially, myocyte hypertrophy is accomplished by the addition of myofibrils in parallel, thus increasing the cross-sectional area of the individual myocytes.<sup>21</sup> This response to increased wall tension appears to involve expression of immediate early genes (IEGs), such as those encoding transcription factors, e.g., *c-fos*, *c-myc*, *c-jun*, and *egr-1*.<sup>30–33</sup> The IEG response is followed by an expression of a fetal genetic pattern, which may be characterized by the reexpression of ventricular mRNA for atrial natriuretic peptide (ANP),  $\beta$ -myosin heavy chain ( $\beta$ -MHC), and skeletal muscle  $\alpha$ -actin. There is subsequently upregulation of several constitutively expressed genes, including vMLC-2 and cardiac muscle (CM)  $\alpha$ -actin. Downregulation of certain genes such as sarcoplasmic reticulum (SR)  $\text{Ca}^{2+}$ -release channel (the ryanodine receptor) and SR  $\text{Ca}^{2+}$ -ATPase-2 (SERCA-2), which are responsible for cycling  $\text{Ca}^{2+}$  into and out of the SR, also occurs in this stage of myocyte hypertrophy.

The interstitium of the myocardium is pivotal to the remodeling of the heart that takes place during the process of the development of hypertensive heart disease. Fibrillar connective tissue, which constitutes the interstitium of the myocardium, contains mainly types I and III collagen. This fibrillar collagen network maintains the architecture of the myocardium and provides a means of tethering and orienting the myocytes, and is responsible for distributing diastolic filling stress throughout the ventricle. An abnormal increase of collagen (e.g., fibrosis) may be responsible for increased myocardial stiffness (i.e., loss of compliance). Hypertension may also be associated with increased perivascular interstitial fibrosis. After a prolonged period of hypertension, parenchymal cell injury and loss of myocytes develop, leading to replacement or reparative fibrosis in response to microscopic scarring resulting from myocyte necrosis. In contrast to the apparently benign myocyte hypertrophy without fibrosis that is seen in athletes who develop physiological LVH, biopsies from patients with hypertension and LVH demonstrate increased collagen content and extensive fibrosis; the degree of this fibrosis is a critical determinant of the severity of diastolic dysfunction. An inverse correlation between diastolic filling volume and percent of myocardial fibrosis as assessed by endomyocardial biopsy has been reported.<sup>34</sup>

A study exploring the fibrotic changes in diastolic heart failure (DHF) divided 86 hypertensive patients into groups according to the presence of DHF (32 with, 54 without) and the extent of diastolic dysfunction (20 with normal function, 38 with impaired relaxation, 10 with pseudonormalization, and 16 with restrictive filling). Serum carboxy-terminal

telopeptide of procollagen type I, carboxy-terminal telopeptide of procollagen type I, amino-terminal propeptide of procollagen type III, MMP-2, and MMP-9 levels ( $P < .001$  for all, controlled for age and gender) were greater in patients with DHF than in those without (see Chapters 5 and 14). When the results were controlled for age and gender, levels of serum carboxy-terminal telopeptide of procollagen type I, tissue inhibitor of MMP-1, amino-terminal propeptide of procollagen type III (all  $P < .001$ ), carboxy-terminal telopeptide of procollagen type I ( $P = .008$ ), and MMP-2 ( $P = .03$ ) were greater in more severe phases of diastolic dysfunction. Within phases of diastolic dysfunction, serum carboxy-terminal telopeptide of procollagen type I, amino-terminal propeptide of procollagen type III, MMP-2, and MMP-9 were elevated in those with DHF compared with those without DHF (all  $P < .001$ ), thus demonstrating active fibrosis.<sup>35</sup> The process governing this fibrosis is not well understood. Fibroblast stimulation is essential for reactive and reparative fibrosis. Recently data have suggested that the mineralocorticoid aldosterone may be important for the fibroblast activation.<sup>36</sup> Treatment with the aldosterone-antagonist spironolactone (25 mg/day) improved echocardiographic evidence of diastolic dysfunction in patients with hypertensive heart disease.<sup>37</sup>

Coronary vessels with a luminal diameter less than 100  $\mu\text{m}$  constitute the resistance vessels of the myocardium and mainly control coronary blood flow. Since these vessels comprise more than 70% of the intramural arterial tree, rarefaction or inadequate growth in relation to hypertrophy of myocytes might diminish oxygen and substrate delivery despite the increased requirement due to hypertrophy. The actual demonstration of alterations of microvessels in hypertension has been somewhat controversial; however, the majority of evidence points to remodeling of the vessels, including hyperplasia of smooth muscle cells, edema, and increased content of collagen and other matrix components.<sup>38</sup> Hormonal stimulation and growth factors are involved (e.g., RAAS). Changes in the coronary circulation contribute to myocardial ischemia, both with and without the presence of epicardial coronary artery disease.

### Clinical Presentations of Hypertensive Cardiomyopathy

The pathway from elevated BP to hypertension to heart failure involves LVH, interactions with comorbidities, and cardiac remodeling. The clinical presentation may be one of several intermediate phenotypes.

**Left Ventricular Hypertrophy.** The earliest clinical indication of hypertensive cardiomyopathy is the detection of asymptomatic LVH. LVH is, as discussed previously, initially adaptive because it permits the maintenance of normal systolic wall stress, fiber shortening, and stroke volume. In a large group of patients with ECG defined LVH enrolled in the LIFE (Losartan Intervention for Endpoint Reduction in Hypertension) study, 19% had normal geometry, 11% had concentric remodeling, 47% had eccentric hypertrophy, and 23% had concentric hypertrophy.<sup>39</sup> The ECG criteria used in LIFE (Cornell voltage-duration product  $>2440$  and/or  $\text{SV1} + \text{RV5-6} >38 \text{ mm}$ ) identify hypertensive patients with a greater than 70% prevalence of anatomical LVH as documented by echocardiography, allowing accurate identification of high-risk status by this commonly used technique.<sup>40,41</sup>

LVH is more closely related to 24-hour BP than to casual (office) BP<sup>40</sup>; even transient increases in pressure may cause LVH.<sup>42</sup> However, the presence of “white coat hypertension” does not necessarily lead to major structural or functional cardiac abnormalities,<sup>43</sup> but may do so.<sup>44</sup> The presence of LVH by ECG predicts the development of heart failure in subsequent years. In the echocardiographic substudy of the LIFE study, inappropriate LVH (observed/predicted LV mass  $>128\%$ ) had a greater incidence of decreased LV systolic function.<sup>45</sup>

**Heart Failure in Hypertensive Cardiomyopathy.** The clinical presentation of hypertensive cardiomyopathy follows the morphological and functional changes associated with ventricular hypertrophy and remodeling. Even though hypertension is associated with alterations in right ventricular function, the clinical presentations involve changes primarily in the left ventricle.

**Heart Failure with Preserved Systolic Function (Diastolic Dysfunction).** Heart failure may be present clinically in patients with hypertension when measured systolic function is normal (see Chapters 14 and 48). Such presentations may be due to diastolic dysfunction that result in impaired filling of the left ventricle due to decreased lusitropy (inability of the ventricle to relax properly). In patients having acute pulmonary edema associated with hypertension and a normal LVEF ( $>0.50$ ), the edema is due to the exacerbation of diastolic dysfunction by increases in systemic arterial pressure and intravascular volume and not to transient systolic dysfunction or mitral regurgitation.<sup>46</sup> Diastolic dysfunction is usually apparent early in hypertension after the development of pathological hypertrophy associated with concentric remodeling or concentric hypertrophy. Patients usually are initially aware of symptoms with exertion but increasing symptoms become apparent at rest.<sup>47</sup> The symptoms of diastolic dysfunction are associated with abnormal diastolic filling pressures required to fill the left ventricle, which result in interstitial lung edema or which limit ventricular filling and thus compromise cardiac output. These symptoms are those of dyspnea and fatigue. Furthermore, pathologically hypertrophied myocardium is a substrate for cardiac arrhythmias. Thus palpitations may be a symptom of hypertensive cardiomyopathy. Physical examination may show jugular venous distention, pulmonary rales, an abnormal cardiac apical impulse (occasionally bifid) and an abnormal early (protodiastolic,  $S_3$ ) or late (atrial,  $S_4$ ) gallop sounds. A more laterally displaced cardiac apical impulse, more systemic venous hypertension, and peripheral edema usually characterize advanced hypertensive cardiomyopathy associated with eccentric ventricular remodeling.

*Systolic dysfunction and heart failure* associated with hypertensive cardiomyopathy may eventually develop late as a complication of the hypertensive process. Although resting systolic function remains normal in hypertensives for a considerable period of time even when LVH is present, systolic dysfunction may become more apparent with exercise.<sup>48</sup> Thus while diastolic dysfunction may be present, it is the same myocardium in systole and diastole—abnormal in both instances.

#### *Hypertension and Pluricausal Cardiomyopathy*

**Myocardial Ischemia, Coronary Heart Disease, and Hypertension.** Myocardial ischemia may be present in patients with hypertension in the face of normal coronary arteries by angiography due to small vessel disease as elaborated earlier.<sup>49</sup> Therefore, patients with hypertension often have symptoms of chest discomfort not due to epicardial coronary artery obstruction. However, hypertension is a risk factor for the development of coronary atherosclerosis. The contribution of hypertension to the progression of ventricular dysfunction in the face of coronary atherosclerosis and subsequent complications, including transient myocardial ischemia and myocardial infarction, is considerable (see Chapter 23).

Myocardial ischemia produced by atherosclerotic epicardial obstruction of coronary arteries is worsened by the presence of hypertensive cardiomyopathy. Hypertrophic cardiomyopathy increases the resistance to blood flow across the myocardial wall; since there is increased wall tension, subendocardial perfusion is impaired, and this may contribute to transient myocardial ischemia and myocardial stunning. Increases in ventricular impedance to ejection by infusion of methoxamine over a 4-hour period has been demonstrated to

produce relative infarct expansion and thinning in the early phase of infarct healing in dogs.<sup>50</sup> Similarly, aortic banding in the rat has been shown to increase infarct expansion independent of infarct size.<sup>51</sup>

Myocardial infarction results in the segmental loss of myocardium that results in increased physical burden for the remaining myocardium.<sup>52-54</sup> The ventricular remodeling that follows myocardial infarction occurring in a heart with hypertensive cardiomyopathy must contend with increased wall tension, now secondary to both ventricular dilation and increased arterial pressure that are consequences of pathological hypertrophy already present in the remaining, noninfarcted myocardium. Hypertensive hypertrophic cardiomyopathy is associated with increased morbidity and mortality after myocardial infarction. Moreover, necropsy studies have shown a positive correlation between a history of systemic hypertension and ventricular expansion and rupture. Thus both experimental and clinical data demonstrate the powerful effects of the mechanical aspects of hypertension in complications of coronary atherosclerosis.

**Interactions of Diabetes Mellitus with Hypertension in Heart Failure.** Diabetes mellitus is associated with the development of cardiomyopathy independent of the increased atherosclerosis often seen in these patients. The risk of heart failure is greatly increased in diabetic patients (see Chapter 26) as evidenced by data from the Framingham Heart Study.<sup>55</sup> In this study, diabetic male patients had more than twice the incidence rate of heart failure compared with nondiabetic cohorts, while diabetic women showed a fivefold increased risk. The cardiomyopathy of diabetes is markedly increased in the presence of increased systemic arterial pressure.<sup>18,19</sup> Mechanisms for the production of diabetic cardiomyopathy include increased oxidative stress, nonenzymatic glycosylation of proteins, alterations in intracellular signaling, and abnormalities in myocardial metabolism.<sup>18,19</sup> Abnormalities in diastolic function assessed by echocardiography occur in 27% to 69% of asymptomatic diabetic patients and may be followed by the development of clinical heart failure.<sup>56</sup>

#### *Prevention and Treatment of Hypertensive*

##### *Cardiomyopathy and Heart Failure*

**Prevention of Heart Failure in Hypertension.** Increased emphasis is being placed on preventive strategies to decrease the incidence and prevalence of heart failure. The American College of Cardiology/American Heart Association (ACC/AHA) Guidelines for the Evaluation and Management of Heart Failure describe criteria for four stages of heart failure (i.e., A-D).<sup>57</sup> Stages A and B are not really heart failure but rather early stages of cardiomyopathy. Notably, hypertension (stage A) and left ventricular hypertrophy (stage B) are important antecedents for the development of heart failure (Table 28-1).

It has been suggested that treatment of hypertension *alone* may result in a reduction in relative risk of developing heart failure by approximately 50%<sup>58,59</sup> (Figure 28-2). The effect of the treatment of hypertension on the development of heart failure in patients with isolated systolic hypertension is striking. Risk was reduced by 51% in the Swedish Trial of Old Persons Hypertension (STOP) Trial (Figure 28-3, A),<sup>60</sup> and by 55% in the Systolic Hypertension in Elderly Program (SHEP) trial (see Figure 28-3, B).<sup>61</sup> Other analyses show that whereas HF accounted for more than half of the deaths in hypertensive patients before the advent of adequate antihypertensive drugs, its contribution to mortality has fallen considerably.<sup>62,63</sup> The risk reduction for heart failure by treating hypertension is strikingly illustrated in a meta-analysis of the efficacy of various antihypertensive therapies used as first-line agents.<sup>64</sup>

In patients with hypertension, a reduction in LV mass during treatment is a favorable prognostic marker that predicts a lesser risk for subsequent cardiovascular morbid events. Such

**TABLE 28–1 The Early Stages of Heart Failure**

Stage	Description	Examples
A	Patients at high risk of developing heart failure (HF) because of the presence of conditions that are strongly associated with the development of HF. Such patients have no identified structural or functional abnormalities of the pericardium, myocardium, or cardiac valves and have never shown signs or symptoms of HF.	<i>Systemic hypertension; coronary artery disease; diabetes mellitus; history of cardiotoxic drug therapy or alcohol abuse; personal history of rheumatic fever; family history of cardiomyopathy</i>
B	Patients who have developed structural heart disease that is strongly associated with the development of HF but who have never shown signs or symptoms of HF.	<i>Left ventricular hypertrophy or fibrosis; left ventricular dilation or hypocontractility; asymptomatic valvular heart disease; previous myocardial infarction.</i>

**FIGURE 28–2** Effect of antihypertensive treatment on the incidence of heart failure, strokes, cardiovascular deaths, and coronary heart disease events (48,000 subjects). (Modified from Hebert PR, Moser M, Mayer, et al. Recent evidence on drug therapy of mild to moderate hypertension and decreased risk of coronary heart disease. *Arch Intern Med* 1993;153[5]:578-581 and Moser M, Herbert PR. Prevention of disease progression, left ventricular hypertrophy and congestive heart failure in hypertension treatment trials. *J Am Coll Cardiol* 1996;27:1214-1218.)

an association is independent of baseline LV mass, baseline clinic and ambulatory BP, and degree of BP reduction.<sup>65</sup>

An attempt to gain insight into the importance of regression of LVH on cardiovascular outcomes was made with the Losartan Intervention For Endpoint reduction in hypertension study (LIFE). The trial was conducted in 9193 participants older than 55 years of age who had hypertension and ECG LVH. Patients were randomized to treatment with either losartan-based or atenolol-based therapy and followed for 4 years. Blood pressure reduction was equal for both treatment groups. Losartan-based therapy was associated with greater prevention of cardiovascular morbidity and mortality and fewer instances of new-onset diabetes than atenolol-based therapy. An analysis with the ECG indices of LVH as time-varying covariates showed a partial (less than one third) relation with the effect of losartan-based treatment on the primary outcome. There was no difference in the losartan-based and atenolol-based treatment groups for admission to the hospital for heart failure.<sup>66</sup>

**FIGURE 28–3** Reduction of cardiovascular events by treating hypertension in the elderly. **A**, Results of the Swedish Trial of Old Persons Hypertension trial (STOP). **B**, Results of the Systolic Hypertension in the Elderly Program (SHEP) trial. (From Dahlöf B, Lindholm LH, Hansson L, et al. Morbidity and mortality in the Swedish trial in old patients with hypertension [STOP hypertension]. *Lancet* 1991;338:1281-1285 and SHEP Cooperative Research Group. Prevention of stroke by antihypertensive drug treatment in older persons with isolated systolic hypertension. Final results of the systolic hypertension in the elderly program [SHEP]. *JAMA* 1991;266:3255-3264.)

Yet further evidence supporting the critical importance of BP reduction comes from the CARDIO-SIS trial,<sup>67</sup> in which 1111 nondiabetic and thus lower risk patients with systolic BP of 150 mm Hg or greater were randomly assigned to a target systolic pressure of 140 mm Hg or to a lower target of less than 130 mm Hg. Antihypertensive medications were not specified and were tailored by the treating physician to individually bring the patient to target. After randomization, patients were followed for 2 years. Over 2 years of observation, systolic and diastolic BP decreased by 23.5 mm Hg and 8.9 mm Hg, respectively, in the usual-control arm and 27.3 mm Hg and 10.4 mm Hg in the tight-control arm. The primary endpoint of electrocardiographic LVH occurred in 17% of patients treated to the usual systolic BP target and in 11.4% of patients treated to less than 130 mm Hg. This translated into a significant 37% reduction in risk. A prespecified secondary endpoint, a composite of death from any cause, MI, stroke, transient ischemic attack, atrial fibrillation, admission for heart failure, angina, or coronary revascularization, occurred in 9.4% of individuals treated to the usual target and 4.8% of those treated to a lower systolic pressure goal.

**Effects of Specific Antihypertensive Drugs on Hypertensive Cardiomyopathy.** BP reduction by drugs with differing mechanisms of action may provide clues to the importance of nonhemodynamic mechanisms in reducing LV mass. Confounding such an analysis is the observation that a reduction in BP and LV mass may result from nonpharmacological means alone, and the resulting reduction in LV mass is similar to that achieved with antihypertensive drugs.<sup>68</sup> Such findings make it difficult to determine if different classes of antihypertensive drugs vary in ability to reduce LVH.

Several meta-analyses have suggested that RAAS blocking drugs are more effective in reducing LVH than other classes.<sup>69-71</sup> BP reduction in patients with hypertensive heart disease results in a decrease in LV mass. Thus it has been difficult to determine whether there is additional benefit to a further reduction of LV mass at any level of BP reduction. In principle, the higher the BP, and thus the greater benefit from BP reduction alone, the greater the difficulty in defining benefits specific to one drug class relative to another. However, high dose diuretics do reduce the risk of developing heart failure compared with low dose diuretics or  $\beta$ -blockers, but increase the risk of sudden death.

The issues of the quantitative efficacy of different classes of blood pressure lowering drugs in preventing coronary heart disease (CHD) and stroke, and of who should receive treatment, has been addressed in a meta-analysis that included 108 trials that studied differences in BP between study drug and placebo (or control group not receiving the study drug) (BP difference trials), and 46 trials that compared drugs (drug comparison trials)<sup>72</sup> (Table 28-2). Seven trials with three randomized groups fell into both categories, totaling 958,000 subjects.<sup>4</sup> In the BP difference trials,  $\beta$ -blockers had a special effect over and above that due to BP reduction in preventing recurrent CHD events in people with a history of CHD: risk reduction 29% (95% confidence interval [CI] 22% to 34%) compared with 15% (CI, 11% to 19%) in trials of other drugs. The extra effect was limited to a few years after myocardial infarction, with a risk reduction of 31% compared with 13% in people with CHD with no recent infarct ( $P = .04$ ). In the other BP difference trials (excluding CHD events in trials of  $\beta$ -blockers in people with CHD), there was a 22% reduction in CHD events (17% to 27%) and a 41% (33% to 48%) reduction in stroke for a BP reduction of 10 mm Hg systolic or 5 mm Hg diastolic, similar to the reductions of 25% (CHD) and 36% (stroke) expected for the same difference in BP from the cohort study meta-analysis, indicating that the benefit is explained by pressure reduction in itself. The five main classes of drugs (thiazides,  $\beta$ -blockers, angiotensin-converting enzyme inhibitors (ACEI), angiotensin receptor blockers (ARB), and calcium channel blockers) were similarly effective (within a few percentage points) in preventing CHD events and strokes, with the exception that calcium channel blockers had a greater preventive effect on stroke (relative risk, 0.92; 95% CI, 0.85 to 0.98). The percentage reductions in CHD and stroke were similar in people with and without cardiovascular disease and regardless of blood pressure before treatment (down to 110 mm Hg systolic and 70 mm Hg diastolic). When these results were combined with those from other studies, analysis showed that in people aged 60 to 69 with a diastolic pressure before treatment of 90 mm Hg, three drugs at half standard dose in combination reduced the risk of CHD by an estimated 46% and of stroke by 62%; one drug at standard dose had about half this effect. Drugs other than calcium channel blockers and noncardioselective  $\beta$ -blockers reduced the incidence of heart failure by 24% (19% to 28%), and calcium channel blockers by 19% (6% to 31%). With the exception of the extra protective effect of  $\beta$ -blockers given shortly after a myocardial infarction and the minor additional effect of calcium channel blockers in preventing stroke, all classes of antihypertensive drugs have a

**TABLE 28-2 Risk Reduction in Heart Failure by Type of Drug Treatment**

Class of Drug	No. of Trials	No. of Episodes	Relative Risk* (95% CI)
<b>Blood Pressure Difference Trials</b>			
<i>Single drug therapy</i>			
Calcium channel blockers	13	1519	0.81 (0.69-0.94)
Thiazides	5	222	0.59 (0.45-0.78)
$\beta$ -Blockers	13	2846	0.77 (0.69-0.87)
Angiotensin-converting enzyme inhibitors	16	3834	0.74 (0.68-0.81)
Angiotensin receptor blockers	3	1675	0.82 (0.73-0.92)
All drug classes except calcium channel blockers	36 <sup>†</sup>	8553 <sup>†</sup>	0.76 (0.72-0.81)
Combination drug therapy	7	144	0.57 (0.36-0.92)
<b>Drug Comparison Trials</b>			
Calcium channel blockers vs. any other drug class	21	4572	1.22 (1.10-1.35)
<i>Drug comparisons not involving calcium channel blockers:</i>			
Thiazides	2	2335	0.91 (0.64-1.30)
$\beta$ -Blockers	2	335	1.04 (0.84-1.29)
Angiotensin-converting enzyme inhibitors	9	5063	0.98 (0.91-1.06)
Angiotensin receptor blockers	7	2436	1.00 (0.93-1.08)

\*Relative risk <1.0 indicates specified drug class reduces risk of heart failure; >1.0 increases risk.  
†All trial totals are less than column totals because one trial had two treated groups sharing same placebo group.  
Results are shown from 64 blood pressure difference trials and 31 drug comparison trials of blood pressure lowering drugs.  
(Reprinted with permission Law MR, Morris JK, Wald NJ. Use of blood pressure lowering drugs in the prevention of cardiovascular disease: meta-analysis of 147 randomised trials in the context of expectations from prospective epidemiological studies. *BMJ* 2009;338:1245-1253.)

similar effect in reducing CHD events and stroke for a given reduction in pressure, thus apparently excluding effects other than BP itself. The proportional reduction in cardiovascular disease events was the same or similar regardless of pretreatment BP and the presence or absence of existing cardiovascular disease. Lowering systolic pressure by 10 mm Hg or diastolic pressure by 5 mm Hg using any of the main classes of drugs reduced CHD events (fatal and nonfatal) by about a quarter and stroke by about a third, regardless of the presence or absence of vascular disease and of pretreatment BP. Heart failure is also reduced by about 25%.  
However, in these trials BP was measured as brachial cuff pressure; only recently has there been recognition of differential effects of antihypertensive drugs upon central aortic pressure, and of the potential impact of these differences in central pressure reductions on target organs. Data from the Anglo-Cardiff Collaborative Trial II demonstrated that cardiovascular risk factors affect the pulse pressure ratio and that central pressure cannot be reliably inferred from peripheral pressure. These observations suggested that assessment of central pressure may improve the identification and management of patients with elevated cardiovascular risk.<sup>73</sup>

In a separate trial,<sup>74</sup> central pulse pressure was reduced significantly by perindopril, the dihydropyridine lercanidipine, and bendrofluazide, whereas atenolol had no effect. Lercanidipine reduced the augmentation index, whereas atenolol increased it. However, aortic pulse wave velocity was not changed by any of the drugs. The vasodilating  $\beta$ -blocker nebivolol has also been demonstrated to reduce both forearm vascular resistance, central aortic pressure, and augmentation index to a greater extent than nonvasodilating  $\beta$ -blockers<sup>75,76</sup> (Figure 28-4). An analysis from the Strong Heart Study suggests that noninvasive measurements of central aortic pressure more closely identify the presence of vascular disease, as detected by carotid ultrasound, than do standard brachial pressure readings and are also more predictive of outcomes.<sup>77</sup> That central aortic pressure and augmentation indexes are differentially reduced by different drug classes despite the presence of similar effects on brachial artery blood pressure was shown in the CAFE (Conduit Artery Function Evaluation) substudy of the ASCOT (Anglo-Scandinavian Cardiac Outcomes Trial); importantly, central pulse pressure was significantly associated with a post hoc-defined composite outcome of total cardiovascular events/procedures and development of renal impairment.<sup>78</sup> Furthermore, in end-stage renal disease patients, the insensitivity of central aortic pressure to decreased blood pressure is an independent predictor of mortality.<sup>79</sup>

**Hypertension, Diabetes Mellitus, and Heart Failure.** Understanding of BP management in diabetes began to change with the publications of the United Kingdom Prospective Diabetes Study beginning in 1998<sup>80,81</sup> in which 1148 hypertensive diabetics were randomized to “tight” (<150/85 mm Hg) versus “less tight” (<180/105 mm Hg) BP control. Within the “tight” control group, 400 diabetics were assigned to ACE inhibitors and 358 patients to  $\beta$ -blockers. The “less tight” control group ( $n = 390$ ) could not receive either of these classes of drugs. Diabetic-related deaths were significantly reduced equally well with  $\beta$ -blockers as with ACEI. However, the less tightly controlled group had significantly more diabetic-related deaths ( $P = .019$ ). There was no reduction in all cause mortality ( $P = .17$ ) or myocardial infarction ( $P = .13$ ); however, there was a significant reduction in heart failure ( $P = .0043$ ), strokes ( $P = .013$ ), and microvascular disease ( $P = .0092$ ) in the tightly controlled diabetic group. Furthermore, microvascular endpoints (renal failure, death, vitreous hemorrhage or photocoagulation) were reduced equally well with  $\beta$ -blockers as with ACEI in the tightly controlled group and less well in the less tightly controlled group. It is now known that the benefits seen in the UKPDS extend to blood pressures of less than 110 mm Hg systolic BP. These findings have been further reinforced in the SANDS using the surrogate marker of intimal/medial thickness in American Indians with type 2 diabetes.<sup>82</sup>

**Studies Treating Isolated Systolic Hypertension: SHEP and Syst-Eur.** Systolic BP is recognized as an important marker for cardiovascular disease. The overall cardiovascular mortality is two to three times greater in diabetics compared with nondiabetics for every level of systolic pressure.<sup>16</sup> This observation led to expectations for BP interventions in diabetics with isolated systolic hypertension. The Systolic Hypertension in the Elderly Program (SHEP) showed that a diuretic-based therapy in diabetics was effective in heart failure by heart failure by 49% (see Figure 28-3, B), and by reducing major cardiovascular events by 34%, strokes by 22% (not significant), nonfatal myocardial infarctions and fatal coronary heart disease events by 54%, CHD events by 56% and all cause mortality by 26% (not significant).<sup>8</sup> Post hoc analysis of the Systolic Hypertension in Europe (SYS-EUR) Trial showed that overall cardiovascular mortality was reduced in diabetics.<sup>83</sup> The dihydropyridine nitrendipine given with or without an ACEI and/or a diuretic reduced stroke risk in

**FIGURE 28-4** Differential effects of brachial versus central aortic pressure of atenolol compared with nebivolol. (Modified from Pederson ME, Cockcroft JR. The vasodilatory beta-blockers. *Curr Hypertens Rep* 2007;9[4]: 269-277.)

492 diabetics by 69% compared with placebo ( $P = .02$ ) and reduced cardiac events by 57% (not significantly different compared with placebo). With an adjusted analysis for baseline differences, overall mortality, cardiovascular mortality, cardiovascular events and stroke events and cardiac events were all significantly reduced in the 492 diabetic patients, but not in the 4203 non diabetic patients.

**Hypertension Optimal Treatment Trial.** The Hypertension Optimal Treatment (HOT) Trial, a prospective, open-labeled, blinded endpoint (PROBE) design trial, enrolled subjects with a diastolic pressure of 100 to 115 mm Hg.<sup>84</sup> Participants received antihypertensive medicines according to an algorithm in which felodipine, either an ACEI or a  $\beta$ -blocker, and a diuretic were given to achieve one of three levels of blood pressure goals (<90 mm Hg, <85 mm Hg, or <80 mm Hg). Compared with the treatment goal of less than 90 mm Hg versus less than 80 mm Hg, major cardiovascular events among the 1501 diabetics were reduced by 51% ( $P = .005$  for trend), an observation not explained by the trend in the reduction in myocardial infarction ( $P = .11$ ) and stroke ( $P = .34$ ). Furthermore, there was no significant reduction in overall mortality ( $P = .068$ ). However, in the subset of patients with diabetes, there was a significant reduction with lower diastolic pressure targets.

**Heart Outcomes Prevention Evaluation Study.** The Heart Outcomes Prevention Evaluation (HOPE) study was a randomized, double blind two by two factorial design study involving 9541 subjects, who had to be at least 55 years of age and have a high risk for vascular disease, which could include coronary artery disease, stroke, peripheral vascular disease, or diabetes mellitus with one other risk factor (hypertension, elevated total cholesterol, low HDL cholesterol, cigarette smoking, or documented microalbuminuria).<sup>85</sup> The risk of cardiovascular disease was significantly reduced when 10 mg of ramipril was given once daily. There was a 22% reduction in myocardial infarction, stroke, and cardiovascular death and all cause mortality. The diabetic subgroup ( $n = 3577$ ) and the patients with microalbuminuria ( $n = 1956$ ) treated with ramipril significantly benefited relative to the placebo group.

**Candesartan in Heart Failure-Assessment of Reduction in Mortality and Morbidity (CHARM)-Preserved Study.** A total of 3023 patients with heart failure symptoms and LVEF of 40% received candesartan (32 mg/day) or placebo for 36.6 months.<sup>86</sup> Candesartan reduced BP by a mean of 7/3 mm Hg, and, when adjusted for covariates, reduced the primary

endpoint (cardiovascular death and heart failure hospitalization) by 14%, a finding of borderline significance ( $P = .051$ ). Although there was no effect on cardiovascular mortality, candesartan treatment resulted in a significant decrease in hospitalizations for heart failure.

**I-PRESERVE.** In the I-PRESERVE trial, 4128 patients who were 60 years old with heart failure and LVEF greater than 45% were randomized to irbesartan (300 mg) or placebo and followed for 49.5 months<sup>87</sup> (see Figure 28-4). The patient population was typical for diastolic heart failure; the mean age was 72 years, 60% were women, 88% had a history of hypertension, and 63% had a hypertensive cause for heart failure. Irbesartan reduced BP by a mean of 3.8/2.1 mm Hg. There was, however, no difference in the occurrence of the primary endpoint (death or hospitalization for cardiovascular causes), mortality, heart failure hospitalization, or quality of life.

Together with CHARM-Preserved, this trial RAAS inhibition again reinforces the concept that extent of BP control, rather than any specific pharmacological mechanism of drug action in the absence of significant blood pressure reduction, is the determinant of clinical outcome.

**Valsartan in Diastolic Dysfunction (VALIDD) Trial.** VALIDD was designed to address the role of diastolic dysfunction as an important pathophysiological intermediate between hypertension and heart failure, testing the possibility that inhibitors of the RAAS, which can reduce ventricular hypertrophy and myocardial fibrosis, can improve diastolic function to a greater extent than can other antihypertensive agents (Figure 28-5).<sup>88</sup> Patients with hypertension and evidence of diastolic dysfunction were randomly assigned to receive either valsartan (titrated to 320 mg once daily) or matched placebo. Patients in both groups also received concomitant antihypertensive agents that did not inhibit RAAS to reach targets less than 135 mm Hg systolic pressure and less than 80 mm Hg diastolic pressure. The primary endpoint was the change in diastolic relaxation velocity between baseline and 38 weeks as determined by tissue Doppler imaging. Analyses were done with the intention to treat 186 patients who were randomly assigned to receive valsartan and 198 who received a placebo. Over 38 weeks, there was a 12.8/7.1 mm Hg reduction in pressure in the valsartan group and a 9.7 mm Hg reduction in the placebo group that was not significant between the two groups. Diastolic relaxation velocity increased in both groups, with no significant difference between the groups ( $P = .29$ ). Thus this carefully conducted trial, together with the two other angiotensin receptor blocker trials described earlier, have demonstrated that lowering BP improves diastolic function irrespective of the type of antihypertensive agent used.

**Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT).** ALLHAT was designed to determine whether newer antihypertensive agents (lisinopril or amlodipine) reduce the incidence of cardiovascular disease when compared with diuretics (chlorthalidone or doxazosin). ALLHAT randomized a total of 33,357 patients (aged  $\geq 55$  years) with hypertension and at least one other coronary heart disease (CHD) risk factor to receive chlorthalidone (12.5 to 25 mg/day) amlodipine (2.5 to 10 mg/day); or lisinopril (10 to 40 mg/day). The primary outcome was combined fatal coronary heart disease or nonfatal myocardial infarction, analyzed by intention-to-treat. Secondary outcomes were all-cause mortality, stroke, combined CHD (primary outcome, coronary revascularization, or angina with hospitalization), and combined cardiovascular death (combined CHD, stroke, treated angina without hospitalization, heart failure or hospitalized/fatal heart failure). As shown in Figure 28-6, there was a significant 38% decreased risk of heart failure and a 35% decreased risk of hospitalization/fatal heart failure in the chlorthalidone treated group when compared with the amlodipine treated group, consistent with prior reports with calcium channel blockers

**FIGURE 28-5** Change in diastolic function by quartile reduction in systolic blood pressure (SBP). (Modified from Solomon SD, Janardhanan R, Verma A, et al. Effect of angiotensin receptor blockade and antihypertensive drugs on diastolic function in patients with hypertension and diastolic dysfunction: a randomised trial. *Lancet* 2007;369[9579]:2079-2087.)

**FIGURE 28-6** Cumulative event rates for heart failure and hospitalization with fatal heart failure in the ALLHAT trial. **Top,** Event rates for heart failure. **Bottom,** Event rates for hospitalization plus fatal heart failure. (Modified from The ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group. Major outcomes in high-risk hypertensive patients randomized to angiotensin-converting enzyme inhibitor or calcium channel blocker vs. diuretic: the antihypertensive and lipid-lowering treatment to prevent heart attack trial [ALLHAT] *JAMA* 2002;288:2981-2997.) Copyright (2011) American Medical Association. All rights reserved.

in hypertension. There was also a significant 19% decreased risk of heart failure and a nonsignificant 10% decreased risk of hospitalization/fatal heart failure in the chlorthalidone treated group when compared with the lisinopril treated group. The treatment effects were consistent among subgroups by gender,

diabetic status, and underlying CHD status. Whether the salutary effects of chlorthalidone in ALLHAT represent better control of blood pressure, superior control of “congestion” with a diuretic, or an unknown effect on the development and progression of heart failure are not known.<sup>89</sup> Data from a separate arm of the ALLHAT showed that there was a twofold increase in the incidence of heart failure (8.1% vs. 4.4%) for doxazosin when compared with chlorthalidone.<sup>90</sup>

## CONCLUSION

Hypertension is the number one modifiable risk factor for the development of heart failure associated both with reduced and preserved left ventricular systolic function. Data from multiple clinical trials have demonstrated convincingly that reducing elevated systemic arterial pressures produces marked decreases in the incidence of heart failure. Yet, only one third of patients with known hypertension have BP controlled to the minimum of 140/80 mm Hg. Only 35.8% of participants in the Third National Health and Nutrition Examination Survey (NHANES III, conducted 1988-1994) and NHANES 1999-2000 achieved the target of systolic blood pressure (SBP) less than 130 mm Hg and diastolic blood pressure (DBP) less than 80 mm Hg, and 40.4% had hypertensive blood pressure levels (SBP  $\geq$  140 or DBP  $\geq$  90 mm Hg). NHANES 1999-2000 percentages did not change significantly from NHANES III ( $P = .10$  and  $P = .56$ , respectively).

Although hypertension alone may result in heart failure, heart failure usually results when hypertension coexists with other diseases that affect the myocardium (e.g., coronary atherosclerosis, diabetes mellitus). In particular, aggressive treatment of increased blood pressure in patients with diabetes mellitus is warranted to reduce cardiovascular morbidity in general, and heart failure in particular.

Thus the choice of drugs for the treatment of hypertension should be based upon their efficacy in preventing heart failure rather than their ability to induce LVH regression. However, the direct acting vasodilators hydralazine and minoxidil should probably not be first line therapy because they do not cause LV regression either in experimental animals or in humans and better drugs are available. American and European guidelines suggest that the most effective agents in reducing heart failure are diuretics, ACEI, ARB, and  $\beta$ -blockers.<sup>91,92</sup> The Antihypertensive and Lipid-Lowering treatment to prevent Heart Attack Atrial (ALLHAT) trial demonstrated that the  $\alpha_1$ -blocking agent doxazosin was less effective in preventing heart failure than were diuretic, calcium channel blocker, or ACE inhibitor<sup>90</sup>; this class is also no longer recommended as first-line therapy.

It is, however, critically important to recognize that the selection of antihypertensive agents may be driven by the need to treat comorbidities. It is very interesting to note that there is evidence that RAAS inhibition in type 2 diabetic patients with nephropathy may have renoprotective effects beyond that of blood pressure reduction alone, thus necessitating early use of RAAS inhibition in patients in this category.<sup>93</sup>

Based on recent trials, the JNC VII has slightly modified its recommendations for the treatment of hypertension in diabetics.<sup>94</sup> The treatment goal remained less than 130/85 mm Hg; ACE inhibitors remained initial therapy in the presence of albuminuria or proteinuria. However, from the initial drug selection  $\alpha_1$ -blockers were eliminated and  $\beta$ -blockers were added.

Much of the role of hypertension on the heart may be attributed to the increased mechanical effects of an increased BP, which does not preclude the influence of other neuro-hormonal and local cellular mechanisms in the production of pathological left ventricular hypertrophy. Nevertheless, it is apparent that the major step in preventing hypertension-associated heart failure is to control BP.<sup>95</sup> This is supported by the 2009 ACC/AHA guidelines in which control of systolic

and diastolic hypertension is a class I recommendation (level of evidence A) for the treatment of diastolic heart failure.<sup>96</sup>

 Conclusion, 453

admissions due to coronary artery disease have fallen over the last decade, admissions for the treatment of valvular heart disease have progressively increased.<sup>1</sup> This has occurred primarily because valvular heart disease in western culture today is often a consequence of aging and our population is getting older. While the incidence of valve disease due to rheumatic fever has fallen dramatically, both aortic stenosis and mitral regurgitation have increased with the aging population. A persistent background incidence of infective endocarditis adds additional cases of both aortic and mitral insufficiency.

All valvular heart diseases impart a hemodynamic load on the left and/or right ventricles. If this load is severe and acute, or severe and prolonged, it causes heart failure and death. The importance of valvular disease is further heightened because proper recognition and management of these diseases removes the hemodynamic overload and can either prevent or reverse the heart failure syndrome, a situation rare in the realm of heart failure where most diseases that cause it confer persistent systolic and/or diastolic dysfunction.

On the following pages, each valvular heart disease will be addressed regarding mechanisms by which acute and chronic hemodynamic overload leads to heart failure, the medical and surgical options for treating heart failure, and proper timing of intervention so as to prevent heart failure from occurring or at least from becoming permanent.

## Aortic Insufficiency

### Acute Aortic Insufficiency

Acute aortic insufficiency such as might occur due to perforation of an aortic leaflet by infective endocarditis is usually a surgical emergency. The hemodynamics of acute aortic insufficiency is demonstrated in [Figure 29-1](#).<sup>2</sup> While the clinician is accustomed to finding a myriad of hyperdynamic signs produced by chronic aortic insufficiency, these are usually absent in acute disease. In chronic aortic insufficiency, eccentric hypertrophy allows the ventricle to generate increased total stroke volume to help compensate for that which is regurgitated. This large total stroke volume is ejected into the aorta where it produces a widened pulse pressure and a hyperdynamic circulation responsible for Corrigan pulse, de Musset sign, Quincke pulse, etc. However, in acute disease, left ventricular (LV) dilation has not developed and thus, acute aortic insufficiency causes little increase in total stroke volume, a sudden fall in forward output, and a fall in systemic blood pressure. At the same time, backward flow into the left ventricle stretches sarcomeres toward their maximum. This volume overload does allow the ventricle to generate increased force by the Frank Starling mechanism, but also exposes the unprepared small ventricle to a large increase in diastolic pressure. While the lungs are partially protected by this increased pressure by preclosure of the mitral valve, the ventricle is not. The driving gradient for generating coronary blood flow is the aortic diastolic pressure minus the LV filling pressure (which compresses the endocardium preventing coronary inflow.) As can be seen in [Figure 29-2](#), these pressures may become equal mid-way through diastole, reducing coronary blood flow, in turn, leading to myocardial ischemia and worsening muscle function.<sup>3</sup> While unproven, it is likely that it is this sequence of events that often generates a rapid downhill course so that a patient with acute aortic insufficiency can go from mild decompensation to death within hours. Medical therapy is often to no avail. Vasodilators, which

might help to increase forward flow, further decrease blood pressure leading to worsening myocardial perfusion. Pressor agents, some of which increase blood pressure by causing vasoconstriction, are also likely to worsen the amount of regurgitation severely limiting the usefulness of these agents. Agents, which increase heart rate, can help by decreasing the time for aortic runoff but these drugs also increase myocardial oxygen consumption, potentially worsening ischemia. Intraaortic balloon pumping is obviously contraindicated and ineffective since diastolic inflation of the balloon dramatically worsens the amount of aortic insufficiency. Thus, in acute aortic insufficiency, acute severe volume overload forces the operation of the left ventricle to the high right-hand side of the pressure volume relationship leading to pulmonary congestion. The sharp reduction in forward output further compounds the heart failure syndrome. Reduced output diminishes systemic blood pressure, leading to reflex vasoconstriction in turn worsening regurgitation.

The therapy for this syndrome requires aggressive action. As indicated previously, while it is often hoped that medical therapy may stabilize the patient and give more time for antibiotics (in infective endocarditis), to become effective, continued hemodynamic deterioration usually occurs despite medical therapy. Even the mildest symptoms and signs of heart failure, such as slight orthopnea or tachycardia unexplained by the patient's fever, should be taken as an early warning that aortic valve replacement should be imminent.<sup>4</sup> It should be recognized that despite the worry that replacement valve may become infected, this worry is usually not justified even in mechanical valves where the reinfection rate is less than 10%.<sup>5</sup> The reinfection rate with homografts appears to be even lower and this valve has become the preferred prosthesis in patients with active infection.<sup>6</sup>

### Chronic Aortic Insufficiency

Common causes of chronic aortic insufficiency include annuloaortic ectasia, Marfan syndrome, rheumatic heart disease, and endocarditis that was not severe enough to require immediate valve replacement. In chronic aortic insufficiency, volume overload

A

B

**FIGURE 29-1** A, Normal physiology. B, Pathophysiology of acute aortic regurgitation. In response to acute volume overload, end-diastolic volume (EDV) increases modestly, allowing for a modest increase in total stroke volume. This small increase widens pulse pressure only slightly. The regurgitant volume is summed with that returning from the pulmonary veins, causing LV volume overload. This overload on the unprepared left ventricle causes a large increase in LV end-diastolic pressure (LVEDP). At the same time, forward stroke volume is reduced. Thus all the manifestations of heart failure are present even though myocardial function is normal. *EF*, ejection fraction; *ESV*, end-systolic volume; *RF*, regurgitant fraction. (Reprinted from Carabello BA. Hemodynamic determinants of prognosis. In Cohn LH, DiSesa VJ, editors. *Aortic regurgitation: medical and surgical management*, New York, 1986, Marcel Dekker.)

**FIGURE 29-2** Hemodynamic effects of aortic regurgitation. End-diastolic aortic and ventricular pressure become equal in mid-diastole, a point at which there can be no significant coronary blood flow. *RFA*, right femoral artery; *LV*, left ventricle. leads to the development of eccentric hypertrophy where sarcomeres laid down in series increase the length of individual myocytes. Increased myocyte length leads to increased LV volume, allowing total stroke volume to increase. This mechanism may be quite effective, allowing the patient with even severe chronic aortic insufficiency to be totally asymptomatic. Indeed young patients who have developed the disease from endocarditis can often engage in sports activities (although

**FIGURE 29-3** Pathophysiology of chronic compensated aortic regurgitation. Compared with Figure 29-1B, eccentric hypertrophy has developed, allowing a large increase in end-diastolic volume (EDV), increasing total stroke volume and in turn returning forward stroke volume toward normal. The larger ventricle can now accommodate the volume overload at much lower LV end-diastolic pressure (LVEDP). The large total stroke volume results in a widened pulse pressure, which is responsible for many of the signs of chronic aortic regurgitation. *EF*, ejection fraction; *ESV*, end-systolic volume; *RF*, regurgitant fraction. (Reprinted from Carabello BA. Hemodynamic determinants of prognosis. In Cohn LH, DiSesa VJ, editors. *Aortic regurgitation: medical and surgical management*, New York, 1986, Marcel Dekker.)

this is contraindicated if there is substantial left ventricle dilation) without symptoms. At the same time, increased ventricular size allows the regurgitant volume to be accommodated at a lower filling pressure, in turn relieving or preventing the symptoms of congestion that are seen in acute aortic insufficiency when the ventricle is small (Figure 29-3).<sup>2</sup> Accordingly, severe aortic insufficiency may be extremely well compensated with a normal forward output and normal filling pressure. As noted previously, the large stroke volume produced in aortic insufficiency causes a wide pulse pressure and systolic hypertension. Thus there is an element of increased afterload seen in aortic insufficiency that is not present in mitral insufficiency.<sup>7</sup> This increased afterload leads to an element of concentric hypertrophy in addition to the eccentric hypertrophy generated by the volume overload.<sup>8</sup> Concentric hypertrophy helps to normalize systolic wall stress, allowing ejection fraction (EF) to be normal. However, as the disease progresses, this mechanism may become inadequate to normalize stress, wall stress increases, and ejection fraction is reduced.<sup>9</sup> At this time, symptoms may develop because the systolic dysfunction engendered by increased systolic wall stress places the ventricle on a higher portion of its operating pressure volume relationship. In addition, the concentric hypertrophy that develops diminishes diastolic function, further contributing to the syndrome of heart failure. Apart from the abnormal loading, which helps generate the heart failure syndrome, muscle dysfunction may also intervene. The mechanisms of myocardial dysfunction are not yet well worked out for aortic insufficiency. However, it is known that coronary blood flow, especially to the endocardium, is reduced in these patients. Thus ischemia especially during exercise may contribute to the syndrome.<sup>10</sup> In an important rabbit model of aortic insufficiency, increased extracellular matrix deposition leads to increased myocardial stiffness and to myocyte destruction, thus contributing both to diastolic and systolic dysfunction.<sup>11</sup> In patients with aortic insufficiency, increased fibrosis and decreased myosin content in the myocardium has also been detected and both obviously could lead respectfully to diastolic and systolic dysfunction.<sup>12</sup>

## Management of Congestive Heart Failure in Aortic Insufficiency

### Avoidance of CHF

Aortic insufficiency is a mechanical problem, which places an overload on the myocardium. This mechanical problem can be corrected by valve replacement or occasionally by valve

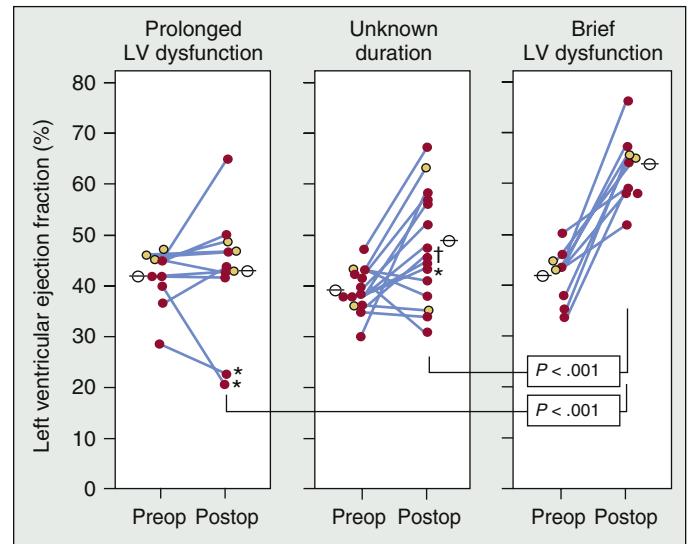

**FIGURE 29-4** The importance of symptoms. Whether ejection fraction was normal (left panel) or reduced (right panel), survival in patients with aortic regurgitation was most influenced by symptom severity. (From Klodas E, Enriquez-Sarano M, Tajik AJ, et al. Surgery for aortic regurgitation in women: contrasting indications and outcomes compared with men. *Circulation* 1996;94:2472-2478.)

repair. Close surveillance of the patient with aortic insufficiency allows for the timing of this correction to occur before irreversible muscle damage has developed and also in time to allow for a normal life expectancy following valve replacement. Further, as surgical techniques and prosthetic valves have improved, their risk has diminished—making earlier timing of surgery progressively more attractive because as risk diminishes, benefit increases.

**Symptoms.** Once even mild symptoms of congestive heart failure develop in chronic aortic insufficiency, prognosis worsens as shown in Figure 29-4.<sup>13</sup> Although it seems intuitive that the symptoms from valvular heart disease would have the same implications as those from other types of heart disease, the higher risk of prosthetic valves and surgery decades ago, generated a strategy of withholding surgery until it was inevitable. Typically, patients were not operated upon until their symptoms were far advanced. However, once the detrimental cascade of congestive heart failure has been initiated, a downhill course can be expected until that cascade is halted. Fortunately, in valvular heart disease, the cascade can be reversed and prognosis restored to normal. Thus, even mild symptoms are an indication for mechanical intervention in this disease especially in light of improved modern surgical techniques.

#### Asymptomatic Left Ventricular Dysfunction

While many patients develop symptoms when LV dysfunction develops or may become symptomatic even before there are objective signs of LV dysfunction, other patients remain asymptomatic despite LV dysfunction. Lack of symptoms may result from denial or unknown factors limiting perception by the patient. Nonetheless, it is generally accepted that some patients may remain asymptomatic despite relatively far advanced contractile dysfunction. To prevent dysfunction from becoming irreversible, it must be detected and corrected in a timely fashion. Figure 29-5 demonstrates that even if fairly advanced LV dysfunction has developed, it returns to normal if correction occurs within 15 months of onset.<sup>14</sup> Because by definition the patient under consideration is asymptomatic, the clinician needs a tool other than patient complaint

**FIGURE 29-5** The effects of the duration of left ventricular (LV) dysfunction on recovery of function after valve replacement. If ejection fraction was reduced for 15 months or less before surgery (right panel), ejection fraction improved; improvement was less likely (left panel) if ejection fraction had been depressed for longer periods. (From Bonow RO, Rosing DR, Maron BJ, et al. Reversal of LV dysfunction after aortic valve replacement for chronic aortic regurgitation: influence of duration of preoperative LV dysfunction. *Circulation* 1984;70:570-579.)

to alert him or her that dysfunction is developing. Currently, echocardiographic surveillance is the standard technique for early detection of LV dysfunction, although it may be that in the future brain natriuretic peptide (BNP) or other serological examinations will be determined to be useful. Several studies have examined echocardiographic markers associated with poor versus good outcome following surgery. These can be summarized most simply as stating that when ejection fraction falls below 0.50 or when end systolic dimension exceeds 50 to 55 mm, postsurgical outcome is reduced.<sup>15</sup> Presumably, these markers of poor outcome indicate that LV dysfunction is becoming irreversible and therefore, are an indication for mechanical relief from the volume and pressure overload.

Following surgery, ejection fraction usually improves if it was reduced preoperatively. As noted, this is especially true if correction of the mechanical lesion is provided within 15 months of the onset of LV dysfunction. Improvement in function is predicated upon a fall in afterload as both the pressure and radius terms of the La Place equation (stress = pressure × radius/2 × thickness) are reduced following surgery and also due to improved myocardial function.<sup>9</sup> Improved function following surgery is predicated upon a reduction in collagen content and an improvement in myosin content.<sup>16</sup>

#### Medical Therapy

Because aortic insufficiency increases LV afterload, afterload reducing agents have been used in an attempt to forestall the onset of LV dysfunction. In a controlled study, nifedipine compared to digoxin forestalled the need for surgery as indicated by the development of symptoms or LV dysfunction by 2 to 3 years.<sup>17</sup> However, a more recent study of randomized patients receiving nifedipine versus a true placebo (instead of digoxin), employed a third arm, enalapril.<sup>18</sup> It found no benefit to vasodilator use. Thus the AHA/ACC Guidelines for the management of valvular heart disease reduced the indication for vasodilator use in aortic insufficiency from a class 1 indication (beneficial) to a class 2b indication (uncertain benefit).<sup>15</sup> However, in the patient with heart failure due to aortic insufficiency in whom surgery cannot be performed, standard heart failure therapy should be initiated.

**FIGURE 29-6** Postoperative survival for patients with aortic insufficiency is plotted according to preoperative ejection fraction. (From Chaliki HP, Mohty D, Avierinos JF, et al. Outcomes after aortic valve replacement in patients with severe aortic regurgitation and markedly reduced LV function are impaired. *Circulation* 2002;106[21]:2687-2693).

It has generally been held that  $\beta$ -blockers should be contraindicated in aortic insufficiency. It was thought that slowing of the heart rate would increase the period during which regurgitation could occur, worsening the volume overload. However, a recent report suggests that some patients with severe aortic insufficiency actually benefitted from  $\beta$ -blockade.<sup>19</sup> In a retrospective study, aortic insufficiency patients taking  $\beta$ -blockers had improved survival compared with those who were not receiving them. Most had heart failure and the presence of coronary disease and hypertension did not account for  $\beta$ -blockade benefit. While this finding goes against current wisdom and must be confirmed, it may be that the beneficial effects of  $\beta$ -blockade in heart failure in general outweigh the potential negative potential of increasing the diastolic leak in aortic insufficiency. It should also be noted that paradoxically, the  $\beta$ -blockade group actually had slightly faster heart rates than the unblocked group and it was the group with the fastest heart rates that benefitted most from  $\beta$ -blockade.

#### Far Advanced Left Ventricular Dysfunction

The question often arises, "Has left ventricular dysfunction ever become so far advanced that surgery is impossible?" As indicated in Figure 29-5, even patients with very low ejection fractions may benefit from aortic valve replacement especially if LV dysfunction has been of short duration. Thus, no specific ejection fraction provides a cutoff that prohibits surgery, although as demonstrated in Figure 29-6 low ejection fraction negatively impacts prognosis.<sup>20</sup> It does seem logical that since one of the major mechanisms of improvement following surgery is reduction in afterload, that the absence of afterload excess preoperatively is a bad prognostic sign and thus in the patient with severe aortic insufficiency and a reduced ejection fraction, who also has low, rather than elevated systolic blood pressure, outcome may be reduced. The exact prognosis in such patients awaits further study.

### Mitral Regurgitation

#### Acute Mitral Regurgitation

In acute mitral regurgitation such as might occur with rupture of a chordae tendineae, there is the sudden opening of a new pathway for ejection from the left ventricle. This pathway produces two unwanted consequences leading to congestive heart failure. First, there is volume overload of the unprepared left atrium and left ventricle as the regurgitant flow is summed with flow returning from the pulmonary veins. This volume overload acutely raises left atrial and LV diastolic

pressures, in turn leading to pulmonary congestion and dyspnea. At the same time, forward cardiac output is reduced by the amount of flow lost to regurgitation. As shown in Figure 29-7, there is partial compensation for this insult as the volume overload stretches existing sarcomeres in the left ventricle to their maximum, increasing end-diastolic volume and the pumping capacity of the left ventricle.<sup>21</sup> Also, the reduced afterload created by the new ejection pathway into the relatively low pressure of the left atrium enhances ejection and reduces end-systolic volume. Increased end-diastolic volume and decreased end-systolic volume increase total stroke volume in part compensating for that which is lost to regurgitation. However, this increase is inadequate to normalize forward stroke volume. In this instance, LV contractile function is normal; ejection fraction is markedly increased due to the favorable loading conditions on the left ventricle, yet, all of the hemodynamic and clinical facets of congestive heart failure are present. If the regurgitant lesion is severe, reduced forward stroke volume leads to lower blood pressure while at the same time, the patient develops pulmonary edema. In such patients, arterial vasodilators may allow for a preferential increase in forward flow while diminishing regurgitant flow, in turn improving the hemodynamic situation.<sup>22</sup> However, if hypotension is already present, the use of vasodilators may further lower blood pressure and cannot be used. In such cases, intraaortic balloon pumping is used to maintain mean arterial pressure while reducing afterload and increasing forward stroke volume until surgical correction of the defect can be performed.

If the acute regurgitation is less severe, it may be attended by only mild symptoms, which can be treated successfully with diuretics. Currently, at issue is what constitutes the best management in patients who have been rendered asymptomatic by relatively minimal medical therapy. As shown in Figure 29-7, eccentric cardiac hypertrophy may develop over time, allowing for normalization of forward stroke volume. At the same time, atrial and ventricular chamber enlargement can accommodate the regurgitant volume, resulting in normal filling pressure and thus the symptoms of pulmonary congestion are relieved. Such patients may remain asymptomatic for months or years thereby avoiding cardiac surgery. However, one study has found that a few such patients rendered asymptomatic by medical therapy may have been at risk for sudden death although asymptomatic.<sup>23,24</sup> Thus whether successful medical therapy is in fact beneficial or whether it simply masks the potential risk for sudden death awaits further study.

**FIGURE 29-7** Normal physiology (left panel) is compared with that of acute mitral regurgitation (MR) and chronic compensated mitral regurgitation (right panel). In acute MR, volume overload increases end-diastolic volume (EDV), whereas the new pathway for ejection into the left atrium (LA) reduces afterload, in turn reducing end-systolic volume. These factors increase total stroke volume but not enough to compensate for that which is lost to regurgitation; thus, forward stroke volume is reduced. The volume overload on the small left atrium and left ventricle increase left atrial pressure, leading to pulmonary congestion. In chronic compensated MR (right panel), eccentric hypertrophy develops, allowing an increase in both total and forward stroke volumes; the now-enlarged left-sided chambers accommodate the volume overload at lower filling pressure. CF, contractile function; EF, ejection fraction; ESS, end-systolic stress; ESV, end-systolic volume; FSV, forward stroke volume; RF, regurgitant fraction; SL, sarcomere length. (From Carabello B. Mitral regurgitation: basic pathophysiologic principles. *Mod Concepts Cardiovasc Dis* 1988;57:53-58.)

### Chronic Mitral Regurgitation

It appears that moderate mitral regurgitation can be tolerated for years or perhaps, indefinitely. In studies of patients undergoing mitral valve replacement for mitral regurgitation, regurgitant fraction almost always exceeds 50%.

In a dog model of mitral regurgitation that causes myocardial dysfunction, there is almost complete recovery of function if mitral valve repair reduces regurgitant fraction to less than 35%.<sup>25</sup> Thus it seems that it requires a regurgitant fraction of between 40% and 50% to create and maintain LV dysfunction. Figure 29-7 demonstrates that the major compensatory mechanism for mitral regurgitation is the development of eccentric cardiac hypertrophy. Here individual myocytes add sarcomeres in series so that the individual cell becomes longer, increasing ventricular volume. In addition, the volume overload causes sarcomere stretch, increasing preload. Thus increased preload together with normal contractile function of an enlarged left ventricle allows for increased total stroke volume, increasing forward stroke volume toward normal. At the same time, enlargement of the left atrium and left ventricle allows for accommodation of the regurgitant volume at fairly normal filling pressure. In this compensated phase of mitral regurgitation, patients might be entirely asymptomatic even during vigorous activities. It should be noted, however, that such patients may have activation of the adrenergic nervous system, which can maintain both contractile and pump function at normal levels despite concealed intrinsic muscle dysfunction.<sup>26,27</sup>

If mitral regurgitation is severe, eventually muscle dysfunction does occur. While once believed that mitral regurgitation

was well tolerated for prolonged periods of time, it is now evident that most patients with severe mitral regurgitation develop adverse clinical events within 5 years of recognition of severe disease.<sup>28,29</sup> The mechanisms of this dysfunction are now being worked out. In both an experimental model of mitral regurgitation and in man, at the papillary muscle level there is a loss of contractile proteins and contractile elements, obviously reducing muscle function.<sup>30</sup> The second cause of the muscle dysfunction that develops is a shift in the force-frequency relationship such that the muscle develops less force with peak force developed at a slower heart rate than normal. These changes imply that abnormalities in calcium handling are at the source of the dysfunction.<sup>31</sup>

In addition, the hypertrophy that occurs in mitral regurgitation is both adaptive and maladaptive. It is adaptive because it allows the chamber to pump an increase in total volume. It is maladaptive because as volume increases, the radius term in the La Place equation also increases, thereby increasing both systolic and diastolic stress. While mitral regurgitation is usually viewed as a lesion that reduces LV afterload (and it does in acute mitral regurgitation), as the radius increases, afterload returns first to normal and then even to higher than normal levels when LV dysfunction has developed. This abnormality of chamber geometry further contributes to LV dysfunction in chronic mitral regurgitation.<sup>32</sup>

Besides the changes in chamber geometry noted previously, the hypertrophy that develops in mitral regurgitation, seems to be qualitatively different than that which occurs in pressure overload. In LV pressure overload, hypertrophy accrues primarily by an increase in synthesis of contractile

proteins.<sup>33</sup> However, in both canine and lapinine models of mitral regurgitation, hypertrophy seems to accrue not by an increase in synthesis but rather by a diminution in degradation rate.<sup>34</sup> These changes would mean that the contractile proteins in mitral regurgitation are turning over more slowly and thus are older than normal, which could in some way be implicated in the muscle dysfunction that accrues.

#### Reversal of Left Ventricular Dysfunction in Mitral Regurgitation

Both in man and in dog, correction of the mitral regurgitation can lead to an improvement in contractility.<sup>35,36</sup> This improvement is presumably time-dependent, although it is not clear at what point the ventricular dysfunction is irreversible. Of interest, much of the LV dysfunction that develops in experimental mitral regurgitation also can be corrected by initiation of  $\beta$ -blockade.<sup>37</sup> The benefits of  $\beta$ -blockade are now not surprising in view of their usefulness in treating the contractile dysfunction of dilated cardiomyopathy (see Chapters 24 and 46). Presumably, overactivation of the adrenergic nervous system leads to myocardial damage and this damage can be corrected by protecting the myocardium from catecholamines. The efficacy of  $\beta$ -blockade in patients with mitral regurgitation has yet to be tested. A recent report in man shows that  $\beta$ -blockade decreased stroke work but increased stroke volume, potential mechanisms by which  $\beta$ -blockade could be beneficial.<sup>38</sup>

#### Strategies for Detection and Correction of Congestive Heart Failure in Chronic Primary Mitral Regurgitation

Once even mild symptoms of congestive heart failure develop in the patient with chronic mitral regurgitation, prognosis is reduced.<sup>39</sup> Thus it seems clear that mitral valve repair or replacement should be performed at the onset of symptoms. There is no evidence that medical therapy at this point in the disease is beneficial, although no human trials of either  $\beta$ -blockers or ace inhibitors have been performed in a scale large enough to know whether these therapies might be of benefit.

As with aortic regurgitation, patients with mitral regurgitation may develop LV dysfunction without developing symptoms. Once ejection fraction declines below 60%<sup>39</sup> or once the left ventricle is unable to contract to an end-systolic dimension of 45 mm,<sup>40</sup> prognosis worsens (Figure 29-8). In fact recent data suggest that for EF to return to normal postoperatively, end-systolic dimension should not exceed 40 mm.<sup>41</sup> It is likely, therefore, that these markers indicate the presence of enough muscle dysfunction to impact prognosis. Thus mitral valve surgery should be performed when ejection fraction falls toward 60% or when end-systolic dimension increases toward 40 mm.<sup>15</sup>

In protecting the patient with mitral valve regurgitation from congestive heart failure, it is crucial that during surgery all, or at least part, of the mitral valve apparatus and its natural connections be preserved.<sup>42-45</sup> It is clear that the mitral valve apparatus contributes substantially to LV contraction and to maintaining the shape of the left ventricle. If the apparatus is destroyed, there is a substantial and irreversible decline in the ejection performance following surgery.<sup>42</sup> Even if a prosthetic valve is inserted, the posterior connections between the papillary muscles, the chordae, and the posterior leaflet can be maintained and this amount of preservation is beneficial to the outcome.<sup>45</sup> However, it should be noted that despite the wealth of evidence that preservation of the mitral apparatus during surgery is crucial, only approximately 60% of mitral valves are being repaired in the United States today. Indeed, there is substantial variation in repair rate from institution to institution with some institutions reporting a 95% repair rate.

Strategies to control mitral regurgitation less invasively using transcatheter mitral repair are currently undergoing testing in clinical trials. The MitraClip (Evalve, Inc.) uses a triaxial catheter-based system to create a double-orifice mitral

**FIGURE 29-8** Survival following mitral valve surgery for mitral regurgitation. Whether repair or replacement is done, survival is excellent as long as the preoperative ejection fraction (EF) exceeds 0.60. (From Enriquez-Sarano M, Tajik AJ, Schaff HV, et al. Echocardiographic prediction of survival after surgical correction of organic mitral regurgitation. *Circulation* 1994;90: 830-837.)

valve similar to the Alfieri surgical technique. The ongoing Endovascular Valve Edge-to-Edge REpair Study (EVEREST II) and Real World ExpANded MuLtiCenter Study of the MitraClip System (REALISM) trials are prospective, multicenter, randomized studies to evaluate the safety and effectiveness of an endovascular approach to the treatment of mitral valve regurgitation using the MitraClip edge-to-edge implant (ClinicalTrials.gov Identifier: NCT00209274). Patients are randomized 2:1 to the study and control arms, respectively. The primary endpoints of the trial are freedom from surgery for valve dysfunction, death, and moderate to severe (3+) or severe (4+) mitral regurgitation at 12 months and freedom from major adverse events at 30 days or hospital discharge, whichever is longer. The study is powered to show noninferiority of effectiveness of the MitraClip compared with a treatment strategy of mitral valve repair or replacement surgery. The study is also powered to show superiority of safety at 30 days of an endovascular treatment strategy with the MitraClip compared with a treatment strategy of mitral valve repair or replacement surgery. Although this trial is not recruiting heart

failure patients per se, the patients must be symptomatic from their mitral regurgitation or have evidence of LV dysfunction.

The MOBIUS leaflet repair system (Edwards, Inc.) is another edge-to-edge technique that uses a percutaneous stitch to create a double-orifice mitral valve.<sup>50</sup> There are also several direct annuloplasty techniques that imitate a surgical annuloplasty procedure, including the Mitralign System (Mitralign, Inc.), the AccuCinch (Guided Delivery Systems), and the QuantumCor device (QuantumCor). In addition, there are transcatheter coronary sinus techniques that reduce the septal-lateral dimensions of the mitral annulus using a reshaping device that is implanted in the coronary sinus. Several systems, including the MONARC device (Edwards, Inc.), the Percutaneous Mitral Annuloplasty device (PTMA, Viacor), and the CARILLON Mitral Contour System (Cardiac Dimensions) are in early phase testing. Whether these systems can be used in patients with heart failure and dilated ventricles remains to be determined.

### Secondary Mitral Regurgitation

As systolic function worsens in patients with ischemic or dilated cardiomyopathy, ventricular dilation and wall motion abnormalities frequently lead to mitral incompetence. In this case the burden of volume overload caused by regurgitation is added to the already serious problem of the primary disease. The presence of functional MR worsens the prognosis of heart failure.<sup>46</sup> But what is not certain is whether the MR is the cause of the worsened prognosis or simply a marker of poorer LV function. The exact implications of secondary mitral regurgitation and its management are currently undergoing intense scrutiny (see also Chapter 55). In a seminal study, surgical correction of mitral regurgitation using a simple ring angioplasty substantially decreased the amount of mitral regurgitation, had a 70% one year survival rate and significantly reduced cardiac volumes while improving ejection fraction.<sup>47</sup> However, follow-up of these patients found no survival benefit compared with medical therapy.<sup>48</sup> Other studies have found little or no benefit to correcting MR in the face of severe heart failure.<sup>49</sup>

## Aortic Stenosis

### Acute Aortic Stenosis

The occurrence of acute aortic stenosis is limited to the sudden malfunction of a prosthetic aortic valve in which thrombus or other material prevents the valve leaflets from opening properly. Unlike chronic aortic stenosis where the obstruction to outflow develops gradually, allowing the left ventricle time for hypertrophic compensation, in acute aortic stenosis sudden obstruction increases afterload and impairs left ventricle ejection. Depending on the severity of the obstruction, the amount of impairment may range from mild to catastrophic. The only satisfactory therapy is immediate release of the obstruction by replacing the prosthesis, or, if a clot is the cause of the obstruction, thrombolytic agents have been used safely for dissolution of thrombus on the aortic valve.<sup>51</sup>

### Chronic Aortic Stenosis

Little hemodynamic consequence develops as the aortic valve becomes narrowed from its normal aperture to one half its normal orifice area. However, further narrowing creates progressive obstruction to LV outflow resulting in a pressure gradient between the left ventricle and aorta. This gradient represents the additional pressure work that the left ventricle must perform to drive blood past the stenotic valve. It is generally agreed that an adaptive response to this pressure overload is the development of concentric LV hypertrophy.<sup>52,53</sup> Examining the Laplace equation, when pressure in the numerator is increased, it can be offset by increased wall thickness in the denominator. Thus even though there is an

increase in LV pressure, wall stress can remain normal and afterload on an individual muscle fiber can be maintained in the normal range despite the presence of aortic stenosis.

However, while the LV hypertrophy is adaptive in some cases of aortic stenosis, it is maladaptive in others. Even if the amount of hypertrophy that develops is just enough to offset the increased LV pressure, the increased wall thickness requires a higher filling pressure to distend the ventricle to a given volume than if thickness were normal. Although the characteristics of the muscle in concentric hypertrophy can be normal, increased thickness mandates diastolic dysfunction. In addition as the pressure overload becomes more severe and more prolonged, collagen content of the myocardium increases, further increasing ventricular stiffness and decreasing diastolic function.<sup>54,55</sup>

With regards to systole, as noted previously, the amount of hypertrophy that develops may exactly offset the pressure overload to maintain normal stress. However, in some patients, especially men, the amount of hypertrophy is not adequate to normalize wall stress, wall stress rises, and ejection fraction is depressed.<sup>56,57</sup> In other patients, especially older women, the amount of hypertrophy that develops appears to be in excess of that which is needed to normalize stress. Stress becomes subnormal and ventricular function becomes supernormal at the chamber level. However, although systolic function is normal, or even supernormal, diastolic function is compromised. Recently attention has been called to another pattern of muscle distribution in aortic stenosis, that of concentric remodeling.<sup>58,59</sup> In such patients there is an increase in wall thickness with a decrease in LV radius so that stress normalization occurs without an increase in LV mass. Patients with this pattern demonstrate better LV function than those with LV hypertrophy. However such patients also have reduced stroke volume because LV end-diastolic volume is reduced. This may cause the symptoms of low output heart failure with a normal ejection fraction.

Irrespective of the effects of hypertrophy in normalizing or failing to normalize wall stress, LV muscle function eventually declines. The cellular mechanisms leading to the transition from compensated to decompensated LV hypertrophy remains a topic of intense investigation.<sup>60</sup> Several mechanisms have been delineated but none entirely explain the LV dysfunction which is present. In concentric hypertrophy, especially that which has been acquired in adults, coronary blood flow to the subendocardium is reduced especially during activity.<sup>61</sup> Thus it is likely that subendocardial ischemia plays a role in the LV dysfunction of aortic stenosis, although there is little evidence that ischemia is present at rest. In the case of aortic stenosis where persistently high wall stress has been created by inadequate hypertrophy, there is a densification of the microtubules compromising a portion of the cytoskeleton of the heart.<sup>62</sup> These tubules act as internal stents increasing internal load on the myocytes, inhibiting LV contraction. In other circumstances, abnormalities in calcium handling appear to be part of the mechanism causing contractile dysfunction. Finally, while many believe in a gradual transition from normal to compensated hypertrophy to hypertrophy with failure, this concept has recently been challenged.<sup>63</sup> Buermans et al found genetic expression differed in animals with hypertrophy destined to develop failure from those that remained compensated very early in the course of hypertrophy, well before failure developed. These data suggest diverging pathways to decompensated versus compensated hypertrophy rather than one transitioning to the other.

## Treatment of Heart Failure from Aortic Stenosis

Heart failure from aortic stenosis responds well only to aortic valve replacement. In almost all cases of aortic stenosis complicated by heart failure, afterload mismatch plays at least

**FIGURE 29-9** Postoperative outcome for aortic stenosis patients with low preoperative ejection fraction and low transvalvular gradient is demonstrated. Group I patients demonstrated preoperative inotropic reserve during dobutamine infusion while group II patients did not. An obvious advantage to surgical intervention in group I patients is demonstrated. (From Monin JL, Quere JP, Monchi M, et al. Low-gradient aortic stenosis: operative risk stratification and predictors for long-term outcome: a multicenter study using dobutamine stress hemodynamics. *Circulation* 2003;108:319-324.)

a partial role in causing LV dysfunction.<sup>57</sup> By replacing the valve, LV pressure overload is reduced, afterload is reduced, and ejection fraction improves. Even patients with severely reduced preoperative ejection fraction can have the ejection fraction return to normal following aortic valve replacement. This is especially true if the mean transvalvular gradient exceeds 40 mm Hg. In patients with reduced ejection fraction and transvalvular gradient of less than 30 mm Hg, output and gradient are reduced because of severe muscle dysfunction.<sup>64</sup> While in many cases this dysfunction is irreversible and prognosis is poor,<sup>64-67</sup> recent studies have demonstrated an advantage to aortic valve replacement even in this group of patients, especially if they demonstrate inotropic reserve preoperatively.<sup>68</sup> However, while operative risk is high in patients lacking inotropic reserve, even those patients who survive surgery may have a dramatic improvement in LV function.<sup>69</sup> Additionally, it appears that those patients with the most severely stenotic valves are the ones who benefit the most from valve replacement. The conundrum has been that at rest, two different groups appear to exist even though each has a similar valve area.<sup>70,71</sup> In one group, there is mild stenosis but a myopathic ventricle from another cause is unable to open the valve completely. In this case, the cardiomyopathy is primary and the mild stenosis does not constitute the major pathophysiological problem. In such cases, it is unlikely that aortic valve replacement will be helpful although this hypothesis is virtually untested. In other cases where severe stenosis has led to LV dysfunction, valve replacement appears warranted.<sup>67</sup> The two groups can be divorced by increasing cardiac output either with exercise or pharmacologically. If output increases and gradient fails to increase proportionally, valve area increases substantially and it is these patients who are likely to do better with medical than surgical therapy. In other cases where gradient increases proportionally with the output, there is likely severe aortic stenosis and it is this group with low ejection fraction and low gradient most likely to benefit from the aortic valve replacement (Figure 29-9).

While aortic valve replacement is the only effective therapy for aortic stenosis, many patients with the disease have acquired so many comorbidities as they have aged that aortic valve replacement is too risky to perform. However development of percutaneous valve replacement may expand the availability of aortic valve replacement for patients too infirm to undergo surgery. The ongoing PARTNERS trial (Placement

**FIGURE 29-10** The SAPIEN transcatheter aortic prosthesis is mounted on a balloon-expandable stainless steel stent that is placed in the subcoronary position. The trileaflet bovine pericardial prosthesis is attached to the stent and treated with an anticalcification treatment. The stent has a polyethylene terephthalate fabric skirt that decreases perivalvular leaks. (From Zajarias A, Cribier AG. Outcomes and safety of percutaneous aortic valve replacement. *J Am Coll Cardiol* 2009;53:1829-1836.)

of AoRTic TraNscathetER Valve Trial; [ClinicalTrials.gov Identifier NCT00530894] is a randomized open label clinical trial that is intended to determine the safety and effectiveness of a SAPIEN® Transcatheter Heart Valve (Edwards) (Figure 29-10) in high-risk, symptomatic patients with severe aortic stenosis. There are two cohorts: Cohort A will compare the percutaneous transcatheter heart valve (transfemoral or transapical) against surgery, whereas Cohort B will compare the percutaneous transcatheter heart valve (transfemoral) against medical therapy in patients who cannot tolerate aortic valve surgery. The endpoint for both cohorts is freedom from death. Although patients with severe LV dysfunction (EF < 0.20) are excluded from this study, patients with heart failure and aortic stenosis will be studied. This trial will likely provide important new information regarding the treatment of patients with aortic stenosis who have developed heart failure.

## Mitral Stenosis

Mitral stenosis inhibits LV filling by preventing decompression of the left atrium during diastole. In turn, left atrial pressure and pulmonary venous pressure are elevated leading to pulmonary congestion. These changes in LV and left atrial loading cause heart failure (diminished cardiac output and increased pulmonary venous pressure), yet, in most cases LV muscle function in mitral stenosis is normal.<sup>72</sup> However, in some cases of aggressive rheumatic fever (the usual cause of mitral stenosis), myocarditis and depressed LV function may ensue.<sup>73</sup>

Interestingly, about a third of patients with mitral stenosis have reduced LV ejection performance. In most cases, this accrues from abnormal loading of the left ventricle.<sup>72</sup> Reduced forward output initiates reflex vasoconstriction, increasing LV afterload—cause for reduced ejection performance. At the same time, inhibition of LV inflow prevents the use of preload reserve to overcome the afterload access and ejection fraction remains depressed. However, after mitral valve commissurotomy, ejection fraction often returns to normal indicating that it was these abnormalities in loading that were primarily responsible for the preprocedure LV dysfunction.

LV filling is primarily driven by an early transmitral gradient in diastole. This gradient accrues (1) from ventricular suction as the restoring forces created by systolic compression of the ventricle are released in diastole and, (2) from increased left atrial pressure as the atrium fills following mitral valve closure in systole. In mitral stenosis, however, obstruction to inflow into the left ventricle reduces LV filling. The obstruction

is compensated in part by an increased pressure head delivered by the right ventricle. Thus mitral stenosis leads to pulmonary hypertension. In addition to the mitral gradient, pulmonary vasoconstriction develops, further increasing pulmonary artery pressure.<sup>74</sup> Eventually pulmonary hypertension leads to right ventricular dysfunction, which clearly worsens outcome in mitral stenosis; thus surgery should be timed before the onset of severe pulmonary hypertension.

The issue of right ventricular contractile function in mitral stenosis has not been resolved. Pulmonary hypertension in experimental animals induces right ventricular muscle dysfunction. However, studies of right ventricular function in mitral stenosis in man have not confirmed muscle dysfunction,<sup>75</sup> but it must be pointed out that ventricular loading on the right ventricle has been extremely difficult to study. The shape of the right ventricle has defied easy expression of wall stress used to calculate afterload. Thus stress-strain relations used to analyze LV function have been difficult to use in estimating right ventricular function.

### Therapy

Ultimately the only satisfactory therapy for the treatment of mitral stenosis is relief of the obstruction at the mitral valve. In cases of mild disease with mild symptoms, diuretics alone may be sufficient to lower left atrial pressure and render the patient asymptomatic. There is no evidence that this kind of therapy results in either sudden death or increased mortality. However, once the symptoms of mitral stenosis advances beyond NVHA class II or if asymptomatic pulmonary hypertension develops, surgical outcome is worsened. Thus mechanical correction of the lesion should take place before symptoms become far advanced or before pulmonary hypertension has been well established. In most cases, balloon valvulotomy produces a durable improvement in the orifice area with enhanced postoperative diastolic function and a rapid decline in pulmonary artery pressure toward normal. In cases where valvulotomy is impossible, mitral valve replacement produces a similar benefit.

### Tricuspid Regurgitation

Most cases of tricuspid regurgitation are secondary to right ventricular pressure overload induced either from LV disease or from pulmonary parenchymal or pulmonary artery disease. However, occasionally tricuspid regurgitation is primary due to either tricuspid valve endocarditis or other abnormalities in the tricuspid valve. Recent animal studies indicate that tricuspid regurgitation, unlike mitral regurgitation, even when severe and prolonged does not cause intrinsic muscle dysfunction.<sup>76</sup> Rather, tricuspid regurgitation increases systemic venous pressure leading to the symptoms of right ventricular failure. Presumably, in some way, differences in loading between the right ventricle in tricuspid regurgitation and the left ventricle in mitral regurgitation are responsible for the differences in myocyte adaptation to the volume overload of each chamber.

The usual therapy for tricuspid regurgitation is to improve the primary disease responsible for it. Thus if left-sided failure has resulted in pulmonary hypertension and secondary tricuspid regurgitation, improvement in left-sided failure will result in reduced pulmonary pressure, reducing the tricuspid regurgitation.

### Conclusion

Valvular heart disease accounts for only about 5% of all cases of heart failure. However, because this group of diseases is easily recognized and reversed it should be a focus of the clinician's attention. Proper timing of surgical intervention is crucial in managing this group of illnesses and the burgeoning improvement in surgical practice has pushed this timing

earlier and earlier in the course of these diseases. The advent of percutaneous devices may advance the timing of mechanical intervention yet further or may make such intervention available to patients considered too risky for a standard surgical approach.<sup>77</sup>

# Heart Failure as a Consequence of Congenital Heart Disease

Julian Booker and Wayne Franklin

In Western societies, the most common cause of heart failure in adults is “acquired” and generally arises secondary to coronary artery disease and/or hypertension (see Chapters 22, 23, and 28).<sup>1,6</sup> The lifetime risk of developing acquired heart failure in North America and Europe is approximately one in five for a 40-year-old. However, the true incidence of heart failure in adults with congenital heart disease is not known, particularly in the United States where univer-

sal health care data bases are not available. Moreover, as will be discussed later, the cause of heart failure in adults with congenital heart disease is exceedingly complex, and manifests either as systolic and/or diastolic dysfunction of the left, right, or a single ventricle, which makes it difficult to obtain epidemiological data regarding the true incidence of heart failure in this population. In the following chapter we will address what types of patients with adult congenital heart disease develop heart failure, and discuss what treatment options are available.

## ROLE OF CONGENITAL HEART DISEASE

The term congenital heart disease refers to structural abnormalities of the heart, pericardium, and/or great vessels that are present from birth.<sup>7</sup> Some defects can be functionally significant at birth or may become so throughout life into adulthood. The rate of congenital heart disease is about six to eight per 1000 live births. However, many of these, such as small atrial septal defects, will never become clinically significant.<sup>8-10</sup> Extrapolation of these data indicate that there may be as many as 1.3 million persons with congenital heart disease in the United States alone<sup>10</sup> with 800,000 or more being adults.<sup>11-13</sup>

Approximately 15% of the children born with CHD will have potentially life-threatening defects.<sup>10</sup> Many of these patients will have complex or cyanotic lesions. These defects include various combinations of shunts, obstructive lesions, chamber malformation and discordance between the cardiac chambers including the great vessels. The abnormal anatomy leads to derangements in intracardiac pressure and volumes with nonphysiological flow.<sup>14</sup> If no other form of cardiac injury supervenes, adults with congenital heart disease may live chronically for years with an indolent disease process that is slowly progressive until the individual presents with overt symptoms of heart failure. In contrast to the majority of HF in the adult where the culprit abnormality is acquired (e.g., coronary artery disease or viral myocarditis), some congenital defects that predispose to eventual cardiomyopathy and HF are present at birth. Because of this, it has been referred to as the “original heart failure syndrome.”<sup>14</sup>

Surgical intervention is the cornerstone of the therapy for complex congenital heart disease. In the presurgical era, only 20% of children with complex congenital heart disease could be expected to reach adulthood. Today, nearly 90% of all patients with congenital heart disease will live to adulthood.<sup>15</sup> The higher prevalence is primarily related to improved survival, which coincides with the development and subsequent improvement in surgical techniques and post-operative medical care. The goal of surgery is to approximate normal anatomical and hemodynamic function as closely as possible. A minority of patients are able to undergo a truly corrective procedure and thus surgical repairs are

typically palliative. The chronic abnormalities in hemodynamics frequently result in HF years to decades later. Even when corrective procedures lead to a seemingly structurally normal heart, there is evidence that subtle physiological derangements may persist. Most varieties of complex congenital heart disease ultimately lead to some form of heart failure. The timing and the type of cardiac failure will depend upon the extent of the congenital defect in conjunction with the success of surgical and medical intervention. As a result, a portion of the burden of adult HF can be directly attributed to congenital heart disease.

Heart failure in adults with congenital heart disease is characterized using the bimodal classification system focusing on systolic dysfunction and diastolic dysfunction of the left, right, or single ventricle. The clinical severity of disease is most frequently graded using the New York Heart Association (NYHA) classification of heart failure symptoms, which focuses on functional status. NYHA classification is a prime determinant of outcomes in persons with acquired heart disease, and this trend continues to hold true for the subcategory of heart failure secondary to congenital heart disease.

Piran et al looked at a cohort of 188 patients with either a system right ventricle or single ventricle physiology and evaluated the prevalence of heart failure. Ventricular function was assessed by echocardiography or radionuclide angiography. In Mustard patients, congenitally corrected transposition of the great vessels and Fontan patients the prevalence of heart failure by Framingham criteria was 22%, 32%, and 40% respectively. Within this subgroup, 82.4% were classified as either NYHA class I or II, 13.3% were NYHA class III, and 4.3% were NYHA class IV (Figure 30-1).<sup>16</sup> Long-term follow-up revealed a substantial difference in mortality between symptomatic and asymptomatic patients (47.1% vs. 5% at 15 years). The most powerful predictors of mortality were similar to what would be expected in a typical heart failure population: (1) NYHA classification, (2) ejection fraction of the systemic ventricle, and (3) age at onset.<sup>16</sup> When the cause of death of a large cohort of patients with adults with congenital heart disease was reviewed, the second most common cause of death was

**FIGURE 30-1** New York Heart Association (NYHA) functional classification of patients with systemic right ventricle or single ventricles (percentage of patients in each functional class). For deceased patients, this information was also obtained from last follow-up. (From Piran S, Veldtman G, et al. Heart failure and ventricular dysfunction in patients with single or systemic right ventricles. *Circulation* 2002;105:1189-1194.)

reported as heart failure. Heart failure accounted for 21% of the total number of deaths. “Sudden death” which constituted 26% of the total mortality was the leading cause of death and most likely consisted of some patients with heart failure.<sup>17</sup> These findings were corroborated by Nieminen et al who found that over a 45-year period of follow-up, 40% of patients died as a direct result of heart failure.<sup>18</sup>

## Systemic Right Ventricle

There is a widely held misconception that the right ventricle plays a limited role in the overall hemodynamic requirements of the circulatory system. Compared with the left ventricle, it has a very complex and poorly understood physiology and anatomy. Because of these differences, the role of the right ventricle in the cardiac cycle and cardiac output is often understated and likely underestimated. In contrast to the left ventricle, the right ventricle is well suited to tolerate the dramatic changes in volume and preload that may occur with changes in intrathoracic pressure and venous return, whereas its ability to meet acute increases in afterload is limited.<sup>19</sup>

In the normal heart, the right ventricle supports the pulmonary circulation. However, in congenital heart disease, the morphological right ventricle may be forced to meet the higher resistance of the systemic circulation such as in patients with transposition of the great arteries or in the single ventricle physiology with a right ventricle. Mechanically, the morphological right ventricle is not equipped to withstand systemic resistance indefinitely. The right ventricle undergoes adaptive changes like hypertrophy to help sustain systemic pressures though maladaptive changes like ventricular dilation invariably follow. As a result, a large portion of heart failure in complex congenital heart disease results from dysfunction of the morphological right ventricle.

It is unclear as to whether the pressure overload alone is responsible for the failure of the right ventricle. Impaired flow reserve and myocardial perfusion defects have been noted, which suggest insufficient blood flow.<sup>20,21</sup> The insufficient blood flow does not appear to be a result of coronary artery disease, but rather supply-demand mismatch from elevated wall tension and inadequate coronary distribution to the right ventricle to accommodate the increased demand.<sup>22</sup> Evaluation by gadolinium-enhanced cardiac magnetic resonance (CMR) imaging reveals islands of myocardium consistent with regional fibrosis

**FIGURE 30-2** Magnetic resonance imaging in systemic right ventricle. **A**, Full-thickness late gadolinium enhancement of anterior wall of right ventricle. **B**, RV anterior wall enhancement (arrow) and multiple foci of late gadolinium enhancement, suggesting fibrosis of RV trabeculae (curved arrow). **C**, Late gadolinium enhancement of a spontaneously closed perimembranous VSD (arrow). **D**, Superior and inferior left ventricle and RV insertion point enhancement (arrows). (From Babu-Narayan SV, Goktekin O, Moon JC, et al. Late gadolinium enhancement cardiovascular magnetic resonance of the systemic right ventricle in adults with previous atrial redirection surgery for transposition of the great arteries. *Circulation* 2005;111:2091-2098.)

(Figure 30-2).<sup>23,24</sup> As a result, failure of the systemic right ventricle ultimately leads to heart failure that is clinically similar to classical heart failure that arises secondary to left ventricular (LV) failure.

## L-TGA (Levo-Transposition of the Great Arteries)

The nomenclature for congenitally corrected transposition of the great arteries varies from cc-TGA to L-TGA to atrio-ventricular, ventriculo-arterial discordance, to more simply ventricular inversion. Anatomically, this results in the aorta arising from the right ventricle and the pulmonary artery originating from the left ventricle. Congenitally corrected TGA, either alone or in combination with other congenital cardiac defects, is a relatively rare entity occurring in less than 1% of all congenital heart lesions. Isolated cc-TGA (i.e., with no additional congenital cardiac defects) is exceedingly rare, occurring in less than 2% of cases.<sup>28</sup> Associated cardiac lesions in the setting of cc-TGA are to be expected, with pulmonic or subpulmonic valvular stenosis occurring in 74%, ventricular septal defect in 74%, and systemic atrioventricular (tricuspid) valve abnormalities in 38% of patients. Also, complete heart block occurs in up to 2% of patients per year. The population of patients with cc-TGA is largely heterogeneous and there are relatively small numbers of patients with this primary lesion, which makes epidemiological studies difficult.

Unlike cyanotic congenital heart disease where childhood palliative or corrective surgery is frequently necessary for long-term survival, this is not always the case with cc-TGA. Many of these patients survive through adolescence and their first presentation of clinical ventricular failure is in adulthood. Historically, if an operation was performed, it involved repair of associated hemodynamically significant lesions. If subpulmonic outflow tract obstruction was present, then a valved conduit bypassed the obstruction, leaving the morphological left ventricle as the subpulmonic ventricle and the

morphological right ventricle supporting the systemic circulation. In some surgical studies, long-term survival after surgical intervention has been disappointing, with approximately 50% to 60% post-operative survival at 10 years. Seventy percent to 100% of the deaths could be directly attributable to progressive morphological right ventricular (RV) failure.<sup>25-27</sup>

A study by Presbitero et al found that 24% of patients in their fifth decade of life had heart failure. By the sixth decade of life, 77% were diagnosed with heart failure. Failure of the systemic right ventricle is part of the natural history of the disease but the heterogeneous nature of the population makes prediction of its occurrence difficult. Twelve percent had developed significant AV valve regurgitation in their fourth decade of life. However, this number rose to approximately 70% by the sixth decade.<sup>28</sup> It is unclear whether AV valve regurgitation was a result of worsening ventricular failure or if the resulting volume overload precipitated the failure. Nonetheless, systemic AV valve regurgitation may be a marker for imminent systemic RV failure.

Over the last 2 decades, more cc-TGA patients have undergone the “double-switch” operation. In these patients, the morphological left ventricle has become conditioned to meet the workload of the pulmonary circulation. The majority of these patients have some degree of pulmonic LVOT obstruction, usually subpulmonic stenosis. In these patients, the afterload that the subpulmonic left ventricle has to overcome is higher than what would be seen by a normal subpulmonic right ventricle. However, a significant minority of cc-TGA patients will have insufficient (or absent) subpulmonic stenosis to adequately prepare the morphological left ventricle. These untrained left ventricles will not be adequately conditioned to contend with the systemic pressures after the double switch has taken place. In these patients, as the first stage of their “double-switch operation,” this subgroup may undergo pulmonary artery banding, which increases the afterload that the subpulmonic left ventricle must face and serves to retrain the left ventricle. The left ventricle can be converted to the systemic position, and the right ventricle is switched to subpulmonic position.

### **D-TGA (Dextro-Transposition of the Great Arteries)**

Dextroposition-transposition of the great arteries (d-TGA, ventriculo-arterial discordance, or complete transposition) is incompatible with long-term life, since most unrepaired babies died within their first year of life. The result of the congenital defect is two separate circulations, without mixing. Like other cyanotic congenital heart disease, surgical intervention is usually required to reach adulthood. Long-term survival requires a redirection of the circulation to create two circulatory paths via two inter-atrial baffles that are in series.

The atrial switch operations as described by Senning in 1959<sup>29</sup> and Mustard in 1964<sup>30</sup> revolutionized treatment of patients with d-TGA. Before the development of the atrial switch procedure, there was an approximate 90% mortality within the first year of life. With the advent of the procedure, greater than 90% long-term survival has been possible. Physiologically, the result of the atrial switch is similar to that of cc-TGA, where the morphological right ventricle becomes the systemic ventricle. As with cc-TGA, dysfunction of the systemic right ventricle plays a significant role in heart failure in d-TGA though the reported incidence of RV dysfunction is highly variable ranging up to 66%.<sup>31</sup> The time of onset of right ventricular dysfunction has been shown to be equally variable.<sup>32-34</sup> Reich et al found that concomitant LV diastolic function may play as important a role in heart failure in d-TGA.

After many years with a systemic right ventricle after the Mustard or Senning procedure, surgical options for long-term survival are limited, leaving only a heart transplantation/ventricular assist device or the “switch conversion” procedure. The arterial switch conversion is a two step process designed to “retrain” the left ventricle take over as the systemic pump chamber, similar in theory to the “double-switch” operation

for cc-TGA. This is achieved by placing a pulmonary artery band in position to increase the afterload against the left ventricle. This surgically implemented increase in afterload causes the left ventricle to hypertrophy in the presence of systemic vascular resistance. It is unclear as to how long to leave the pulmonary artery band in place, and sometimes several rounds of band-tightening need to be done to “mimic” the systemic resistance. At least 18 months is often the usual time for retraining. Then, when the left ventricle is deemed sufficiently “retrained,” the atrial baffles are taken down, an atrial septum is created, and an arterial switch operation is performed, in which the great arteries are transected above the valve leaflets, and switched so the pulmonary artery arises from the former aortic valve (now called the “neopulmonic valve”) and the aorta arises from the former pulmonic valve (now called the “neo-aortic valve”). The procedure has shown promise in pediatric population but has had decidedly mixed reviews in adults. Two large case series have shown that the procedure is feasible in the adult population but a relatively low long-term survival has not met expectations.<sup>35,36</sup> In a study by Poirier and Mee, age greater than 12 years old was associated with a higher chance of LV failure and mortality.<sup>36</sup> A second study by Cochrane et al demonstrated an 80% one year actuarial survival.<sup>37</sup> These findings have been corroborated by a number of smaller case series, which taken together may suggest that at present cardiac transplantation or mechanical support may be the preferred option over the arterial switch conversion.<sup>38-41</sup> However, once past the immediate postoperative period, some studies report that 89% of patients will normalize RV function and up to 91% will normalize LV function.<sup>36</sup>

Jatene et al first reported in 1976 an attempt at a true anatomic correction for d-TGA in which they describe the “arterial switch operation.”<sup>42</sup> Reported long-term results have been very good with reports of approximately 90% survival at 10 years.<sup>43,44</sup> Quality of life following the arterial switch is superior to that of patients who undergo the atrial switch operation.<sup>45</sup> Ninety-six percent of patients report no subjective limitations in their daily activity.<sup>44</sup> There is a small but distinct percentage of patients who have problems with coronary perfusion related to coronary ischemia, either from an abnormal coronary course or from the long-term sequelae of coronary reimplantation at the time of operation, which can lead to ostial disease.<sup>46</sup> The long-term outcomes of these arterial switch patients have yet to be determined since most are now in their late teens and early 20s.

### **Fontan and Single Ventricle Physiology**

A sizable number of the individuals with complex congenital heart defects have a functionally single ventricle. By definition, a single ventricle is defined anatomically by the lack of nontrabeculated portion of a ventricle, which is the ventricular inlet of either ventricle. Clinically this can present itself as a double inlet or common inlet ventricle with a primary larger functioning ventricle and a smaller rudimentary ventricle. In patients with single ventricle physiology, there is mixing of arterial and venous blood. This mixing can result in cyanosis if there is inadequate pulmonary blood flow, or in pulmonary overcirculation (with possible development of subsequent pulmonary hypertension later) if there is significantly too much pulmonary blood flow from a left-to-right shunt.

The Fontan procedure serves as definitive palliation for single ventricle patients.<sup>47</sup> The Fontan procedure has evolved since its inception in 1971, although the basic premise remains the same. The original operation performed by Fontan et al was a direct atriopulmonary connection, creating a direct anastomotic connection between the right atrium and main pulmonary artery.<sup>48</sup> In recent years, this technique has been supplanted by the “modified Fontan” variation, incorporating a lateral tunnel through the right atrium or, in more recent

**FIGURE 30-3** Cumulative hazard by mode of death following the Fontan procedure. Cumulative hazard values over time are depicted for sudden, heart failure-related, thromboembolic, and other deaths. (From Khairy P, Fernandes SM, Mayer JE Jr, et al. Long-term survival, modes of death, and predictors of mortality in patients with Fontan surgery. *Circulation* 2008;117:85-92.)

years, an extra cardiac conduit, in which a Gore-Tex tube from the IVC to the right pulmonary artery is used to bypass the hypoplastic right heart. The Fontan circulation, also known as the total cavopulmonary connection (TCPC), results in direct diversion of systemic venous blood with passive flow through the pulmonary circuit since there is no RV pump. The Fontan operation is now the most common surgery performed for congenital hearts defects after the age of 2 years. An entire generation of patients with single ventricles, who underwent the palliative Fontan operation, has now reached adulthood.

We now know the tendency of the Fontan circulation to do well for 20 years but then have progressive clinical decline with the end-stage of this process often referred to as the “failed Fontan.” The “failed Fontan” term refers to a several clinical events that contribute to low cardiac output. The failed Fontan circuit can exist in isolation but can also be seen in combination with ventricular systolic dysfunction. More specifically, the failing Fontan state deals with inefficiency of the atriopulmonary circulation, complicated by the lack of a true RV pump to assist with pulmonary blood flow. Other complications that contribute to this state are recurrent atrial tachycardias (often intra-atrial reentrant tachycardia) and elevated right-atrial-Fontan circuit pressure.

Normal Fontan physiology relies upon a normal, low pulmonary vascular resistance.<sup>49</sup> Deterioration of the atriopulmonary circuit can be caused by inadequate flow at two levels: (1) inadequate systemic venous return, or (2) inadequate pulmonary venous return. Restriction of systemic venous return may be iatrogenic, related to thrombus formation or some other obstructive process. Also, any increase in the pulmonary vascular resistance (such as from respiratory infections, sleep apnea, or pulmonary emboli) can lead to decreased pulmonary circulation and may ultimately result in hemodynamic compromise, which can present as ascites and lower extremity edema. The role that thrombi play in the deterioration of the Fontan circuit cannot be overstated. The classic Fontan predisposes to massive atrial dilation, which may have less laminar flow and potential areas of stasis blood. This altered hemodynamic milieu predisposes to a “slow flow state” and thrombus formation. Thrombus at any level of the systemic venous return, but particularly those involving the right atrium or pulmonary artery emboli are frequently responsible for failure of the circuit. However, compression of the pulmonary veins by a severely dilated

atrium is significantly less common but a recognized entity nonetheless.

Clinically, it can be difficult to differentiate symptoms related to the failed Fontan circuit from those related to ventricular failure as there may be significant overlap. The failed Fontan state may lead to cardiopulmonary compromise and a clinical syndrome analogous to “right-sided” heart failure in the biventricular heart, including lower extremity edema, protein losing enteropathy, easy fatigability, and exercise intolerance. Additionally, these patients are at risk for macroreentrant atrial arrhythmias (such as intraatrial reentrant tachycardia) from severe right atrial dilation and/or atrial surgical scars. Also, cyanosis can develop from small leaks in the Fontan circuit (that cause a right-to-left shunt into the left atrium) or venovenous collaterals (such as from the subclavian vein to the pulmonary veins). Tachycardia or cyanosis are two conditions that warrant further investigation immediately. Concomitant left ventricular failure results in pulmonary congestion and an overall clinical scenario similar to that of biventricular failure.

Vigilant surveillance is necessary because failure of the Fontan circuit is common, especially in patients who are 20 years status-post initial Fontan palliation. There are a number of risk factors that have been shown to place a patient at an increased risk of Fontan circuit failure. The presence of the atriopulmonary connection (known as the “classic Fontan”), younger age at the time of operation, absence of a baffle fenestration, distorted pulmonary artery anatomy, the presence of a right-sided tricuspid valve as only atrioventricular valve, a mean pulmonary artery pressure greater than or equal to 19 mm Hg, worse NYHA classification,<sup>50</sup> and the presence of a permanent pacemaker. In contrast, a morphological left ventricle with normal arterial concordance or single right ventricle tends to be protective. However, in patients with the Fontan repair, independent predictors of heart failure-related death are the presence of a single morphological right ventricle, elevated right atrial pressure, and protein-losing enteropathy.<sup>51</sup>

Careful observation for the development of heart failure is critical to care of these patients. The primary treatment option for failure of the Fontan circuit is surgical. The Fontan revision procedure, a corrective surgical procedure performed when a Fontan circuit has failed, has become relatively commonplace at our institution over the past several years. The Fontan revision involves debulking the enlarged right atrium, converting the classic Fontan or one of its earlier iterations to a lateral tunnel or extracardiac conduit, performing a modified Maze operation, and placement of an epicardial pacemaker.<sup>52</sup> Some indications for revision include supraventricular tachycardia, persistent cyanosis, protein-losing enteropathy, or simply “failing Fontan physiology.” Careful patient selection and close clinical follow-up postoperatively is mandatory.

## Volume Overload Lesions

RV failure may also develop in response to RV volume overload as a consequence of increased flow to the right ventricle. The most common congenitally related causes are atrial septal defects or a regurgitant atrioventricular valve, which frequently is seen in the setting of the Ebstein abnormality. Patients with repaired tetralogy of Fallot may have cardiac failure from volume and pressure overload as a consequence of chronic pulmonary insufficiency.<sup>53-55</sup> The increased volume leads to compensatory dilation of the right ventricle, which initially helps to augment cardiac output by improving contractility via the Starling mechanism. Over time, the dilation becomes maladaptive and RV contractility declines once dilation exceeds an optimum size.

Hemodynamically significant volume overload lesions should be corrected surgically. Most atrial septal defects have the option of being closed percutaneously or surgically. The option of percutaneous closure means that once

a hemodynamically significant lesion is identified, it may be electively repaired as soon as possible to prevent or reverse the complications of the chronic volume overload state. Heart failure related to surgical repair of the tetralogy of Fallot and chronic pulmonary valve regurgitation generally should be addressed either with surgical pulmonary valve replacement or percutaneous pulmonary valve implantation. These patients have undergone at least one operation and in many cases multiple operations by the time they reach adulthood. Surgical repair of the pulmonary insufficiency may not be durable and the prospect of additional repairs via repeat sternotomies is challenging. Therefore the goal is often to defer as long as possible before pulmonary valve replacement in an attempt to limit the total number of cardiac operations but prevent permanent negative cardiac remodeling. There are recent data that advocates routine noninvasive surveillance with cardiac magnetic resonance (CMR) imaging and surgical repair before the right ventricle volume index reaches 170 cc/m<sup>2</sup>.<sup>56</sup>

## MEDICAL TREATMENT OF HEART FAILURE IN ADULTS WITH CONGENITAL HEART DISEASE

The hemodynamic model has been traditionally used to describe the heart failure that arises in adults with congenital heart disease. This model states that the heart consists of two positive displacement pumps in series and that heart failure is caused by dysfunction of one or both of the pumps. Treatment dictated by this model has focused primarily on improving pump contractility and/or decreasing the resistance that the pump must work against. The pharmacological focus of this therapy involves inotropes, diuretics, and vasodilators.

In recent years, there has been a paradigm shift in the understanding of adult heart failure. The neurohormonal model now forms the basis for understanding and treating heart failure. Along with the increased activation of several neurohormonal systems (see Chapters 9 and 10), there is a commensurate increase in cytokine release (see Chapter 11).<sup>57-60</sup> The altered neurohormonal milieu is associated with the clinical signs and symptoms of heart failure and resultant cardiac remodeling.<sup>61,62</sup> The degree of neurohormonal imbalance is directly related to heart failure related mortality,<sup>63</sup> LV dysfunction,<sup>64,65</sup> and poor functional capacity.<sup>61,62</sup> Subsequent studies examining the effects of neuroendocrine inhibitors, such as  $\beta$ -blockers,<sup>66-70</sup> angiotensin-converting enzyme (ACE) inhibitors,<sup>71-73</sup> angiotensin receptor blockers,<sup>74-77</sup> and aldosterone inhibitors,<sup>78,79</sup> have led to the formulation of the neurohormonal hypothesis for heart failure. There is a small but growing body of evidence that the maladaptive neurohormonal response plays a large role in heart failure related to congenital defects, much in the same way that it does in heart failure from acquired heart disease. As in heart failure of acquired heart disease, there is activation of multiple tiers of the neuroendocrine system. There is concomitant activation of the sympathoadrenergic (Figure 30-4), renin-angiotensin-aldosterone (RAAS) (Figure 30-5), and the endothelin systems (see Figure 30-4)<sup>14,80-85</sup> and release of inflammatory cytokines.<sup>86,87</sup> Similarly, the degree of elevation of these neurohormones corresponds with the clinical severity of heart failure (see Figure 30-5).<sup>14</sup>

### Outpatient Medical Management

There are very limited data available regarding medical therapy for treating heart failure that develops patients with adult congenital heart disease. Accordingly, at the time of this writing there are insufficient clinical data to develop “evidence-based” treatment algorithms. Indeed, data are primarily limited to retrospective analysis, case series, and

case reports for treating these patients. Indeed, virtually no prospective trials exist in the adult congenital heart disease literature. Thus far most of the therapies that are used in clinical practice with adult congenital heart disease patients has been extrapolated from heart failure studies in the adult with acquired heart disease that affects the left ventricle.

The foundation of pharmacotherapy for symptomatic heart failure in patients with adult congenital heart disease includes diuretic therapy to control vascular congestion and pulmonary edema. Caution should be exercised when using diuretics in those patients who have undergone Fontan repair. Fontan physiology leads to passive, nonpulsatile filling of the pulmonary vascular bed, which is therefore entirely preload dependent. Accordingly preload reduction with or without volume depletion can be detrimental to overall cardiac output. Similarly, patients with Eisenmenger syndrome or pulmonary outflow tract obstruction with RV hypertrophy and subsequent diastolic dysfunction are similarly dependent upon preload.

The renin-angiotensin aldosterone system (RAAS) is activated by decreased renal perfusion caused by intravascular volume depletion or low cardiac output, sodium restriction, or increased adrenergic drive, and is activated in patients with adult congenital heart disease (see Figure 30-4). Although a number of studies in adults with advanced heart failure have demonstrated the benefits of ACE inhibitors on LV function and LV remodeling in NYHA class I-IV heart failure patients (see Chapter 45),<sup>72,88-90</sup> treatment with ramipril for 1 year had no effect on RV ejection fraction, nor right ventricle size in a small prospective randomized study of patients with systemic right ventricles after a Mustard or Senning procedure (Figure 30-7).<sup>91</sup>

Angiotensin receptor blockers (ARB) act to inhibit the renin-angiotensin axis at its final common pathway by directly blocking angiotensin-II from binding to its receptor (see Chapters 9 and 45). Data from the CHARM-Alternative,<sup>75</sup> ELITE, ELITE II, and STRETCH trials among others demonstrate the effect that ARBs have on LV dysfunction and heart failure. Data from the CHARM-Added trial<sup>74</sup> suggests that concomitant therapy with an ACE inhibitor has added benefit. In heart failure, activation of the RAAS leads to increased expression of aldosterone. Increased expression of aldosterone may lead to a number of pathological states, including endothelial damage, myocardial fibrosis, and hypertrophy (see Chapter 45).<sup>92-97</sup> Based on the wealth of data on ARBs and aldosterone antagonists in acquired heart failure, these agents may also be considered early in the course of treatment for heart failure that arises in the setting of adult congenital heart disease.

One of the most powerful drug classes in the armamentarium for the treatment of heart failure treatment is that of the  $\beta$ -blockers (see Chapter 46). Chronically elevated levels of catecholamines can be cardiotoxic and cause apoptosis of myocytes.<sup>98-100</sup> Catecholamines are also potent activators of the RAAS.<sup>101,102</sup> Moreover,  $\beta$ -blockade helps to prevent and/or reverse negative cardiac remodeling. Clinical trials such as the U.S. Carvedilol,<sup>103</sup> MERIT-HF,<sup>69</sup> and CIBIS-II<sup>66</sup> have repeatedly demonstrated the importance of  $\beta$ -blockade not only for suppression of arrhythmias, but also for progressive pump failure in acquired forms of heart failure. Based on current data in acquired heart disease,  $\beta$ -blockers may also be considered for the treatment for heart failure that arises in the setting of adult congenital heart disease. The dosing and precautions about starting these agents in patients with adult congenital heart disease are identical to those with acquired forms of heart disease (see Chapter 46).

### Inpatient Medical Management

Intravenous administration remains the primary mode of delivery for medications used to treat decompensated heart failure requiring hospitalization. As with the outpatient

**FIGURE 30-4** Neurohormone levels in all subjects according to NYHA functional class and in adults with congenital heart disease according to systemic ventricular function. Note differing y-scales for each measure. As shown, there was a highly significant stepwise increase in the concentrations of all four neurohormones with increasing disease severity. Neurohormonal activation was evident even in patients with asymptomatic disease when compared with control subjects. (From Bolger AP, Sharma R, Li W, et al. Neurohormonal activation and the chronic heart failure syndrome in adults with congenital heart disease. *Circulation* 2002;106:92-99 and modified from Franklin WJ, Webb GD. Heart failure in adults with congenital heart disease. In Chang AC, Towbin JA, editors. *Heart failure in children and young adults*, ed 1, Philadelphia, 2006, Elsevier.)

population, the diuretics remain a cornerstone of the treatment of symptomatic heart failure. They can be used frequently in the treatment of heart failure associated with congenital heart defects. However, as with outpatient therapy, extreme caution should be taken when using diuretics in patients post-Fontan repair.

In hypotension with or without low cardiac output, vasopressors, inotropes, or a combination of the two should be used (see Chapter 43). There is very limited data on the use of inotropes to treat decompensated heart failure in congenital heart failure. At our institution, dopamine and dobutamine are considered first-line therapy if inotropic support is required. Vasopressin, epinephrine, and norepinephrine may be added in various combinations if either more  $\alpha$ -agonism or  $\beta$ -agonism is required. There appears to be a growing role for the phosphodiesterase inhibitor milrinone in the treatment of congenital heart disease. In the pediatric population, phosphodiesterase inhibition has been successful at not only prevention but also the treatment of a postoperative low cardiac output state following cardiac surgery<sup>104-106</sup> and specifically following Fontan

palliation.<sup>107</sup> The hemodynamic impact of milrinone, specifically, inotropy, lusitropy, and vasodilation appears to be favorable for the treatment of certain congenital heart failure syndromes. There are no trials published on using vasopressin antagonists in patients with adult congenital heart disease.

## Surveillance

The clinical history and physical examination are still the most important components of successful follow-up of heart failure patients with congenital heart disease. Close follow-up of symptoms and volume status are paramount. The cardiopulmonary stress test or the exercise tolerance test may provide objective data, which can help determine the functional status of the patient and the extent of heart failure.

Ventricular dysfunction, either left or right,<sup>108-110</sup> portends a poorer prognosis in the setting of heart failure than does normal ventricular function. Elevated pulmonary artery pressure is also a predictor of worse outcomes. These variables are important not only for prognostic information but they are critical in

the decision-making process for proper medical and surgical management. Two-dimensional echocardiography can provide anatomical information and functional information. The addition of the Doppler examination allows for assessment of cardiac hemodynamics including pulmonary artery pressure. As a result of multiple cardiac operations, many adults with complex congenital heart disease frequently have poor acoustic windows, which may yield suboptimal visualization by echocardiography. Many patients with complex congenital heart

disease will have a systemic morphological right ventricle or a single common ventricle. A potential obstacle to examining the function of the morphological RV function or single common ventricle has related to difficulties in accurate, noninvasive assessment of their function. Unlike the left ventricle, the complex anatomy of the right ventricle precludes traditional echocardiographic estimation of RV ejection fraction. Echocardiographic techniques used to assess RV function rely heavily on surrogates of ejection fraction, like annular excursion measured by tissue Doppler or require complex geometric assumptions to calculate the ejection fraction.<sup>111-113</sup>

CMR imaging is a newer imaging modality, which is not limited by some of the shortcomings of echocardiography but has a set of its own that prevents it from being all inclusive. CMR has excellent spatial resolution. This allows for accurate structural information and shunt quantification. One of the most important aspects of CMR, it provides the practitioner the tools for accurate volumetric analysis including reproducible calculation of both the left and right ventricular ejection fractions.<sup>114-116</sup> Unfortunately, patients with defibrillators and pacemakers are generally not able to undergo CMR evaluation because of the strong magnetic field. If either of the aforementioned modalities is unavailable, then radionuclide angiography or a gated SPECT study, both nuclear imaging techniques, can be used to provide reasonable assessment of ventricular ejection fraction without geometric assumptions. However, these tests require radiation and give limited structural and functional information.<sup>117</sup> Serial evaluation of cardiac function should be performed routinely since results will guide therapy. If more detailed hemodynamic data are required, cardiac catheterization can be performed by clinicians trained in congenital heart disease.

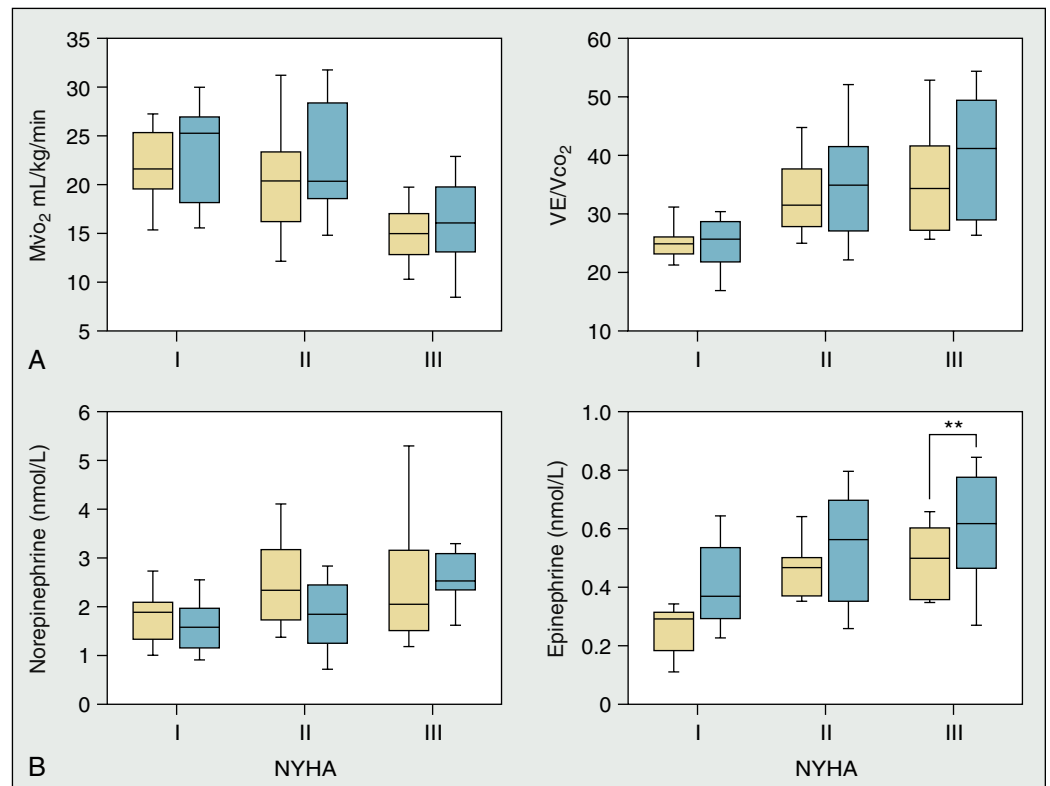

**FIGURE 30-5** Renin and aldosterone levels in adult congenital heart disease patients according to NYHA functional class. As shown, activation of the renin-aldosterone axis was apparent in symptomatic adult congenital heart disease patients versus control subjects or versus those without symptoms. (From Bolger AP, Sharma R, Li W, et al. Neurohormonal activation and the chronic heart failure syndrome in adults with congenital heart disease. *Circulation* 2002;106:92-99.)

## Mechanical Support (see also Chapter 56)

Over the past 2 decades, the use of mechanical circulatory support has become more prevalent. For many patients with acute, severe decompensation, temporary mechanical

**FIGURE 30-6** Exercise limitation and neurohormonal activation in adults with congenital heart disease and patients with heart failure due to other causes. **A**, The relationship between peak oxygen consumption ( $\dot{V}O_2$ ) and the ventilatory response to exercise ( $\dot{V}E/\dot{V}CO_2$ ) with NYHA functional class in 47 patients with noncachectic chronic heart failure due to ischaemic or dilated cardiomyopathy no white bars in figure and in 28 adult patients with congenital heart disease of varying type no gray bars in figure. There are no statistical differences between the two groups at each level of functional impairment. **B**, The relationship between plasma norepinephrine and epinephrine levels with NYHA functional class in the same 47 patients with chronic heart failure and in 52 adult patients with congenital heart disease of varying type. There are no statistical differences between the two groups in respect to norepinephrine. Epinephrine levels tend to be higher at all levels of functional impairment in adults with congenital heart disease and are significantly so with respect to NYHA class III (key \*\*  $P < .01$ ). (From Bolger AP, Gatzoulis MA. Towards defining heart failure in adults with congenital heart disease. *Int J Cardiol* 2004;97:[suppl 1]15-23.)

**FIGURE 30-7** Effect of ramipril on RV structure and function in patients with systemic right ventricles. **A**, Right ventricular ejection fraction at baseline and after 1 year of therapy with ramipril or a placebo. (RVEF, right ventricular ejection fraction). **B**, Right ventricular end-diastolic volume at baseline and after 1 year of therapy with ramipril or a placebo. (RVEDD, right ventricular end-diastolic volume). **C**, Right ventricular end-systolic volume at baseline and after 1 year of therapy with ramipril or a placebo. (RVESD, Right ventricular end-systolic volume). (From Therrien J, Provost Y, Harrison J, et al. Effect of angiotensin receptor blockade on systemic right ventricular function and size: a small, randomized, placebo-controlled study. *Int J Cardiol* 2008;129:187-192.)

support is often required. Intraaortic balloon counterpulsation is widely used as a temporizing therapy in the treatment of adult heart failure. In the failing Fontan circuit, intraaortic balloon counterpulsation (IABP) has been shown to improve pulmonary circulation by lowering LV end-diastolic pressure resulting in reduction in left atrial pressure.<sup>118</sup> The additional hemodynamic support helps to reestablish the Fontan circulation.<sup>118,119</sup> However, anecdotal experience and further studies of IABP use in Fontans have not shown benefit and do not support its widespread use.

The ventricular assist device is a semipermanent device used to augment cardiac output in the setting of severe cardiomyopathy and decompensated heart failure. The devices can either be primarily extracorporeal or primarily intracorporeal. Use of the ventricular assist device as either destination therapy, bridge to transplantation, or bridge to recovery has been well established in the adult population. There is a small but growing body of evidence supporting VAD use in some capacity for congenital heart disease-related heart failure.<sup>120-123</sup> And, devices such as the Berlin heart have been implanted into patients as small as 4 kg. However, there are some limitations to using ventricular assist devices in patients because of their complex anatomy, which can include abnormal arterial and venous connections.

Extracorporeal membrane oxygenation (ECMO) has been used for many years for critically ill pediatric patients. It serves as a means to temporarily oxygenate patients with refractory hypoxemia due to respiratory or cardiovascular causes. Survival in both children and adults who receive ECMO support for cardiac reasons is approximately 40%.<sup>124</sup> Although there is evidence that heart failure related to congenital heart disease may have worse outcomes on ECMO than does cardiomyopathy.<sup>125</sup> The population of adults with congenital heart disease continues to grow as does the prevalence of mechanical cardiopulmonary support in the general population. It is likely that the number of patients with heart failure and congenital heart defects receiving mechanical assist devices will grow in parallel.

## Surgical Therapy

A variety of surgical options may be available as salvage therapy as these patients develop heart failure. The most common surgical options for each abnormality have been discussed earlier in their respective sections. The final surgical option for some patients is cardiac transplantation. According to UNOS, nearly 7% of the cardiac transplants performed in 2007 were as a direct result of cardiac failure secondary to congenital heart disease. This is an increase from the 5% of heart transplants in 2002, but is still inadequate for the amount of congenital heart patients with advanced heart failure. In addition, patients with a history of congenital heart disease often pose many problems surgically. They often have abnormal or distorted anatomy as a result of their defects. Many will have undergone multiple cardiac operations during their lifetime, which places them at high risk for adhesions and bleeding. There is often an extensive history of exposure to blood products. In light of high levels of circulating antibodies, finding a suitable blood donor may be problematic. At experienced centers, the 1-year mortality rates for cardiac transplant for congenital anomalies has been worse than that of acquired cardiomyopathies.<sup>126-128</sup>

## Future Challenges

Since patients with heart failure are one of the fastest growing subsections of cardiology, and since the majority of children with congenital heart disease are now surviving into adulthood, the number of adults with congenital heart disease and heart failure will undoubtedly continue to expand. This necessitates preparation for this new population, which should include better evidence-based therapies and more clinicians with expertise in this field. In addition, as mechanical circulatory support continues to improve, cardiac transplantation for these heart defects may be needed less often. This will continue to provide great challenges and opportunities in cardiovascular medicine as we strive to provide the best care for these complex patients.

of virulent CVB or encephalomyocarditis virus strains in genetically predisposed rodents and cell culture systems. In these models, direct viral injury and innate and subsequently adaptive, lymphocyte-mediated, tissue specific immunity leads to acute myocarditis and often dilated cardiomyopathy (DCM) (see Chapter 24). In contrast, the pathogenesis of DCM due to newer viruses such as parvovirus B19 is not well understood. For most viruses, the diagnosis requires molecular analysis of endomyocardial biopsy tissue. Studies differ on the prognostic importance of viral genomes in the heart. The role of antiviral and immunomodulatory treatments for patients with cardiomyopathy associated with viral genomes or features of postviral autoimmunity are now being evaluated in randomized clinical trials.

## Cause

Myocarditis, defined histologically as inflammation of the myocardium, can be considered in two broad categories: viral, which includes the immune-mediated damage following the initial injury, and nonviral. Viral myocarditis is a significant cause of fulminant and acute DCM.<sup>1</sup> Viral persistence in the absence of typical inflammation is seen in up to 67% of patients with chronic DCM.<sup>2</sup> Some viruses, particularly parvovirus B19, can cause diastolic dysfunction and chest pain and DCM possibly through endothelial cell dysfunction and microvascular ischemia.<sup>3</sup> Virus associated myocardial damage may be mediated through direct toxicity or through an innate and acquired immune response.<sup>4</sup> Thus viral cardiomyopathy may occur without cellular inflammation. In contrast, nonviral myocarditis may be caused by a variety of toxic, metabolic, allergic, and infectious disorders. These uncommon forms of myocarditis, including giant cell myocarditis (GCM), eosinophilic myocarditis, and granulomatous myocarditis, will be discussed in the latter sections of this chapter.

Bowles et al demonstrated enteroviral genome in the heart tissue of myocarditis patients in 1986.<sup>5</sup> Through the 1990s enteroviruses, typically detected by polymerase chain reaction (PCR), were commonly associated with acute and chronic dilated cardiomyopathy. Beginning in the mid-1990s, adenovirus genomes were identified in patients undergoing heart transplantation and those with acute myocarditis.<sup>6</sup> In contrast to enterovirus, adenovirus infection was associated with little cellular inflammation. The importance of viral infection has been documented in multiple case series in which viral infection is linked to

poor clinical outcomes. For example, Shirali et al demonstrated that children with viral genomes detected on endomyocardial biopsy (EMB) samples had a 5-year survival rate of 66% compared with PCR-negative patients who had a 95% 5-year survival rate following heart transplantation.<sup>7</sup>

The frequency of enteroviral and adenoviral genome identification has decreased in the past decade. Newer viruses associated with DCM and myocarditis include the hepatitis C virus, particularly in Asia; cytomegalovirus (CMV); and Epstein-Barr virus (EBV).<sup>8,9</sup> Recently, parvovirus B19 has been frequently linked to dilated cardiomyopathy (DCM) anginal chest pain, and isolated diastolic dysfunction.<sup>10</sup> human herpesvirus 6 (HHV6) and multiple viral coinfections have been associated with chest pain and progressive cardiomyopathy, respectively.<sup>11,12</sup>

## Pathogenesis of Postviral Cardiomyopathy

The pathogenesis of postviral DCM is complex and involves the interaction of viral and host genetic susceptibility and environmental variables, including trace elements (Figure 31-1). Since the original description of CVB myocarditis,<sup>13,14</sup> the molecular pathogenesis of viral and postviral autoimmune myocarditis has been elucidated from studies of inbred rodent strains and cultured cells that are susceptible to virulent CVB strains.<sup>15,16</sup> The severity of CVB infection is modified by variations in the 5' untranslated region of the viral genome.<sup>17</sup> However, primary cell culture studies have also revealed that most wild-type CVB strains are not cardiomyocyte virulent<sup>18</sup> and that the host cell plays a major role in CVB phenotype. Briefly, CVB virus first enters cells by binding with decay accelerating factor for primary attachment and the coxsackie adenovirus receptor (CAR), a junctional molecule, for internalization.<sup>19-21</sup> CAR expression increases in experimental autoimmune myocarditis and in human DCM, which may partly explain the affinity for the heart. However, other organs with high CAR expression, such as the liver, do not display much CVB-damage, demonstrating that host organ factors besides receptor expression are important in viral pathogenesis.<sup>22</sup>

Following entry into cells, CVB shuts down host RNA synthesis by inhibition of

**FIGURE 31-1** Pathogenesis of myocarditis. The current understanding of the cellular and molecular pathogenesis of postviral and autoimmune myocarditis is based solely on animal models. In these models, the progression from acute injury to chronic dilated cardiomyopathy may be simplified into a three-stage process. Acute injury leads to cardiac damage, exposure of intracellular antigens such as cardiac myosin, and activation of the innate immune system. Over weeks, specific immunity that is mediated by T lymphocytes and antibodies directed against pathogens and similar endogenous heart epitopes cause robust inflammation. In most patients, the pathogen is cleared and the immune reaction is downregulated with few sequelae. However, in other patients, the virus is not cleared and causes persistent myocyte damage, and heart-specific inflammation may persist because of mistaken recognition of endogenous heart antigens as pathogenic entities. APC denotes antigen-presenting cell. (Cooper LT Jr. Myocarditis. *N Engl J Med* 2009;360:1526-1538.)

eukaryotic initiation factor 4 $\gamma$  and other host proteins.<sup>23</sup> CVB causes cell cycle arrest by ubiquitin-dependent proteolysis of cyclin D1.<sup>24</sup> Necrosis and apoptosis cause myocyte death within hours of infection.<sup>4</sup>

The innate immune response is essential for host defense. Early in the course of an infection (see also Chapter 11), CVB upregulates toll-like receptor (TLR) 4 on macrophages, stimulates antigen presenting cell maturation, leads to proinflammatory cytokine release,<sup>25</sup> and decreases regulatory T-cell function.<sup>26</sup> Human cardiac myosin, which is released in the course of acute viral myocarditis, can stimulate TLR 2 and 8 as an endogenous ligand. TLR 2 and 8 activation on monocytes releases proinflammatory cytokines.<sup>27</sup> In the first few days after

infection, dendritic cells and other resident myocardial cells produce cytokines, including interferon- $\gamma$ , tumor necrosis factor- $\beta$ , interleukin-1, and interleukin-6 by a myeloid differentiation factor (MyD)-88 dependent pathway.<sup>28</sup> The character of the initial immune response, in particular higher levels of a Th1 and Th2 cytokines, are associated with the development of cardiomyopathy.<sup>29</sup> One effort to translate these insights from animal models into prognostically useful information is the recently completed IMAC-2 study, which seeks to correlate circulating cytokine levels and gene polymorphisms with left ventricular (LV) recovery in patients with acute DCM.

Inflammatory lesions develop from natural killer, CD4 and CD8 positive lymphocytes. T lymphocytes are key mediators

### BOX 31-1 Factors Associated with Heart Failure Suggestive of Myocarditis

1. Viral prodrome
2. Elevated troponins in the absence of acute coronary syndrome
3. Ischemic ECG changes in the absence of obstructive coronary artery disease
4. Acute, new onset heart failure with hemodynamic perturbations
5. Elevated ESR
6. Peripheral eosinophilia
7. Failure to respond to standard medical therapy
8. Declining left ventricular ejection fraction despite standard medical therapy
9. Refractory ventricular arrhythmias
10. Second- or third-degree AV block

of experimental autoimmune myocarditis.<sup>30,31</sup> Experimental studies in mice suggest that low-avidity, circulating T cells that evade central and peripheral tolerance can cause immune-mediated heart disease if stimulated with large amounts of self-antigens.<sup>32</sup> A T helper subset, TH17 cells, that produce IL-17<sup>33</sup> have recently been implicated in myocarditis as well.<sup>34</sup>

In contrast to effector T-cell subsets, regulatory T-cell populations, such as CD4(+)CD25(+)FOXP3(+) T cells are important negative regulators of inflammation in CVB myocarditis.<sup>35,36</sup> Regulatory T-cell subsets have not yet been studied in human myocarditis, but offer an exciting opportunity for mechanistic studies with the potential for significant diagnostic and therapeutic impact.

Autoantibodies to a variety of cardiac antigens are present in up to 80% of patients with myocarditis and DCM.<sup>37</sup> Epitopes on CVB and streptococcal M protein are shared with cardiac myosin, which can lead to anti-self-immunity through antigenic mimicry.<sup>38</sup> After the initial injury and viral clearance, cardiac myosin may provide an endogenous source of antigen in chronic myocarditis. Antibodies to cardiac myosin can cause myocyte damage by binding to the  $\beta$ -adrenergic receptor and stimulating protein kinase A.<sup>39</sup>

A major challenge is to distinguish immune autoreactivity, which occurs commonly in the course of normal viral clearance, from autoimmune disease, in which anticardiac antibodies and T cells are actually contributing to cardiomyopathy. Therefore a major theme of ongoing research includes a search for biomarkers that reflect inflammation and infection and that impact prognosis in clinically suspected myocarditis.<sup>40</sup>

Host factors that impact viral virulence include trace element deficiency. In murine models of CVB myocarditis, copper and selenium deficiency are associated with increased viral virulence.<sup>41</sup> Mercury exposure exacerbates infection with virulent strains of encephalomyocarditis virus,<sup>42</sup> herpes simplex virus type 2,<sup>43</sup> and a myocarditic strain of coxsackie B3 virus,<sup>44,45</sup> possibly through sequestration of selenopeptides.<sup>46</sup> In a case series from Italy, mercury concentration in the myocardium was reportedly higher in DCM patients (178.5  $\mu\text{g/g}$ ) than it was in control subjects (0.008  $\mu\text{g/g}$ ).<sup>47</sup>

Myocardial damage in enteroviral infections may also occur independently of any immune reaction. Protein products of the enteroviral genome, including viral protease 2a and 3a can cleave host proteins, including dystrophin, and lead to cardiomyopathy.<sup>48</sup> Dystrophin deficiency markedly increases enterovirus-induced cardiomyopathy.<sup>49</sup> Active CVB infection is associated with disruption of dystrophin in patients who die of myocardial infarction, suggesting that CVB can contribute to the pathogenesis of myocardial infarction and DCM.<sup>50</sup>

In contrast to the relatively abundant data on viral myocarditis, the pathogenesis of nonviral myocarditis is poorly understood, largely because of the rarity of the diseases and fewer model systems. In the case of giant cell myocarditis, CD4 positive T lymphocytes are the main effectors of inflammation,<sup>51</sup> although anticardiac myosin antibodies are also elevated in a minority of patients.<sup>39</sup> In the case of cardiac sarcoidosis or idiopathic granulomatous myocarditis, T lymphocytes are also thought to be the main effector cells involved in disease pathogenesis.<sup>52</sup> In contrast, myocarditis following smallpox vaccination seems to be an allergic type of reaction characterized by an eosinophil rich infiltrate, interleukin-4 and interleukin-5.<sup>53</sup>

## DIAGNOSIS OF CARDIOMYOPATHY DUE TO MYOCARDITIS

### Typical Presentations in Heart Failure

The question of whether myocarditis is a cause of heart failure arises typically in a patient who has acute decompensated heart failure and less often in patients who have been found to

have asymptomatic dilated cardiomyopathy. Factors associated with heart failure suggestive of myocarditis are listed in [Box 31-1](#). Less commonly patients with myocarditis can present as hypertrophic cardiomyopathy due to the presence of myocardial edema or as restrictive cardiomyopathy in older patients.<sup>54</sup> Recently, there have been reports of patients with myocarditis presenting as arrhythmogenic right ventricular dysplasia.<sup>55</sup> Patients with infiltrative cardiomyopathy such as in amyloidosis can also develop concomitant myocarditis.<sup>56</sup> Patients with chronic heart failure can also decompensate due to development of interval myocarditis and the diagnosis of this phenomenon has been made retrospectively, either during autopsy or examination of the explanted heart.<sup>57</sup> Occasionally patients who have sudden cardiac death or chest pain and preserved ejection fraction can have myocarditis.<sup>58</sup>

### Clinical Features

The various heart failure syndromes that patients with myocarditis can have are outlined in [Box 31-2](#). In patients with heart failure due to myocarditis there appears to be a male preponderance as seen in the Myocarditis Treatment Trial in which 62% of the patients were male.<sup>59</sup> A prodrome of fever, myalgias, and gastrointestinal or respiratory symptoms is variably reported and may reflect systemic effects of acute viral infection in patients with viral myocarditis and commonly precedes acute fulminant myocarditis usually within 2 weeks before hospitalization. There appears to be a short duration of heart failure symptoms in patients with acute fulminant myocarditis, typically lasting less than 1 to 2 weeks.<sup>60</sup> These clinical features are important to recognize since these patients decompensate rapidly and usually require inotrope or mechanical circulatory support. Acute fulminant myocarditis is usually due to acute lymphocytic myocarditis but rarely can be caused by acute giant cell myocarditis. The differentiation of the two conditions is important and requires endomyocardial biopsy.<sup>61</sup> Patients with heart failure due to myocarditis could have symptoms of chest pain due to accompanying pericarditis or ischemia from underlying vasculitis or coronary vasospasm.<sup>62</sup> The presence of significant ventricular arrhythmias should alert the clinician to the possibility of nonviral causes of myocarditis, such as cardiac sarcoidosis and giant cell myocarditis.<sup>63</sup>

A variety of specific disorders should be considered in the patient with suspected myocarditis. Patients with Lyme myocarditis can have accompanying atrioventricular conduction abnormalities and often have traveled or live in endemic regions or give a history of a tick bite.<sup>64</sup> Patients with drug-induced hypersensitivity myocarditis are typically older, on multiple medications, and have systemic complaints of rash, fever, and possibly

### BOX 31-2 Heart Failure Syndromes as a Consequence of Viral and Nonviral Myocarditis

1. Acute coronary syndrome with “normal coronaries”
  - a. Acute lymphocytic myocarditis
  - b. Giant cell myocarditis
2. Acute heart failure with hemodynamic compromise
  - a. Acute fulminant lymphocytic myocarditis
  - b. Giant cell myocarditis
  - c. Eosinophilic myocarditis
3. Heart failure with ventricular arrhythmias and high degree AV block
  - a. Giant cell myocarditis
  - b. Cardiac sarcoidosis
  - c. Lyme myocarditis (consider coinfection with *Babesia* and *Ehrlichia*)
  - d. Chagas myocarditis
4. Heart failure with eosinophilia
  - a. Eosinophilic myocarditis
  - b. Hypersensitivity myocarditis

*Drugs:* azithromycin, benzodiazepines, clozapine, cephalosporins, dapsone, dobutamine, gefitinib, lithium, loop diuretics, methyl dopa, mexiletine, nonsteroidal antiinflammatories, penicillins, phenobarbital, smallpox vaccination, streptomycin, sulfonamides, tetanus toxoid, tetracycline, thiazide diuretics, tricyclic antidepressants

*Other:* bee venom, wasp venom, black widow spider venom, scorpion venom, snake venom

5. Heart failure associated with systemic diseases
  - a. Churg-Strauss
  - b. Systemic lupus erythematosus
  - c. Inflammatory bowel disease
  - d. Thyrotoxicosis
  - e. Takayasu arteritis
  - f. Wegener granulomatosis
  - g. Celiac disease
  - h. Kawasaki disease
  - i. Sarcoidosis (idiopathic granulomatous myocarditis)

eosinophilia on peripheral blood.<sup>65</sup> Eosinophilia with a concomitant pulmonary infiltrate should alert the treating physician to possible Churg-Strauss syndrome. Eosinophilic myocarditis may also occur in the setting of malignancy, parasitic infection, after vaccination, and early in the course of Loeffler endomyocardial fibrosis.<sup>66</sup> Hypereosinophilic syndrome, a diagnosis of exclusion is rare and affects predominantly males, resulting sometimes in endomyocarditis and intracardiac thrombi. Chagas cardiomyopathy should be suspected in patients from endemic areas of rural Central and or South America, who can have accompanying arrhythmias including AV block but who can also be asymptomatic (see Chapter 33).<sup>67</sup> Patients with HIV who have cardiomyopathy are usually asymptomatic and the incidence appears to be decreasing with the advent of effective antiretroviral therapy. The causes of cardiomyopathy in HIV are multifactorial including toxicity of antiretroviral agents, nutritional deficiencies, and autoimmune factors such as development of antimyosin antibodies. Presentation with myocarditis due to the virus itself is unusual, but the gp120 protein can directly cause myocyte dysfunction.<sup>68, 69</sup> Rarer causes of myocarditis in these patients are concomitant opportunistic infections such as toxoplasmosis and aspergillosis.

### Biochemical Markers (see also Chapter 37)

There are no available biomarkers at present that clearly differentiate myocarditis from other causes of acute heart failure since acute decompensated heart failure in itself can

cause elevations of cardiac enzymes that indicate cardiomyocyte death. Cardiac troponin T and I elevations are seen in a minority of patients with acute myocarditis but suggest the diagnosis, especially in the absence of obstructive coronary artery disease. Standard markers of myocardial damage including troponin I have a high specificity (89%) but limited sensitivity (34%) in the diagnosis of myocarditis especially with a shorter duration (less than 4 weeks) of symptoms when analyzed in the Myocarditis Treatment Trial population.<sup>70</sup> With the advent of CMR, myocarditis is being increasingly recognized as a cause of chest pain in patients with raised troponin levels and normal epicardial coronary arteries. Clinical and experimental data suggest that cardiac troponin I is increased much more frequently than creatinine kinase MB subunits (CK-MB) in patients with myocarditis.<sup>71</sup> Natriuretic peptides such as NT-proBNP may be elevated in patients with myocarditis and cardiac dysfunction, and with troponin levels could be used to monitor patients on immunomodulatory therapy and is a marker of persistent cardiac dysfunction.<sup>72</sup> Patients with myocarditis who have increased serum levels of soluble Fas and soluble Fas ligand at initial presentation have an increased short-term risk of death.<sup>73</sup> High interleukin-10 levels are also a marker of poor prognosis and predict patients who will develop cardiogenic shock in acute fulminant myocarditis.<sup>74</sup> Erythrocyte sedimentation rate although commonly used has a low sensitivity and specificity for acute myocarditis.

### Noninvasive Cardiac Testing (see also Chapter 36)

The ECG in acute myocarditis may show sinus tachycardia with nonspecific ST-segment and T-wave abnormalities. Occasionally, the ECG changes are suggestive of an acute myocardial infarction; and may include ST-segment elevation in two or more contiguous leads (54%), widespread ST-segment depressions (18%), and pathological Q waves (18% to 27%).<sup>75</sup> Global T-wave inversions may also be present. In a small proportion of patients, various degrees of heart block may occur. Ventricular arrhythmias may also be present, but occur more commonly in cardiac sarcoidosis and giant cell myocarditis.<sup>76</sup>

An echocardiogram should be performed in all patients with suspected acute myocarditis; however, echocardiographic findings while useful in confirming the presence of reduced LV ejection fraction are not specific for myocarditis. Nondiagnostic findings such as regional wall motion abnormalities, increased LV wall thickness, and absence of LV cavity dilation in the presence of LV systolic dysfunction, diastolic dysfunction, and changes in echocardiographic texture have been reported.<sup>77</sup> Echocardiographic patterns of dilated, hypertrophic, restrictive, and ischemic cardiomyopathies have also been described in histologically proven myocarditis. In the Myocarditis Treatment Trial, increased sphericity and LV volume occurred in acute, active myocarditis. Left ventricular cavity size may initially be normal primarily due to increased LV wall thickness in very early myocarditis and subsequent increase over time may occur due to resolution of inflammation and edema, and adverse remodeling. Echocardiography may be useful in distinguishing acute fulminant myocarditis from acute myocarditis by echocardiographic criteria as suggested by Felker et al.<sup>78</sup> Patients with fulminant myocarditis had near normal left ventricular diastolic dimensions with increased septal thickness at presentation likely due to a greater inflammatory component and edema, while those with acute myocarditis had increased diastolic dimensions but normal septal thickness. The increased wall thickness has been shown to be spontaneously reversible in acute fulminant myocarditis over time or after treatment with corticosteroids in acute eosinophilic myocarditis.<sup>79</sup>

**FIGURE 31-2** Contrast-enhanced cardiac magnetic resonance image of the heart showing focal late enhancement (arrow) of gadolinium in a patient with myocarditis.

Cardiac magnetic resonance (CMR) imaging is being increasingly used as a diagnostic test in acute dilated cardiomyopathy and suspected acute myocarditis due to the noninvasive nature of the test and its ability to detect inflammation in myocardial tissue (see Chapter 36).<sup>80,81</sup> CMR is able to provide information similar to echocardiography that may serve as corroborative evidence for the presence of myocarditis such as the presence of ventricular systolic dysfunction, pericardial effusion, and increased LV mass. Techniques used for tissue characterization include T2-weighted imaging for myocardial edema, contrast enhanced fast spin echo T1-weighted images for hyperemia, and delayed gadolinium enhancement for necrosis or fibrosis (Figure 31-2 and Box 31-3). The combination of these markers enhances the diagnostic capability of CMR and when compared with histopathology the sensitivity is 63% with a specificity of 89% for a diagnosis of myocarditis.<sup>82</sup> Although CMR has great potential for noninvasive diagnosis and prognosis, motion artifacts and arrhythmias can affect image accuracy and quality. The main limitations of the published CMR studies are that most have used clinical parameters to define myocarditis, and all have used patients with acute myocardial infarction on normal controls for comparison. As of March 2009, only 289 patients had been reported in eight controlled trials of CMR for the diagnosis of myocarditis.

### Endomyocardial Biopsy

The gold standard in diagnosing myocarditis is histopathology. Therefore endomyocardial biopsy has played an important role in the evaluation of a patient with suspected myocarditis. In patients with unexplained cardiomyopathy, endomyocardial biopsy identified approximately 9% of patients with myocarditis.<sup>83</sup> In the Myocarditis Treatment Trial, the average incidence of positive endomyocardial biopsy was 10% in patients with heart failure of less than 2 years of duration using traditional Dallas criteria, which are outlined in Table 31-1<sup>59</sup> (Figure 31-3A). The sensitivity of EMB for myocarditis increased if immunoperoxidase staining for specific cells and/or MHC antigen expression is used. Such stains are commonly

### BOX 31-3 Select Diagnostic Tests in Myocarditis

1. Endomyocardial biopsy
  - a. Dallas criteria for myocarditis require an inflammatory infiltrate with necrosis and/or degeneration of adjacent myocytes without evidence of Chagas' disease or features of ischemic heart disease
  - b. Immunoperoxidase-based stains are used to identify more sensitive markers for myocardial inflammation such as MHC antigens HLA-A, B, C, and HLA-DR, and surface antigens such as anti-CD3, anti-CD4, anti-CD20, and anti-CD68.
  - c. Viral genomes can be detected using molecular methods such as the polymerase chain reaction (PCR)
2. Cardiac magnetic resonance imaging
  - a. T1-weighted spin-echo images with gadolinium enhancement using appropriate absolute or normalized to skeletal muscle quantitative measurements
  - b. T2-weighted spin-echo images showing gadolinium enhancement with a high signal intensity ratio normalized to skeletal muscle or the presence of myocardial edema

**TABLE 31-1** Dallas Criteria for the Diagnosis of Myocarditis\*

First Biopsy
Active myocarditis (with or without fibrosis)
Borderline myocarditis (not diagnostic and requiring no further biopsy)
No evidence of myocarditis
Subsequent Biopsies
Ongoing (persistent) myocarditis
Resolving (healing) myocarditis
Resolved (healed) myocarditis

\*The histological diagnosis of active myocarditis requires an inflammatory infiltrate with necrosis and/or degeneration of adjacent myocytes without evidence of Chagas disease or features of ischemic heart disease.

used in recent reports, including the European Study of Epidemiology and Treatment of Cardiac Inflammatory Diseases Study, and large case series from Padua and Tubigen<sup>84,85-87</sup> (see Figure 31-3, B). Viral genomes can be identified in heart tissue using polymerase chain reaction (PCR) techniques. Endomyocardial biopsy for histopathological or molecular analysis is limited by sampling error and procedural risks.

The overall complication rate in experienced centers is approximately 6%; 2.7% occurring during sheath insertion and 3.3% occurring as a result of the biopsy procedure itself. The most common complications being arterial puncture, arrhythmias, pneumothorax, and damage to the tricuspid valve and the most grievous being cardiac perforation, which occurs in 0.5% of cases.<sup>88</sup> These complications can be minimized by use of ultrasound guidance to access the vein and the use of echocardiography during tissue procurement. The relative insensitivity of the endomyocardial biopsy in diagnosing myocarditis has been demonstrated in autopsy and explanted hearts and more recently by CMR studies. The risks are likely lower if a smaller tip bioprobe is used.<sup>89</sup> The accepted indications and recommendations for endomyocardial biopsy have been driven primarily by prognostic and therapeutic considerations. In a consensus statement endorsed by the American Heart Association, American College of Cardiology, and European Society of Cardiology, the indications for endomyocardial biopsy in various heart failure scenarios were outlined and shown in Table 31-2.<sup>61</sup> The

**FIGURE 31-3** A, Acute myocarditis on hematoxylin and eosin stained section. A lymphocytic and histiocytic infiltrate (arrow) is associated with myocyte damage (arrowhead). B, CD68 immunostain for macrophages in a patient with peripartum cardiomyopathy.

class 1 indications for endomyocardial biopsy are primarily for clinical scenarios that are suggestive of fulminant or GCM, conditions with unique prognoses and treatments.

#### Clinical Aspects of Nonviral Myocarditis

Although most cases of acute DCM are relatively mild and resolve with few short-term sequelae, certain signs and symptoms predict GCM, a disorder with a mean transplant-free survival time of only 5.5 months.<sup>90</sup> GCM is associated with a variety of autoimmune disorders, thymoma,<sup>91</sup> and drug hypersensitivity.<sup>92</sup> At presentation ventricular tachycardia is present in 15%, complete heart block in 5%, and an acute coronary syndrome in 6%, rates higher than are typically seen in non-inflammatory DCM. In follow-up, 29% of GCM patients developed ventricular tachycardia and 15% developed AV block (8% complete).<sup>93</sup> The sensitivity of EMB for GCM in patients who subsequently had definitive pathology evaluation from ventricular tissue cores, explanted or autopsied hearts is 80% to 85%.<sup>94</sup> Thus clinical clues to suggest GCM and prompt an EMB include association with other autoimmune disorders or thymoma, failure to respond to usual care, and the presence of complete heart block or ventricular tachycardia.

Patients with acute heart failure due to GCM respond well to heart transplantation. Alternatively, treatment with combination immunosuppression may improve transplant-free survival time compared with patients with GCM not receiving immunosuppressive treatment. In a multicenter registry,

patients treated without immunosuppressive therapy had a median transplant-free survival time of 3.0 months, compared with a 12.3-month ( $P = .003$ ) median transplant-free survival time for patients treated with cyclosporine-based immunosuppression. In a prospective series of 11 patients with GCM treated with cyclosporine-based immunosuppression, there was one death and two heart transplants in the first year of therapy.<sup>63</sup> Therefore a diagnosis of GCM on endomyocardial biopsy will likely impact prognosis and treatment.

Cardiac sarcoidosis is present in approximately 25% of patients with systemic sarcoidosis.<sup>95</sup> However, symptoms referable to cardiac sarcoidosis occur in only 5% of sarcoid patients.<sup>95, 96</sup> Up to 50% of patients with sarcoid granulomas in the heart have no evidence of extracardiac disease. Patients with cardiac sarcoidosis may sometimes be distinguished from those with DCM by a high rate of heart block (8% to 67%) and ventricular arrhythmias (29%).<sup>97-100</sup> The rates of ventricular tachycardia and heart block are therefore similar in cardiac sarcoidosis and GCM, but cardiac sarcoidosis generally has a more chronic course. Because the sensitivity of EMB is low in patients with suspected cardiac sarcoidosis, CMR has been used to infer cardiac involvement and follow disease activity.<sup>101,102</sup>

Hypersensitivity myocarditis (HSM) is an uncommon disorder with a wide range of presentations, including sudden death, rapidly progressive heart failure, or more chronic DCM. Drug-associated, toxin-associated, and infectious causes of myocarditis are listed in Box 31-4. Clinical clues that are reported in a minority of cases include rash, fever, and peripheral eosinophilia.<sup>103</sup> A temporal relation with recently initiated medications or the use of multiple medications is usually present.<sup>104</sup> The ECG is often abnormal with nonspecific ST-segment changes or infarct patterns similar to other forms of acute myocarditis. The prevalence of clinically undetected HSM in explanted hearts ranges from 2.4% to 7%<sup>105</sup> and has been associated with dobutamine.<sup>106</sup>

Early suspicion and recognition of HSM may lead to withdrawal of offending medications and administration of high-dose corticosteroids.

Eosinophilic myocarditis associated with the hypereosinophilic syndrome is a form of eosinophilic myocarditis that typically evolves over weeks to months. The presentation is usually biventricular heart failure, although arrhythmias may lead to sudden death. Usually there is a hypereosinophilia that precedes or coincides with the onset of cardiac symptoms; however, the eosinophilia may be delayed.<sup>107</sup> Eosinophilic myocarditis may also occur in the setting of malignancy, parasite infection, and early in the course of endocardial fibrosis.

## TREATMENT

### Physical Activity (see also Chapter 57)

In murine models, exercise early in the course of CVB myocarditis has been shown to enhance viral replication, myocardial inflammation, and necrosis.<sup>108</sup> Myocarditis was also identified as a common cause of sudden death in young Swedish male military recruits between 1979 and 1992<sup>109</sup> and in other case series. Although adequate clinical data are unavailable, it is not unreasonable to recommend that patients refrain from competitive sports and athletic activity until up to 6 months after the onset of the disease and/or myocardial dysfunction and inflammation is felt to have resolved by ECG, echocardiographic, and biochemical data.

### Antiinflammatory Agents

Nonsteroidal antiinflammatory drugs (NSAIDs) have not shown any efficacy in the treatment of myocarditis, despite histological evidence of inflammatory infiltrates in myocarditis.

**TABLE 31–2 The Role of Endomyocardial Biopsy in Various Heart Failure Clinical Scenarios**

Scenario Number	Clinical Scenario	Class of Recommendation (I, IIa, IIb, III)	Level of Evidence (A,B,C)
1	New onset heart failure of less than 2 weeks' duration associated with a normal size or dilated left ventricle and hemodynamic compromise	I	B
2	New onset heart failure of 2 weeks to 3 months' duration associated with a dilated left ventricle, and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1 to 2 weeks	I	B
3	Heart failure of greater than 3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1 to 2 weeks	IIa	C
4	Heart failure associated with a dilated cardiomyopathy of any duration associated with suspected allergic reaction and/or eosinophilia	IIa	C
5	Heart failure associated with suspected anthracycline cardiomyopathy	IIa	C
6	Heart failure associated with unexplained restrictive cardiomyopathy	IIa	C
7	Unexplained cardiomyopathy in children	IIa	C
8	New onset heart failure of 2 weeks to 3 months duration associated with a dilated left ventricle, without new ventricular arrhythmias, or second- or third-degree heart block, and that responds to usual care within 1 to 2 weeks	IIb	B
9	Heart failure of greater than 3 months duration associated with a dilated left ventricle, without new ventricular arrhythmias, or second or third degree heart block, and that responds to usual care within 1 to 2 weeks	IIb	C
10	Heart failure associated with unexplained hypertrophic cardiomyopathy	IIb	C

### BOX 31–4 Infectious and Toxin- or Drug-Associated Causes of Myocarditis

#### Infectious Causes

**Viral:** adenovirus, arbovirus, Chikungunya virus, cytomegalovirus, echovirus, enterovirus (Coxsackie B), Epstein-Barr virus, flavivirus (*dengue fever* and *yellow fever*), hepatitis B virus, hepatitis C virus, herpes viruses (human herpesvirus-6), human immunodeficiency virus (HIV/AIDS), influenza A and B viruses, parvovirus (parvovirus B-19), mumps virus, poliovirus, rabies virus, respiratory syncytial virus, rubeola virus, rubella virus, varicella virus, variola virus (*smallpox*)

**Bacterial:** *Burkholderia pseudomallei* (melioidosis), *Brucella*, *Chlamydia* (especially *Chlamydia pneumonia* and *Chlamydia psittacosis*, *Corynebacterium diphtheriae* (*diphtheria*), *Francisella tularensis* (tularemia), *Haemophilus influenzae*, *Gonococcus*, *Clostridium*, *Legionella pneumophila* (Legionnaire's disease), *Mycobacterium* (tuberculosis), *Neisseria meningitidis*, *Salmonella*, *Staphylococcus*, *Streptococcus A* (rheumatic fever), *Streptococcus pneumoniae*, syphilis, tetanus, tularemia, *Vibrio cholerae*

**Spirochetal:** *Borrelia burgdorferi* (Lyme disease), *Borrelia recurrentis* (relapsing fever), leptospira, *Treponema pallidum* (syphilis)

**Rickettsial:** *Coxiella burnetii* (Q fever), *Orientia tsutsugamushi* (scrub typhus), *Rickettsia prowazekii* (typhus), *Rickettsia rickettsii* (Rocky Mountain spotted fever)

**Fungal:** *Actinomyces*, *Aspergillus*, *Blastomyces*, *Candida*, *Coccidioides*, *Cryptococcus*, *Histoplasma*, *Mucor* species, *Nocardia*, *Sporothrix schenckii*, *Strongyloides stercoralis*

**Protozoal:** *Balantidium*, *Entamoeba histolytica* (amebiasis), *Leishmania*, *Plasmodium falciparum* (malaria), *Sarcocystis*, *Trypanosoma cruzi* (Chagas' disease), *Trypanosoma brucei* (African sleeping sickness), *Toxoplasma gondii* (toxoplasmosis)

**Helminthic:** *Ascaris*, *Echinococcus granulosus*, *Heterophyes*, *Paragonimus westermani*, *Schistosoma*, *Strongyloides stercoralis*, *Taenia solium* (cysticercosis), *Toxocara canis* (visceral larva migrans), *Trichinella spiralis*, *Wuchereria bancrofti* (filariasis)

#### Toxin- or Drug-associated Causes

Aminophylline, amphetamines, anthracyclines, catecholamines, chloramphenicol, cocaine, cyclophosphamide, doxorubicin, ethanol, 5-fluorouracil, imatinib mesylate, interleukin-2, methysergide, phenytoin, trastuzumab, zidovudine, arsenic, carbon monoxide, copper, iron, lead

In fact, they may lead to increased mortality by exacerbating the inflammatory process in the myocardium and increasing the virulence of the infectious agent.<sup>110-112</sup> Tea catechins in experimental autoimmune myocarditis have been shown to reduce inflammation and improve myocardial function, especially when administered early in the course of disease.

### Antiarrhythmic Therapy

The arrhythmic risk may subside after the acute phase of myocarditis; however, determining when this has occurred is often difficult. Arrhythmias may resolve with therapy, for example, atrioventricular nodal block in sarcoidosis or Lyme carditis, and may not warrant placement of a permanent pacemaker.<sup>113</sup> Patients with acute myocarditis should be hospitalized for electrocardiographic monitoring. The 2006 ACC/AHA/ESC guidelines for the management of arrhythmias recommended that acute arrhythmia emergencies be managed conventionally in the setting of myocarditis.<sup>114</sup> For patients with life-threatening ventricular arrhythmias, ICD therapy may be appropriate if they are not in the acute phase of myocarditis and are on optimal medical therapy with reasonable prognosis for recovery of functional status. Amiodarone or dofetilide have been used as antiarrhythmic therapy when indicated in these patients. In the absence of clinical data, there is a low threshold in clinical practice to implant an ICD in patients with heart failure due to giant cell myocarditis and sarcoidosis.

### Specific Therapy

Patients with Lyme myocarditis are treated with a combination of antibiotics including intravenous ceftriaxone or cefotaxime or penicillin G, followed by amoxicillin and doxycycline for at least 4 weeks.<sup>115,116</sup> Myocarditis in systemic lupus erythematosus may be treated with augmentation of immunosuppression such as high dose steroids and cyclophosphamide.<sup>117</sup> Hypersensitivity and eosinophilic myocarditis generally responds well to high dose corticosteroids and withdrawal of the offending agent.

## TREATMENT OF ACUTE HEART FAILURE

Acute heart failure syndromes should be managed as per the current AHA/ACCF, ESC, and HFSA guidelines (see also Chapter 43).<sup>118-120</sup> Diuretics should be given to manage volume status, appropriate use of vasodilator therapy and close observation under a monitored setting for functional decline and arrhythmias should be undertaken. Low-dose inotropes can be used in patients with poor end-organ perfusion; however, patients with acute fulminant myocarditis can decline rapidly and intervention in the form of mechanical circulatory support may need to be instituted.

Intraaortic balloon pumps, ventricular assist devices, or extracorporeal membrane oxygenation (ECMO) as a bridge to transplantation or recovery has been used successfully.<sup>121,122</sup> ECMO support may be especially beneficial for patients with fulminant myocarditis with profound shock, where short-term recovery is expected.<sup>123,124</sup> For patients with cardiogenic shock due to acute (nonfulminant) myocarditis, recovery is more likely to be less rapid and implantation of a ventricular assist device as a bridge to transplantation or recovery may be a more effective strategy.<sup>125, 126</sup>

### Neurohormonal Blockade in Myocarditis

Patients with heart failure and myocarditis in general respond well to supportive measures and pharmaceutical intervention including neurohormonal blockade, an approach used in the traditional patient with chronic heart failure.

The use of angiotensin-converting enzyme inhibitors/angiotensin receptor blockers (ACEI/ARBs) has not been prospectively tested in patients with myocarditis and data supporting its use is extrapolated from the heart failure trials and animal studies (see Chapter 45). Captopril has been found to reduce inflammatory infiltrates, myocardial necrosis,<sup>127</sup> LV mass, and liver congestion.<sup>128</sup> Candesartan has been shown in a murine model of viral myocarditis to significantly improve survival as compared with controls. Therefore it is not unreasonable to use ACEI or ARB in patients with myocarditis and LVEF less than 40%.

The use of nonspecific  $\beta$ -blockers in animal studies of myocarditis have promising results. The first study of carvedilol, a nonselective  $\beta$ -blocker, demonstrated improvement of inflammation and reduction in wall thickness.<sup>129</sup> Carvedilol demonstrated a similar beneficial effect in a model of encephalomyocarditis virus. Viral replication and myocardial necrosis were reduced and survival time increased.<sup>130,131</sup> In human studies, lack of  $\beta$ -blocker therapy in patients with clinically suspected myocarditis was a marker of poor prognosis.<sup>132</sup>  $\beta$ -blockers, preferably nonselective, should therefore be used in patients with heart failure and myocarditis in accordance with current guidelines.

A selective aldosterone antagonist, eplerenone, when used in a mouse model of myocarditis, was found to result in significantly decreased fibrosis in affected hearts probably by its antiinflammatory effect on metalloproteinases and collagen formation.<sup>133</sup> Aldosterone inhibitors improve mortality and heart failure symptoms and should be used in that subset of heart failure patients with myocarditis in accordance with current heart failure guidelines.

### Antiviral Therapy

Key trials of antiviral and immunomodulatory treatments for myocarditis are listed in Table 31-3. Antiviral therapy has limited applicability in patients with acute cardiomyopathy due to viral myocarditis for several reasons. First, detecting the presence of a viral genome in myocardium is challenging due to various technical factors and routine use of endomyocardial biopsy for this purpose is not recommended due to attendant risks.<sup>61</sup> Secondly, antiviral therapy for acute cardiomyopathy would be most effective when administered at the time of inoculation with the virus or soon thereafter, a timeline that is not practical to follow in human cases of acute myocarditis except in immunosuppressed patients who are being closely monitored. Thirdly, data regarding the use of antiviral agents for the treatment of acute myocarditis is limited to animal models and small case series. In one small case series, three of four patients with life-threatening myocarditis treated with pleconaril improved.<sup>134</sup> Antiviral therapy with ribavarin when administered at the time of virus inoculation was shown to improve survival in treated mice and interferon- $\alpha$  A/D in a similar murine model of viral myocarditis, was found to reduce the severity of myocardial inflammation and necrosis, and viral titers.<sup>135,136</sup> Only certain specific interferon subtypes like IFN A6, A9, and B administered by DNA inoculation in murine models of cytomegalovirus myocarditis have been found to inhibit myocarditis and inflammation.

In contrast, in the setting of chronic, dilated cardiomyopathy with enteroviral or adenoviral persistence detected by PCR, treatment with interferon- $\beta$  was associated with viral clearance/eradication in all patients, a significant increase in LV ejection fraction and a significant decrease in LV dimensions in approximately 70% of the treatment group.<sup>137</sup> Similar results have been seen in an open labeled randomized trial in patients with dilated cardiomyopathy treated with interferon- $\alpha$ . Although antiviral therapy cannot be recommended for the routine treatment of acute myocarditis at this

**TABLE 31–3 Important Clinical Trials of Immunomodulatory and Antiviral Therapies in Cardiomyopathy Due to Myocarditis**

Trial	Heart Failure Syndrome	Diagnostic Criteria Used (% patients)	Number of Patients*	Therapy Including Duration	Heart Failure Therapy	Primary Endpoint	Secondary Endpoint	Period of Follow-up
Mason, 1995	Heart failure <2 years, EF ≤ 45%	Active or border-line myocarditis = 64%	N = 111 P = 47 T = 64	Prednisone plus cyclosporine or azathioprine; 6 months	Digitalis ACEI	Improvement in LVEF; no treatment benefit seen	Survival, immune activation markers; no significant difference	28 weeks
McNamara, 1999	Acute heart failure, EF ≤ 40%	Active myocarditis = 7% Borderline myocarditis = 5% Inflammatory markers = 5%	N = 62 P = 29 T = 33	Intravenous immunoglobulin, one time dose	ACEI β-blockers	Improvement in LVEF; no difference between placebo and treatment group	Survival and peak $\dot{V}O_2$ ; no difference seen between 2 groups	6 and 12 months
Wojnicz, 2001	Chronic heart failure, EF ≤ 40%	Active myocarditis = 8% Borderline myocarditis = 19% Upregulation of HLA Class I = 100%	N = 84 P = 43 T = 41	Prednisone plus azathioprine; 3 months	ACEI β-blockers Digitalis Nitrates Spironolactone Amiodarone	Composite of death, heart transplantation, and hospital readmission; no treatment benefit	Improvement in LVEF, NYHA class, LV chamber size	2 years
Kuhl, 2003	Fatigue, chest pain, arrhythmias	Active or border-line myocarditis = 0% Viral genome = 100% Inflammatory markers = 30%	N = 22 EF >50% = 10 EF <50% = 12	Interferon-β; 6 months	ACEI β-blockers Digitalis	Viral clearance, improvement in LV size, LVEF; 100% viral clearance, 70% improvement in LV function	NA	6 months
Frustaci, 2003	Chronic heart failure, EF ≤ 40%	Active myocarditis = 100% Viral genome = 50%	N = 41	Prednisone and azathioprine; 6 months	ACEI β-blockers Digitalis	Improvement in LVEF, NYHA class; treatment benefit for patients with no viral genome in the myocardium	NA	1 year
Cooper, 2008	Acute heart failure, arrhythmias	Giant cell myocarditis by histology = 100%	N = 11	Prednisone, cyclosporine; 1 year ± OKT3 10 days	ACEI or ARB β-blockers Digitalis Hydralazine Amiodarone	Survival or transplant; treatment benefit observed in 90% of patients	Histological parameters; improvement was observed at 4 weeks	1 year
Frustaci, 2009	Chronic heart failure, EF <45%	Active myocarditis = 100% Viral genome = 0%	N = 85 P = 42 T = 43	Prednisone, 5 months; and azathioprine, 6 months	ACEI β-blockers Digitalis	Improvement in LV function; 88% improved in treatment group, none in placebo	NA	6 months

\*N = total number of patients; P = placebo; and T = treatment arm.

time, there may be a role in patients with chronic dilated cardiomyopathy who fail to respond to usual care.

### Immunosuppression and Immunomodulatory Therapy

Myocardial injury sustained in myocarditis appears to be due to a predominantly immune response involving T lymphocytes and production of auto-antibodies. Hence it would seem that immunosuppression would be a useful treatment modality. However, despite earlier anecdotal reports of the promise of immunosuppression, the Myocarditis Treatment Trial failed to show a survival or functional (change in LV ejection fraction) benefit with the use of azathioprine or cyclosporine with prednisone in patients with histologic myocarditis and LV ejection fraction less than 45%.<sup>59</sup> The study did have many limitations, including different treatment arms with small patient numbers in each arm, discrepancy in biopsy interpretation in up to 36% of patients, use of traditional histologic criteria for

patient inclusion, and short duration of symptoms (less than a month) in up to 50% of patients. The duration of symptoms appears to be important as suggested by a recent meta-analysis of immunosuppression and immunomodulation trials wherein trials performed in DCM of less than 6 months duration were negative, and the trials in DCM of greater than 6 months duration were generally positive due to the large improvement in the placebo groups in subjects with acute myocarditis.<sup>138</sup> The utility of using Dallas criteria to identify patients with chronic DCM who will respond to immunomodulatory therapy has been questioned. Up to 40% of patients with chronic DCM will have immunohistochemical evidence of myocardial inflammation, defined by HLA or cell-specific antigen expression on endomyocardial biopsy. In two randomized trials, immunosuppression with azathioprine and prednisone resulted in an improvement in LVEF, NYHA functional class, LV volume, and LV end diastolic diameter.<sup>139</sup> The improvement in one trial was sustained over a period of 2 years in approximately 70% of patients in the immunosuppression arm compared with 30%

of patients in the placebo arm. However, there was no difference in the primary endpoint of death, hospitalization, or readmission rates.

In a case controlled series of patients with active myocarditis and chronic heart failure, unresponsive to conventional therapy, the presence of cardiac autoantibodies and absence of viral genome seem to predict response to treatment with prednisone and azathioprine.<sup>140</sup> Similar results were recently reported in patients with chronic heart failure and active myocarditis and lack of viral genome in myocardial tissue when treated with immunosuppression with an improvement in LVEF from mean of 26% to 46% at 6 months.<sup>141</sup> As is the case for antiviral therapy, the role for immunosuppression may be limited to carefully selected patients with chronic myocarditis (identified by immunoperoxidase based criteria) and those with specific causes such as systemic lupus erythematosus, sarcoidosis, or giant cell myocarditis.

Intravenous immunoglobulin (IVIG) has been shown to be effective in case series of acute myocarditis due to Kawasaki disease and in murine viral myocarditis.<sup>142</sup> In a pediatric population with clinically suspected acute myocarditis, the use of IVIG was associated with improved LV ejection fraction. However, there was no clear survival benefit and  $\beta$ -blockers were not routinely used.<sup>143,144</sup> In the Intervention for Myocarditis and Acute Cardiomyopathy (IMAC-1) trial, adult patients with recent onset myocarditis (less than 5% had active myocarditis) or dilated cardiomyopathy of less than 6 months in duration received IVIG or a placebo. The treatment and placebo groups showed no significant differences.<sup>145</sup> The lack of benefit in this trial is possibly explained by the absence of significant histological myocarditis in treated patients but more importantly could be due to the beneficial effect of IVIG being most pronounced in the acute viremic phase by supplying exogenous neutralizing antibody. A recent systematic review that included IMAC and other smaller studies concluded that there is insufficient evidence to recommend its use in acute myocarditis in adults at this time.<sup>146</sup>

Animal studies have suggested a role for immunomodulatory agents such as interleukin-10 and pimobendan, a phosphodiesterase III inhibitor, in acute viral myocarditis, but these agents remain untested in human studies. Immunoadsorption and other immunomodulatory therapy are currently being tested in human populations.

## Prognosis

The outcome of patients with heart failure due to myocarditis depends largely on the presenting clinical scenario. Prognosis is excellent for adult acute lymphocytic myocarditis patients with mild symptoms and preserved LV ejection fraction. The patient with acute fulminant myocarditis appears to have a similar good prognosis if appropriately supported through the acute illness.<sup>60</sup> Patients who have an acute myocardial infarction pattern similarly do well usually with complete recovery of LV ejection fraction. Patients with giant cell myocarditis have a poor prognosis with a 5-year survival rate of approximately 20%; however, immunosuppression may attenuate the course of this disease extending median transplant-free survival time from 3 to 12 months.<sup>63</sup> In patients with acute dilated cardiomyopathy, 67% of who were confirmed to have myocarditis by biopsy, 40% demonstrate improvement in LV function with supportive therapy before the modern era of heart failure treatment.<sup>147</sup> Current prognosis in such patients with acute dilated cardiomyopathy and the routine use of ACE-I and  $\beta$ -blockers seems to be good with transplant-free survival rate being 95% at 1 year. In a large single center, case series, patients with acute lymphocytic myocarditis had a 5-year transplant-free survival rate of approximately 50% compared with patients who were diagnosed with borderline myocarditis who seem to have a better prognosis, with the 5-year survival rate being greater than

80%.<sup>148</sup> In the era of contemporary heart failure therapy, the composite endpoint of death, transplant, and hospital readmission in patients with chronic heart failure, LVEF less than 40% who have increased HLA expression does not seem to be any different as compared with other patients with chronic heart failure being approximately 20% with or without immunosuppression at 2 years. When patients with myocarditis undergo heart transplantation overall survival is similar to survival for other causes of cardiac transplantation,<sup>149</sup> although in the case of giant cell myocarditis and rarely sarcoidosis there is a risk of recurrence of the disease in the transplanted heart.

**Conclusions, 490**

Chronic congestive heart failure is a highly prevalent and progressive disorder, has a huge economic impact, and is a cause of excess morbidity and mortality worldwide. One factor that may contribute to progression of left ventricular remodeling, and consequently to morbidity and mortality of left-sided heart failure, is sleep-related breathing disorders. Sleep apnea is highly prevalent among patients with left-sided heart failure and, when untreated, contributes to excess mortality. In contrast, effective treatment of sleep apnea improves survival of patients with heart failure. Physicians caring for patients with heart failure need to be aware of sleep-related breathing disorders and various therapeutic options, which are distinct from the standard treatment of heart failure.

## HISTORY AND REDISCOVERY OF CHEYNE-STOKES BREATHING

In 1818, John Cheyne<sup>1</sup> observed an unusual pattern of breathing in a patient whose autopsy later revealed a fatty heart. Thirty-six years later, William Stokes<sup>2</sup> also observed the gradual crescendo-decrescendo changes in breathing with intervening apnea. **Figure 32-1** is a polysomnographic depiction of Cheyne-Stokes breathing in a sleeping patient with heart failure.<sup>3</sup>

George Cheyne, another Scottish physician who practiced in the early 1700s, might actually have been the first person to observe Cheyne-Stokes breathing as a pathological entity.<sup>4,5</sup> However, the best description of Cheyne-Stokes breathing is by a British physician, John Hunter,<sup>6,7</sup> about 37 years before John Cheyne's report.<sup>1</sup> The eponym, therefore, does not credit the main discoverer of the breathing pattern. For this reason, this breathing disorder is referred to as Hunter-Cheyne-Stokes breathing.

Hunter-Cheyne-Stokes breathing has been considered a rare entity associated with severe heart failure and potentially an indicator of terminal prognosis. The reason for its seeming rarity is that the disorder is only occasionally obvious during wakefulness.<sup>8</sup> The reason for heralding a poor prognosis stems from clinical observation that

when Hunter-Cheyne-Stokes breathing is observed during wakefulness, it is associated with impending mortality.

Since 1990, however, Hunter-Cheyne-Stokes breathing has been reanalyzed. Many researchers have reported a high prevalence of this disorder in heart failure.<sup>8-19</sup> The reanalysis is largely related to the availability of polysomnography to diagnose breathing disorders during sleep, the state in which the disorder commonly manifests. In addition to frequent co-occurrence of Hunter-Cheyne-Stokes breathing and central sleep apnea (CSA), polysomnography has also revealed presence of obstructive sleep apnea (OSA) in patients with heart failure.

Other important factors that have contributed to further research and increased recognition of sleep apnea is the high rates of morbidity and mortality among patients with heart failure.<sup>20</sup> As discussed later in this chapter, study findings have strongly suggested that sleep apnea contributes to mortality in patients with heart failure and that effective treatment improves survival rates.

## POLYSOMNOGRAPHY, SLEEP STAGES, AND DEFINITIONS OF SLEEP APNEA AND HYPOPNEA

Polysomnography (from the Latin *Somnus*, god of sleep in Roman mythology) is electrophysiological recording of brain waves (usually two channels) and eye movements, along with chin electromyography. These recordings allow the state of wakefulness to be differentiated from the state of sleep and enable recognition of different stages of sleep.<sup>21</sup> To recognize sleep-related breathing disorders, naso-oral airflow (measured by a thermocouple and a pressure sensor), thoracoabdominal excursions (measured by strain gauges, inductive plethysmography, or impedance pneumography), and arterial oxyhemoglobin saturation (measured by pulse oximetry) are also recorded.<sup>22</sup> Monitoring of the electrocardiogram and of the electromyogram of the anterior tibialis muscles allows, respectively, detection of nocturnal arrhythmias and a sleep disorder called *periodic limb movements*, which are common in patients with congestive heart failure.<sup>23</sup>

**FIGURE 32-1** Polysomnographic example of classic Cheyne-Stokes respiration in stage 2 sleep. *Top to bottom*, Two electro-oculograms (1st and 2nd tracings), chin electromyogram (3rd tracings), two electroencephalograms (4th and 5th tracings), electrocardiogram (6th tracing), abdominal excursion (7th tracing), esophageal pressure excursions (8th tracing), and arterial oxyhemoglobin saturation (9th tracing). Note the smooth and gradual changes in the thoracoabdominal excursions and esophageal pressure of the crescendo and decrescendo arms of the cycle. There is intervening central apnea. Central apnea is characterized by absence of effort to breathe. This is reflected in the absence of naso-oral airflow and excursions in the thoracoabdominal and pleural pressure (as measured by esophageal pressure) tracings. An arousal, characterized by an increase in chin electromyographic and electroencephalographic speeding (alpha waves), occurs at the peak of hyperventilation. Desaturation is somewhat delayed because of long circulation time in heart failure. A 5-second time scale is shown on right bottom corner.

Sleep is not a homogeneous state. According to electroencephalographic criteria, eye movements, and chin electromyography, sleep is divided into periods of rapid-eye-movement (REM) and non-rapid-eye-movement (non-REM) states.<sup>21</sup> Non-REM sleep consists of stages 1 to 4 and accounts for about 80% of total sleep time in adults. REM sleep, which accounts for 20% of total sleep time in adults, is characterized by rapid eye movements (hence the name) that occur intermittently (phasic REM, in contrast to tonic REM), skeletal muscle atonia (characterized by a decrease in the amplitude of the chin electromyogram), and dreaming. REM sleep is therefore a state of brain activity in a paralyzed body. Because of the paralysis, the dream is not enacted.

An adult normally enters sleep in stage 1 (currently referred to as *N1* instead of *S1*; *N* stands for “non-rapid-eye-movement sleep”), which in few minutes progresses to deeper sleep stages of *N2* (formerly *S2*) and *N3* (formerly *S3* and *S4*). In *N3*, brain waves are tall ( $\geq 75 \mu V$ ) and wide ( $\geq 0.5$  seconds). These are *delta waves*, for which reason *N3* may be referred to as *delta sleep*.

After about 90 minutes of non-REM sleep, the first episode of REM sleep occurs, and then the first cycle of sleep is completed.<sup>21</sup> Several sleep cycles occur each night. In a total dark time of 8 hours and a total sleep time of 7.5 hours (sleep efficiency of 94%), there are five cycles, in which non-REM sleep accounts for about 6 hours and REM sleep for 1.5 hours of total sleep time.

For sleep to be refreshing, it should be quantitatively adequate and should also progress normally along its various stages without much interruption. However, in the presence of breathing disorders, sleep becomes fragmented. Sleep fragmentation is characterized by excessive electroencephalographic arousals, awakenings, and a shift toward lighter sleep stages. Consequences of sleep fragmentation are lack of refreshing sleep, excessive daytime sleepiness, fatigue, memory lapses, and difficulty concentrating.

Various sleep-related breathing disorders exist. *Apnea* is defined as the absence of inspiratory airflow for 10 seconds

or more, recorded by a naso-oral pressure probe and a thermocouple. Apnea has three forms: central (see Figure 32-1), obstructive (Figure 32-2), and mixed. In central apnea, the absence of airflow results from the absence of activation of inspiratory pump muscles, including the diaphragm. It is therefore characterized by simultaneous absence of naso-oral airflow and of thoracoabdominal excursions (see Figure 32-1). In obstructive apnea, in contrast, the inspiratory thoracic pump muscles, such as the diaphragm, are active. The absence of airflow is a result of upper airway occlusion. This is secondary to inward collapse of the relaxed dilator muscles of the oropharynx, which cannot resist the negative intra-airway pressure during inspiration.

On polysomnograms, obstructive apnea is characterized by the absence of naso-oral airflow in spite of continual thoracoabdominal excursions (see Figure 32-2). Mixed apnea has an initial central component followed by an obstructive component.

Hypopnea is a reduction in breathing. It may be defined as reduced naso-oral airflow or thoracoabdominal excursions of 10 seconds or more in duration, resulting in either a drop in arterial oxyhemoglobin saturation of at least 4% or an electroencephalographic arousal (Figure 32-3). Like apnea, hypopnea may be either obstructive or central; however, this distinction is very difficult because these two kinds of hypopnea are frequently not reported separately.

To determine the severity of sleep-related breathing disorders, the apnea-hypopnea index (AHI) is calculated as the number of apneic and hypopneic episodes per hour of sleep. An AHI of 5 or more is considered abnormal and has been used as the criterion for polysomnographic diagnosis.<sup>24</sup> When an obstructive AHI of 5 or more is associated with excessive daytime sleepiness, the combination is referred to as *obstructive sleep apnea (hypopnea) syndrome*.

The number of electroencephalographic arousals per hour of sleep, referred to as an *arousal index*, is used as an indication of sleep fragmentation. The severity of hypoxemia during sleep is usually assessed by the lowest oxyhemoglobin saturation and the time spent below saturation of 90%.

**FIGURE 32-2** Polysomnographic example of obstructive sleep apnea in stage 2 sleep. *Top to bottom*, Two electro-oculograms (1st and 2nd tracings), chin electromyogram (3rd tracing), two electroencephalograms (4th and 5th tracings), electrocardiogram (7th tracing), naso-oral airflow measured by thermocouple (8th tracing) and by  $\text{CO}_2$  signal (9th tracing), combined rib cage and abdominal excursions (10th tracing), rib cage excursion (11th tracing), abdominal excursion (12th tracing), time in seconds (13th tracing), and esophageal pressure (14th tracing). Note absence of airflow in the presence of effort observed on rib cage, abdominal, and esophageal pressure tracings. Breathing resumes with the onset of arousal (increase in chin electromyographic and electroencephalographic alpha waves) and consequent relief of upper airway occlusion. Also note the paradoxical thoracoabdominal excursions (rib cage and abdominal tracings), which commonly occur with upper airway occlusion. These excursions can be observed visually at the bedside.

*Periodic breathing* is a pattern of breathing characterized by cyclic fluctuations in the amplitude of tidal volume.<sup>25</sup> It consists of periodically recurring cycles of apnea or hypopnea, or both, followed by hyperpnea. The apnea and hypopnea may be obstructive (i.e., resulting from upper airway occlusion) or central in nature, and both forms may occur in patients with heart failure.<sup>6,9</sup> Hunter-Cheyne-Stokes breathing (see Figure 32-1) is a form of periodic breathing that occurs primarily in systolic heart failure. In contrast to apnea and hypopnea, however, Hunter-Cheyne-Stokes breathing is a subjective description and is not readily quantifiable. For these reasons, the term *central sleep apnea* is preferable, and it also avoids misrepresentation, inasmuch as the credit for the discovery of Hunter-Cheyne-Stokes breathing has not been given to the original discoverers.

## EFFECTS OF SLEEP ON CARDIOPULMONARY SYSTEMS

In wakefulness, in comparison with sleep, the balance of autonomic nervous system reverses.<sup>26-28</sup> Normally, during non-REM sleep, as the depth of sleep increases from N1 to N3, sympathetic activity decreases progressively. During phasic REM sleep, however, surges in sympathetic activity occur. These changes in sympathetic nervous system have been best shown by the use of peroneal nerve microneurography to monitor muscle sympathetic nerve activity.<sup>29-31</sup> Intermittent

sampling of blood and of lumbar and brain ventricular cerebrospinal fluid have also revealed significant reduction in norepinephrine level during sleep, particularly in delta sleep.<sup>32,33</sup> In addition, and in contrast to a reduction in sympathetic activity, parasympathetic activity increases during sleep.<sup>27,34</sup>

As a result of such changes in autonomic nervous system activity in non-REM sleep, systemic blood pressure, heart rate, and cardiac output decrease.<sup>35-37</sup> In phasic REM sleep, however, blood pressure and pulse rate increase.<sup>29</sup> Because non-REM sleep accounts for about 80% of total sleep time in adults overall, sleep should be a restful period for the cardiovascular system.

With onset of sleep and withdrawal of the nonchemical respiratory drive of wakefulness, minute ventilation decreases and arterial partial pressure of carbon dioxide ( $\text{PCO}_2$ ) rises.<sup>37-40</sup> Furthermore, in the absence of respiratory influences of wakefulness drive, breathing during sleep is primarily under metabolic control, exhibiting extreme sensitivity to small changes in  $\text{PCO}_2$ .<sup>38-40</sup>

Sleep-induced cardiovascular and respiratory quiescence, however, could become punctuated by periodic breathing. Among the consequences of periodic breathing are arousals. Electroencephalographically, cortical arousals are characterized by return of alpha waves (see Figures 32-1 to 32-3), which are normally observed during relaxed wakefulness. Arousals are associated with transient reinstitution of wakefulness drive, increased sympathetic activity, and decreased

**FIGURE 32-3** Polysomnographic example of hypopnea occurring in rapid-eye-movement sleep. *Top to bottom*, Two electro-oculograms (1st and 2nd tracings), chin electromyogram (3rd tracing), three electroencephalogram (4th, 5th, and 6th tracings), electrocardiogram (7th tracing), naso-oral airflow measured by CO<sub>2</sub> signal (9th tracing) and by thermocouple (10th tracing), combined rib cage and abdominal excursions (11th tracing), rib cage excursion (12th tracing), and abdominal excursion (13th tracing), time in seconds (14th tracing), esophageal pressure (15th tracing), and saturation (15th tracing). Note reduction in airflow and in rib cage and abdominal excursions, all of which increase with the arousal (increase in chin electromyographic amplitude, and electroencephalographic speeding with alpha waves).

parasympathetic activity.<sup>41-43</sup> Consequently, heart rate, blood pressure, and ventilation increase, and Pco<sub>2</sub> decreases. Therefore, arousals, in addition to disrupting sleep and causing sleep fragmentation, also result in adverse cardiovascular and respiratory consequences.

## SLEEP APNEA IN SYSTOLIC HEART FAILURE

Prevalence of sleep-related breathing disorders has been studied in patients with heart failure arising from a variety of causes, although most systematically in heart failure caused by left ventricular systolic dysfunction (see also Chapter 13).

Studies of patients with stable heart failure and left ventricular systolic dysfunction have revealed that half of consecutive patients suffer from sleep apnea defined as an AHI of 15 or more per hour. Table 32-1 depicts prevalence of sleep apnea, both central and obstructive, in a few studies in which full nighttime polysomnography, or at least four respiratory channels, were used.<sup>44-51</sup>

The most detailed systematic prospective study in systolic heart failure<sup>44</sup> involved 100 ambulatory male subjects with stable, treated heart failure. Several aspects of this study must be emphasized. Of 114 consecutive patients who were eligible to take part in the study, 100 accepted. Exclusion criteria were unstable cardiovascular status and presence of comorbid disorders (e.g., chronic obstructive pulmonary

disease). Patients were recruited from a cardiology unit and a primary care clinic, and no questions regarding the risk factors for sleep apnea (e.g., snoring, witnessed apnea, waking up tired) were asked. Each patient spent 2 nights in the sleep laboratory, the first night for habituation. Polysomnography with simultaneous Holter monitoring was performed during the second night. According to an AHI of a minimum of 5 or 15 per hour as the threshold 68% and 49%, respectively, of the 100 patients had the sleep disorder. At the time of this study, 10% of the patients were taking  $\beta$ -blockers. However, widespread use of  $\beta$ -blockers has had no effect on prevalence of sleep apnea among patients with heart failure<sup>13-16,19,20</sup> (see Table 32-1). According to studies of 1250 patients from around the world, 52% have an AHI of 15 or more per hour; 31% have CSA and 21% have OSA (Figure 32-4). In most of these studies, 80% to 90% of the patients were taking a  $\beta$ -blocker.

In comparison, in a large population study of subjects aged 30 to 60 years without clinically recognized heart failure,<sup>24</sup> only 9% had an AHI of 15 or more per hour. As noted earlier, an AHI of 5 or more per hour has been used to define presence of significant number of disordered breathing events in obstructive sleep apnea (hypopnea) syndrome.<sup>24</sup> Therefore, because sleep apnea (see Table 32-1) is much more prevalent among patients with heart failure than in the general population, systolic heart failure is a leading risk factor for sleep apnea.

**TABLE 32-1 Worldwide Prevalence of Sleep Apnea in Systolic Heart Failure**

Country (Year)	No. of Subjects	% of Patients with AHI $\geq 15$ / Hour	% of Patients Taking $\beta$ -Blockers
United States (2006) <sup>44</sup>	100	49	10
United States* (2008) <sup>50</sup>	108	61	82
Canada (2007) <sup>45</sup>	287	47	80
United Kingdom (2007) <sup>46</sup>	55	53	78
Germany* (2007) <sup>49</sup>	700	52	85

\*Electroencephalography was not recorded.

**FIGURE 32-4** Prevalence of sleep apnea in systolic heart failure (SHF). The data represent a series of world sleep studies (referenced in Table 13-2). AHI, apnea-hypopnea index; CSA, central sleep apnea; OSA, obstructive sleep apnea. (Adapted from Javaheri S. Cardiovascular disorders. In Kryger MH, editor. *Atlas of clinical sleep medicine*, Philadelphia, 2010, Elsevier.)

### Phenotype of Heart Failure Patients with Obstructive and Central Sleep Apnea

As noted earlier, both forms of sleep apnea, central and obstructive, commonly occur in the same patient. Depending on the predominant form of sleep apnea, the phenotype of patients varies, and if these specific characteristics are recognized, they should help the clinician to suspect the presence of either OSA or CSA (Figures 32-5 and 32-6).

Obesity and habitual snoring are important risk factors for OSA in patients with heart failure<sup>10,12,44</sup> (see Figure 32-5), as they are in the general population.<sup>24</sup> However, there is no significant difference in subjective excessive daytime sleepiness between patients with heart failure who do and those who do not have either OSA and CSA (see Figure 32-5).<sup>10,44</sup> We believe that this is related partly to the overlapping nocturnal and diurnal symptoms of chronic heart failure with sleep apnea.

Because patients with heart failure and sleep apnea do not report subjective excessive daytime sleepiness, clinical suspicion for its presence remains low. This is particularly the case for patients with heart failure and CSA because such patients are commonly not obese and do not snore much and CSA remains occult.<sup>8</sup> However, the presence of some important risk factors should increase suspicion for CSA: atrial fibrillation, high New York Heart Association class, very low left ventricular ejection fraction, frequent nocturnal arrhythmias, and low arterial  $PCO_2$  (see Figure 32-6).<sup>44</sup> There are also some important gender issues, which are addressed in the following section.

**FIGURE 32-5** Demographics, historical data, and physical examination findings in patients who had heart failure without sleep apnea, with central sleep apnea (CSA), and with obstructive sleep apnea (OSA). Patients with obstructive sleep apnea were heavier and had a higher prevalence of habitual snoring than did patients with CSA. There was no difference in prevalence of excessive daytime sleepiness (EDS) between the patients with sleep apnea and the patients without sleep apnea. BMI, body mass index; Ht, height. (Modified from Javaheri S. Sleep disorders in systolic heart failure: A prospective study of 100 male patients. The final report. *Int J Cardiol* 2006;106:21-28; adapted from Javaheri S. Cardiovascular disorders. In Kryger MH, editor. *Atlas of clinical sleep medicine*, Philadelphia, 2010, Elsevier.)

**FIGURE 32-6** Clinical and laboratory characteristics that are more likely to be associated with central sleep apnea. A.fib, Atrial fibrillation; CPLT, couplets; LVEF, left ventricular ejection fraction; NSR, normal sinus rhythm; NYHAC, New York Heart Association Class; PVC, premature ventricular contractions; VT, ventricular tachycardia. (Modified from Javaheri S. Sleep disorders in systolic heart failure: A prospective study of 100 male patients. The final report. *Int J Cardiol* 2006;106:21-28; adapted from Javaheri S. Cardiovascular disorders. In Kryger MH, editor. *Atlas of clinical sleep medicine*, Philadelphia, 2010, Elsevier.)

### Gender and Sleep Apnea in Systolic Heart Failure

In general population, the prevalence of OSA is significantly higher among men than among women.<sup>24</sup> This is probably the case in heart failure as well and for CSA in particular. According to the results of several studies in systolic heart failure,<sup>11-15</sup> 40% of the male subjects have CSA, which is significantly higher than the 18% prevalence of CSA among female subjects (Figure 32-7).

The reasons for a low prevalence of OSA and CSA in women are not well understood, but female hormones may play an important role. The results of population studies of subjects without heart failure<sup>52,53</sup> suggest that menopause may be a risk factor for OSA and that the risk is probably

**FIGURE 32-7** Prevalence of obstructive sleep apnea (OSA) and central sleep apnea (CSA) in men and women with systolic heart failure. The prevalence of CSA is much lower among women than among men. A similar trend is found in OSA, although it is not statistically significant. (Data from Allen E, Turk JL, Murley R, editors. *The case books of John Hunter FRS*, New York, 1993, Parthenon, pp 29-30; and from Javaheri S, Shukla R, Zeigler H, Wexler L: Central sleep apnea, right ventricular dysfunction, and low diastolic blood pressure are predictors of mortality in systolic heart failure. *J Am Coll Cardiol*, 49:2028-2034, 2007.)

reduced by hormone replacement therapy.<sup>53</sup> In women with systolic heart failure, risk for CSA was six times higher in those aged 60 years or older than in those younger than 60 years.<sup>12</sup> A similar difference exists for OSA before and after age 60 years.<sup>12</sup>

Progesterone is a known respiratory stimulant, and its various effects on respiratory system may in part explain the lower prevalence of CSA and OSA among menstruating women. Progesterone increases ventilation<sup>54</sup> and the tone of the dilator muscles of the upper airway.<sup>55</sup> Furthermore, premenopausal women have a significantly lower apneic threshold—the level of  $P_{CO_2}$  below which rhythmic breathing ceases—than do men,<sup>56</sup> which should decrease the probability that a woman would develop apnea during sleep (see “Mechanisms of Sleep Apnea in Heart Failure” section).

However, large prospective studies of women with heart failure are needed in order to elucidate the independent effects of various factors, such as age and menopause, on CSA and OSA. A similar view has been expressed for studies of women without heart failure.<sup>57</sup>

## SLEEP APNEA IN ISOLATED DIASTOLIC HEART FAILURE

Depending on age, a considerable number of patients with symptoms of congestive heart failure may suffer from isolated diastolic heart failure with preserved left ventricular ejection fraction (see Chapter 14).

Little is known about prevalence of sleep-related breathing disorders and their effect on isolated diastolic heart failure. Both sleep apnea and diastolic heart failure are prevalent in older populations and the consequences of sleep apnea (such as sympathetic activation, nocturnal and diurnal hypertension, and hypoxemia<sup>58</sup>) impair left ventricular diastolic function and eventually result in remodeling of cardiac chamber. In this regard, the largest study,<sup>59</sup> consisting of 2058 participants in the Sleep Heart Health Study revealed—after accounting for age, gender, ethnicity, smoking, alcohol consumption, body mass index, systolic blood pressure, antihypertensive medication use, diabetes, and prevalent myocardial infarction—that apnea, hypopnea, and hypoxemia indices were

independent predictors of left ventricular mass. In another study<sup>60</sup> of 66 consecutive patients with OSA who underwent pulse-wave Doppler echocardiography of the transmitral valve, an abnormal relaxation pattern was present in 38% (25 patients). In multivariate analysis, saturation of less than 70% during sleep was an independent predictor of abnormal relaxation pattern (odds ratio = 4, 95% confidence interval [CI] = 1.2 to 15.3,  $P = .02$ , irrespective of age and hypertension status). Meanwhile, effective treatment of OSA has been shown to improve left ventricular function and structure (reverse remodeling).<sup>61,62</sup> In one randomized, double-blind trial of 12 weeks' duration, the placebo condition (sham continuous positive airway pressure [CPAP]) was compared with the use of a CPAP device with minimal pressure; effective CPAP therapy resulted in a significant increase in early/late (E/A) ratio and a significant decrease in isovolumic relaxation and mitral deceleration time.<sup>62</sup> In summary, OSA could be a cause of diastolic dysfunction or contribute to its progression.

## MECHANISMS OF SLEEP APNEA IN HEART FAILURE

### Central Sleep Apnea

The mechanisms of periodic breathing and CSA in heart failure are complex and multifactorial. Numerous articles on theoretical and experimental aspects of periodic breathing have been published<sup>63-68</sup> and reviewed elsewhere.<sup>69</sup> In heart failure, various components of the negative feedback system that controls breathing undergo alterations that increase the likelihood that periodic breathing will develop. In addition, specific sleep-related mechanisms underlie augmentation of periodic breathing and the genesis of central apnea during sleep.

#### Negative Feedback Control System and Periodic Breathing

Negative feedback systems are involved in homeostatic control of a number of physiological variables such as blood pressure, temperature, and arterial blood  $P_{CO_2}$ , arterial partial pressure of oxygen ( $P_{O_2}$ ), and arterial hydrogen ion concentration [ $H^+$ ].

In respiratory system, the rate of breathing and tidal volume are normally regulated so that arterial blood gases are precisely controlled. For example, when a breathing disturbance, such as a short pause in breathing, occurs, the  $P_{CO_2}$  increases and the  $P_{O_2}$  decreases, and ventilation normally increases appropriately to minimize the effects of the disturbance. However, in the presence of certain conditions such as systolic heart failure, ventilatory overshoot may occur, resulting in ventilatory instability.

The three major components of the negative feedback system involved in homeostatic control of breathing are (1) the chemoreceptors (the controller), (2) the lungs (the plant), and (3) the communication channels between the chemoreceptors and the lungs (the circulating arterial blood from the lungs to the chemoreceptors, and the nerves from the brain to the respiratory muscles).

In systolic heart failure, the structure and function of the various components of this negative feedback system become altered in a way that favors instability in control of breathing, which results in periodic breathing. These alterations include increased arterial circulation time (which delays the transfer of information regarding changes in  $P_{O_2}$  and  $P_{CO_2}$  from pulmonary capillary blood to the chemoreceptors), enhanced gain of the chemoreceptors (enhanced  $CO_2/O_2$  chemosensitivity, the high responders), and enhanced plant gain (decreased functional residual capacity); collectively, these alterations result in increased loop gain and increase the likelihood of periodic breathing in systolic heart failure.<sup>59-68</sup> Because

these alterations are not state (sleep or wake)–specific, periodic breathing may occur both during wakefulness and sleep (although most frequently during sleep).

In systolic heart failure, arterial circulation time is lengthened as a result of increased blood volume in the pulmonary venous system and the left heart chambers; this lengthening is augmented by a low stroke volume.

A breathing pause results in hypoxemia and hypercapnia in pulmonary capillary blood. With a normal circulation time, these reactions are quickly aborted. In the presence of prolonged circulation time, however, it takes a long time for the chemoreceptors to detect the onset of the breathing pause–induced hypoxemia and hypercapnia; consequently, the pause persists without any compensatory ventilatory effort to abort the reactions. In addition, because the pause is prolonged, the chemoreceptors continue to be stimulated by the abnormal blood gas tensions for some time before they receive any feedback information regarding compensatory changes in  $P_{O_2}$  and  $P_{CO_2}$  in the pulmonary capillary blood. Prolonged circulation time, therefore, converts a negative feedback system to a positive one.

The second factor that increases the likelihood that periodic breathing and central apnea will occur is the increased gain of the chemoreceptors.<sup>68</sup> In patients with heart failure who have increased sensitivity to changes in carbon dioxide (or  $P_{O_2}$ ), the chemoreceptors elicit a large ventilatory response whenever the  $P_{CO_2}$  rises (or  $P_{O_2}$  decreases). The consequent intense hyperventilation, by driving the  $P_{CO_2}$  below the apneic threshold, results in central apnea. As a result of central apnea,  $P_{CO_2}$  rises, and the cycles of hyperventilation and hypoventilation persist.<sup>68</sup>

The third factor that may contribute to the development of periodic breathing in heart failure is decreased functional residual capacity, which causes underdamping. For a given change in ventilation (e.g., a 10-second cessation of breathing), underdamping results in augmented changes in the controlled variables—that is,  $P_{O_2}$  and  $P_{CO_2}$ —which in turn elicit pronounced compensatory ventilatory responses. Overcompensation tends to destabilize breathing. In systolic heart failure, functional residual capacity decreases because of pulmonary congestion or edema, pleural effusion, and reduced compliance of the respiratory system.

#### Specific Sleep Mechanisms and Genesis of Central Sleep Apnea

**The Concept of Apneic Threshold.** The mechanisms involved in the genesis of CSA relate specifically to the state of sleep and removal of nonchemical drive of wakefulness on breathing. As a result, sleep unmasks the apneic threshold and, in addition, breathing becomes extremely  $P_{CO_2}$ -sensitive.<sup>69-71</sup>

As mentioned previously, apneic threshold is defined as the level of  $P_{CO_2}$  below which rhythmic breathing ceases. The difference between two  $P_{CO_2}$  setpoints—the prevailing  $P_{CO_2}$  minus the  $P_{CO_2}$  at the apneic threshold—is a critical factor for occurrence of central apnea. The smaller this difference is, the greater is the likelihood that apnea will occur,<sup>69-71</sup> because it takes only a small rise in ventilation to lower the prevailing  $P_{CO_2}$  toward and below the apneic threshold.

Normally, with onset of sleep, ventilation decreases and  $P_{CO_2}$  increases. As long as the prevailing  $P_{CO_2}$  is above the apneic threshold, rhythmic breathing continues. However, in some patients with heart failure, prevailing  $P_{CO_2}$  does not rise at sleep onset, and CSA occurs because of the proximity of the prevailing  $P_{CO_2}$  to the apneic threshold.<sup>71,72</sup> This could happen because of the lack of normally observed decrease in ventilation at sleep onset; then pulmonary capillary pressure rises, possibly as a result of increased venous return in the supine position. The stiffer the left ventricle is, the higher is the increase in pulmonary capillary pressure. The latter results in increases in respiratory rate and ventilation, which prevent the normally observed rise in  $P_{CO_2}$  at sleep onset.

In summary, during sleep, the unmasking of the apneic threshold, the proximity of the apneic threshold to the prevailing  $P_{CO_2}$ , and the extreme sensitivity of breathing to small changes in  $P_{CO_2}$  are critical for the occurrence of CSA.

### Obstructive Sleep Apnea

Another profound effect of sleep on breathing relates to the neuromuscular control of upper airway dilator muscles.<sup>73</sup> During wakefulness, these muscles receive adequate stimulation; for example, the genioglossus muscle maintains upper airway patency in the presence of negative inspiratory airway pressure generated by contraction of the diaphragm. However, during sleep, these dilator muscles relax. Consequently, subjects with a narrow upper airway become particularly prone to develop complete occlusion (OSA) or narrowing (obstructive sleep hypopnea) of the airway. The mechanisms underlying OSA and obstructive hypopnea during sleep therefore relate to the neuromuscular control of the upper airway muscles and altered upper airway anatomy. These mechanisms are the same in patients who have OSA without heart failure.

Obesity, which causes narrowing of the upper airway, in part as a result of fat deposition in the throat, is a major risk factor for OSA in general population<sup>24</sup> and in patients with heart failure.<sup>10,12,44</sup> The author and colleagues<sup>8,10,44</sup> conducted studies in which polysomnograms were scored blindly and independently of demographics of the patients with systolic heart failure; obesity was found to be the important risk factor for OSA (see Figure 32-6). Snoring, another manifestation of upper airway narrowing, is also very common among such patients (see Figure 32-6).

**Sleep Apnea in Isolated Diastolic Heart Failure.** Both CSA and OSA have been observed in patients with diastolic heart failure,<sup>74</sup> although the latter is the most prevalent form of sleep apnea. The pathophysiological processes in diastolic heart failure are related to a stiff, noncompliant left ventricle that cannot fill adequately at normal diastolic pressure. As left ventricular end-diastolic pressure increases, symptoms of pulmonary congestion and edema develop. Pulmonary congestion is associated with narrowing of the  $P_{CO_2}$  reserve (the difference between the prevailing  $P_{CO_2}$  and the  $P_{CO_2}$  at the apneic threshold), which increases the likelihood that sleep apnea will develop.<sup>75</sup> Meanwhile, OSA is common in obesity, systemic hypertension, and aging, which are conditions also associated with left ventricular dysfunction.

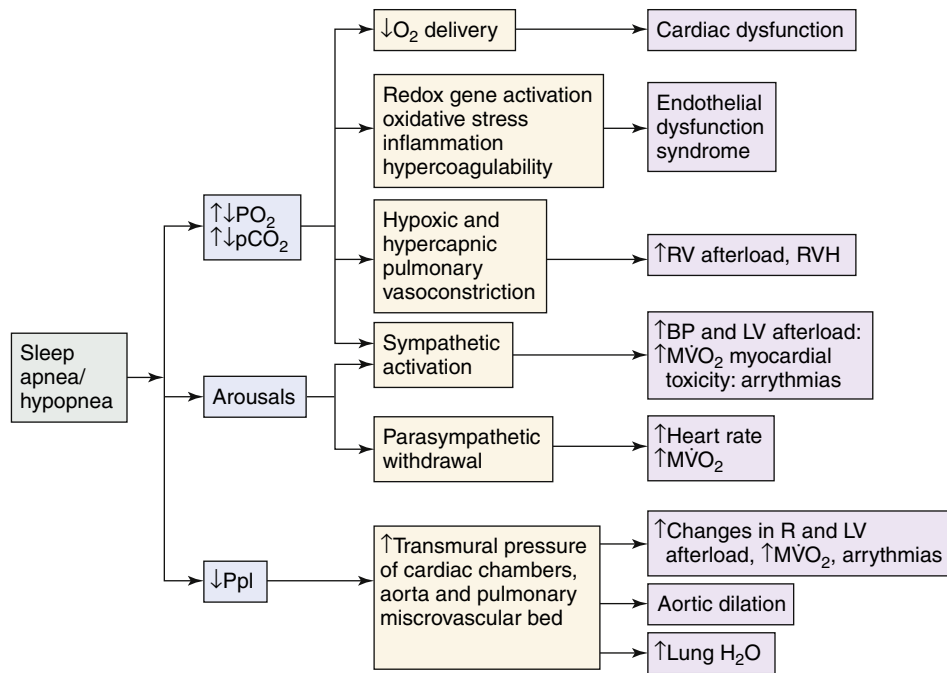

### PATHOLOGICAL CONSEQUENCES OF SLEEP APNEA IN HEART FAILURE

There are three immediate adverse consequences of sleep apnea (see Figures 32-1 and 32-2): (1) arterial blood gas abnormalities, (2) arousals, and (3) large negative swings in intrathoracic pressure. These conditions adversely affect various cardiovascular functions and structure<sup>76-81</sup> (Figure 32-8) and are most detrimental in the presence of established left ventricular systolic and diastolic dysfunction and coronary artery disease.

#### Arterial Blood Gas Abnormalities and Their Consequences

Periodic breathing is characterized by episodes of apnea and hypopnea, which cause hypoxemia and hypercapnia, and episodes of hyperpnea, which results in reoxygenation and hypocapnia.

Hypoxemia may decrease myocardial oxygen delivery, increase sympathetic nervous system activity, and causes pulmonary arteriolar vasoconstriction. In addition, hypoxia and reoxygenation promote endothelial cell dysfunction.

**FIGURE 32-8** The consequences of recurrent sleep apnea and hypopnea include hypoxemia and reoxygenation in association with hypercapnia and hypocapnia, respectively, during apnea, followed by hyperpnea. The other consequences are arousals and negative swings in intrathoracic pressure. These consequences, in conjunction, could eventually result in significant cardiovascular dysfunction. Hypoxemia may result in diminished oxygen delivery to the myocardium, which in turn could result in arrhythmias and systolic and diastolic dysfunction. Hypoxemia and reoxygenation could result in activation of redox-sensitive genes, oxidative stress inflammation, and hypercoagulability, leading to endothelial dysfunction syndrome. Both alveolar hypoxia and hypercapnia (as a result of sleep apnea or hypopnea) result in hypoxic and hypercapnic pulmonary vasoconstriction that increases right ventricular (RV) afterload and its myocardial oxygen consumption. This eventually could result in right ventricular hypertrophy (RVH) and cor pulmonale. Hypoxemia and hypercapnia, along with arousals, could also lead to sympathetic activation that would increase blood pressure (BP). This would result in increased left ventricular (LV) afterload, increased myocardial oxygen consumption (MVO<sub>2</sub>), and arrhythmias. In addition, this increase in sympathetic activation and release of myocardial norepinephrine could result in myocardial toxicity and apoptosis. Arousals also result in parasympathetic withdrawal, which increases the heart rate and myocardial oxygen consumption. Negative swings in intrathoracic pressure increase the transmural pressure of the left and right ventricles, both of which increase the wall tension of the ventricles, leading to an increase in myocardial oxygen consumption. In addition, increasing the transmural pressure also affects the aorta and predisposes to aortic dilation and potentially dissection. Furthermore, increased pleural pressure of the atria predisposes to development of atrial fibrillation. Finally, negative interstitial pressure increases transcapillary fluid flow, facilitating the development of pulmonary edema. Overall, therefore, the consequences of sleep apnea and hypopnea in conjunction could result in cardiovascular dysfunction. Ppl, pleural (intrathoracic) pressure. (Adapted from Javaheri S. Cardiovascular disorders. In Kryger MH, editor. *Atlas of clinical sleep medicine*, Philadelphia, 2010, Elsevier.)

### Direct Effects of Hypoxia on Myocardium

Decreased myocardial oxygen delivery may result in an imbalance between myocardial oxygen consumption and demand and hence in myocardial hypoxia, particularly if coronary artery disease is already present. Potential clinical consequences include nocturnal angina, myocardial infarction, arrhythmias, and sudden cardiac death during sleep. Hypoxia may also impair myocardial contractility<sup>82-86</sup> and diastolic function.<sup>58</sup>

### Hypoxia and Reoxygenation, Reactive Oxygen Species, Oxidative Stress, Inflammation, and Endothelial Dysfunction

A number of human and animal studies, coupled with laboratory studies of cell culture, have demonstrated the pivotal role of hypoxia-reoxygenation, which, through production of reactive oxygen species, results in oxidative stress, diminished availability of nitric oxide, and increased expression of number of redox-sensitive genes; this last result occurs through activation of certain transcription factors such as hypoxia-inducible factor-1 $\alpha$  (HIF-1 $\alpha$ ) and nuclear factor  $\kappa$ B (NF  $\kappa$ B).<sup>80,87-92</sup> HIF-1 $\alpha$  encodes production of endothelin-1 (the most potent vasoconstrictor with proinflammatory properties), vascular endothelial growth factor, and platelet-derived growth factor. Activation of NF  $\kappa$ B which plays a pivotal role in production of inflammatory cytokines (such as tumor necrosis factor  $\alpha$  and interleukin-6), enhancing expression of adhesion molecules, promoting leukocyte rolling, and

endothelial adherence,<sup>93-95</sup> all of which lead to atherosclerosis.<sup>96</sup> Hypoxia and reoxygenation impairs endothelial function and induces endothelial and myocyte apoptosis.<sup>97-100</sup>

### Hypoxia and Pulmonary Arteriolar Vasoconstriction

Alveolar hypoxia (partly through release of endothelin<sup>101</sup>) and hypercapnia cause pulmonary arteriolar vasoconstriction and hypertension, which could adversely affect right ventricular function. In particular, OSA is a known cause of pulmonary hypertension<sup>102</sup> and cor pulmonale (pickwickian syndrome).

### Hypocapnia

Episodes of hyperpnea after apnea and hypopnea result in hypocapnia. Hypocapnia (arterial Pco<sub>2</sub>  $\leq$  35 mm Hg) may impair myocardial oxygen delivery and uptake by causing coronary artery vasoconstriction<sup>103</sup> and shifting the oxygen-hemoglobin dissociation curve to the left. Hypocapnia may also be a cause of arrhythmias. Among hypocapnic subjects with systolic heart failure, the prevalence of CSA and arrhythmias is high.<sup>104</sup>

### Arousals

Disordered breathing events are frequently followed by arousals, which are associated with increased sympathetic activity and decreased parasympathetic activity.<sup>41-43</sup> Consequently, there is a transient rise in blood pressure and heart rate with associated adverse cardiovascular consequences.

**FIGURE 32-9** Transmural (Tm) pressure (Pr) of left ventricle (LV) during systole. As a result of obstructive apnea caused by upper airway occlusion (UAO), a negative pleural pressure (Ppl) of -40 mm Hg is generated. This increases left ventricular transmural pressure from 100 to 140 mm Hg, which is equivalent to an increase in systolic aortic blood pressure from 100 to 140 mm Hg. Note the reduction in left ventricular transmural pressure with application of nasal continuous positive airway pressure (CPAP).

In addition, arousals result in sleep fragmentation, lack of refreshing sleep, daytime fatigue, lack of concentration, and sleepiness.

### Exaggerated Negative Intrathoracic Pressure and Its Consequences

Negative intrathoracic pressures as high as 60 to 80 cm H<sub>2</sub>O may be generated during episodes of obstructive apnea. After central apnea, hyperpnea occurs, and relatively large negative pressure deflections, particularly in the presence of stiff lungs and chest wall, may also be observed. However, pleural pressure changes are generally more pronounced in OSA than in CSA (see **Figures 32-1 and 32-2**). The increased negative pressure increases the transmural pressure (pressure inside minus pressure outside) of the intrathoracic vascular structures, including the aorta, pulmonary vascular bed, atria, and ventricles (**Figure 32-9**).

Numerous studies have addressed the cardiovascular consequences of both negative and positive pressure deflections affecting right and left ventricular function.<sup>105-108</sup> According to the Laplace law, increased transmural myocardial pressure increases wall tension and myocardial oxygen consumption. Atria, because they are more compliant than ventricles, are subject to stretch, which could result in atrial arrhythmias, such as atrial fibrillation observed with sleep apnea. Negative intrathoracic pressure surrounding intrathoracic aorta could contribute to aortic dilation. Negative intrathoracic pressure is also reflected in the perivascular space, decreasing the perivascular pressure. This increases extravascular lung water by favoring fluid transudation across pulmonary microvascular bed and by diminishing lymph outflow from the lungs.<sup>109</sup> Sleep apnea may therefore contribute to excess lung water and pulmonary edema in congestive heart failure (see **Figure 32-5**).

### SLEEP APNEA AUGMENTS THE HYPERADRENERGIC STATE OF HEART FAILURE

During normal sleep, in comparison with wakefulness, the balance of activity of the sympathetic and parasympathetic nervous systems reverses. However, CSA and OSA increase sympathetic activity, as measured by microneurography blood and urinary norepinephrine levels.<sup>110-116</sup> Effective treatment of OSA and CSA with positive airway pressure devices decreases sympathetic activity.<sup>112,114-117</sup> Similarly, treatment of CSA with nasal oxygen decreases sympathetic activity, as measured by urinary norepinephrine level.<sup>118</sup> These findings have important implications because in heart failure, increased sympathetic activity is associated with poor survival rate.

Sleep apnea causes sympathetic activity to increase for several reasons. These include hypoxemia and hypercapnia, arousals, and apnea itself.

In heart failure with left ventricular systolic dysfunction, sympathetic activity is increased as a result of blunting of baroreceptor activity. Blood gas abnormalities associated with sleep apnea augment sympathetic activity through stimulation of chemosensitive carotid bodies,<sup>119-121</sup> which are upregulated in heart failure. In contrast to the inhibitory function of the baroreceptors, increased carotid body activity augments sympathetic outflow by the central nervous system.

Lack of lung inflation (apnea) and arousals are also associated with increased central sympathetic outflow and, along with altered blood gases, collectively contribute and augment the hyperadrenergic state of heart failure.

Sympathetic activation has multiple adverse cardiac consequences, particularly in the setting of left ventricular dysfunction and coronary artery disease. These include increased systemic vascular resistance and left ventricular afterload, venoconstriction with increased right ventricular load, increased myocardial contractility, tachycardia, and arrhythmias (see also Chapter 10). Furthermore, increased myocardial norepinephrine levels cause myocyte toxicity through calcium overload mediated by cyclic adenosine monophosphate<sup>122</sup> and myocyte apoptosis mediated by protein kinase A.<sup>123</sup> These two toxic effects of norepinephrine are prevented by  $\beta$ -adrenergic blockade.<sup>122,123</sup>

$\beta$ -Blockers have been used successfully to minimize long-term sympathetic activation in systolic heart failure. The improvement by  $\beta$ -blockers in survival among patients with heart failure may result in part from counterbalancing the sympathetic activity caused by sleep-related breathing disorders. Furthermore, by improving cardiac function,  $\beta$ -blockers may further improve sleep-related breathing disorders; however, any residual breathing disorders result in failure of maximal sympathetic deactivation, particularly during sleep.

In summary, pathophysiological consequences of sleep apnea in heart failure result in a hyperadrenergic state superimposed on an already overactive sympathetic nervous system. Sleep apnea is also associated with oxidative stress, increased levels of inflammatory cytokines, and endothelial dysfunction. The interaction between sleep apnea and heart failure could result in a vicious cycle, increasing mortality among patients with heart failure, which is discussed next.

### PROGNOSTIC SIGNIFICANCE OF SLEEP APNEA IN HEART FAILURE

Systolic heart failure is a complex disorder in which multiple pathophysiological processes are involved in and contribute to its progression. In the contemporary management of systolic heart failure, the identification and treatment

of neurohormones and the use of angiotensin-converting enzyme inhibitors and  $\beta$ -blockers have improved patients' quality of life and survival. In spite of the many therapeutic triumphs, however, heart failure remains a major public health problem with considerable morbidity and mortality. Of utmost importance are the identification and treatment of residual comorbid factors that contribute to the progression of heart failure. One comorbid condition is sleep apnea; results of studies, reviewed in the following discussion, strongly suggest that both OSA and CSA are associated with excess mortality in patients with heart failure and that effective treatment improves survival.

Many observational studies of subjects who have OSA with or without known heart disease strongly suggest that this disorder is associated with increased mortality. In studies of OSA without known heart failure,<sup>124-143</sup> the most systematic is the Wisconsin Sleep Cohort population study,<sup>130</sup> in which 1522 subjects (not patients or individuals referred to a sleep laboratory) were monitored for up to 18 years. Severe OSA (defined as AHI  $\geq 30$  per hour of sleep) was associated with increased risk of all-cause mortality independently of age, gender, body mass index, and other potential confounders ( $P < .0008$ ). After excluding the 120 persons who reported using CPAP, the researchers found that the hazard ratios were 3.8 (95% CI = 1.6 to 9.0) for all-cause mortality and 5.2 (95% CI = 1.4 to 19.2) for cardiovascular mortality. Similarly, in the Busselton Health Study,<sup>131</sup> the adjusted hazard ratio for all cause mortality was 6.2 (95% CI = 2 to 19) in moderate to severe OSA.

Yaggi and associates<sup>137</sup> monitored 1022 patients for a median of about 3 years. Subjects were referred for evaluation of OSA. They were aged 50 years or older (mean = 61 years), and 68% had an AHI of 5 or more per hour (mean = 35). After adjustment for age, gender, smoking, body mass index, and a number of cardiovascular risk factors (hypertension, diabetes, and hyperlipidemia), OSA was associated with a significantly increased risk for a composite endpoint of death and stroke (hazard ratio = 1.97, 95% CI = 1.12 to 3.38,  $P = .01$ ). In patients with severe OSA (AHI  $\geq 36$ /hour), the hazard ratio was increased to 3.3 for the composite endpoint. Similar results were reported in a study from Israel<sup>135</sup>; according to a Cox proportional analysis in which only AHI and body mass index were used, severe sleep apnea (AHI  $> 30$ /hour) was associated with a significantly increased risk for all-cause mortality (hazard ratio = 2.13, 95% CI = 1.36 to 2.34).

The prospective Sleep Heart Health Study,<sup>139</sup> in which 6441 men and women were monitored for an average of 8.2 years, revealed that severe OSA was associated with a statistically significant increased risk of death primarily in men aged 40 to 70 years (adjusted hazard ratio = 2.1, 95% CI = 1.3 to 3.30). It should be emphasized that in this cohort, 52% had hypertension and 18% had another cardiovascular disease at the time of baseline measurement. Marin and associates<sup>136</sup> monitored 1651 Spanish patients (mean follow-up period, 10.1 years) and reported that severe OSA (AHI  $\geq 30$ /hour) was associated with a statistically significant increased risk of cardiovascular death (odds ratio = 2.87, 95% CI = 1.17 to 7.51). Meanwhile, the circadian pattern of death differs between patients with OSA and those without OSA: OSA patients die mostly at night.<sup>139</sup>

The studies just described were all correlational. However, the notion that OSA is a cause of mortality is supported by several observational studies in which researchers reported improved survival in CPAP-adherent patients with OSA, in comparison with those who were nonadherent.<sup>136,138,142</sup> In Marin and associates' study,<sup>136</sup> the odds ratio of cardiovascular mortality for severe OSA in CPAP-treated patients was 1.05 (95% CI = 0.39 to 2.21), in comparison with 2.87 in patients with similarly severe but untreated OSA. In Campos-Rodriguez and colleagues' study,<sup>143</sup> the 5-year cumulative

survival rates were significantly lower (85.5%) in patients who did not use CPAP (adherence  $< 1$  hour) than in those who were adherent ( $> 6$  hours; 96.4%). Another study, from Germany,<sup>138</sup> revealed that treatment of mild to moderate OSA with CPAP was associated with a cardiovascular risk reduction of 64%.

With regard to heart failure, several studies<sup>18,45,144-156</sup> focused on mortality associated with sleep apnea, both OSA and CSA. With regard to OSA,<sup>45,144</sup> a prospective study<sup>45</sup> revealed that the death rate among 37 patients who had untreated heart failure with OSA was significantly higher than among the 113 patients without (or with mild) OSA. The death rate was significant after confounding factors were controlled. Furthermore, the authors reported no deaths among the 14 patients with heart failure and OSA who were treated with CPAP devices. However, the number of subjects was small, and this difference was significant at  $P = .07$ . In a larger study in Japan<sup>144</sup> of 65 patients with moderate to severe OSA, use of a CPAP device was associated with significant reduction in the rate of hospitalization and mortality in comparison with 23 untreated OSA patients with systolic heart failure. The rate of survival was improved only in CPAP-adherent patients (Figure 32-10). The finding in patients with OSA and heart failure that CPAP adherence improves survival is similar to that in patients with OSA but without heart failure cited earlier (see "Obstructive Sleep Apnea" section under "Mechanisms of Sleep Apnea in Heart Failure" section). A similar observation was reported in patients with systemic hypertension; improvement was noted primarily in those who were CPAP adherent<sup>157</sup> (for reviews, see Becker and Javaheri<sup>158</sup>).

Multiple investigators have studied CSA and mortality; most<sup>145-154</sup> showed that CSA is associated with excess mortality among patients with systolic heart failure. Two studies<sup>156,157</sup> yielded different results; one<sup>156</sup> revealed a tendency for excess mortality among patients with heart failure and CSA, but this finding was not significant, probably because

**FIGURE 32-10** Probability of hospitalization and mortality in patients with heart failure and obstructive sleep apnea. This probability decreases if patients are treated with continuous positive airway pressure (CPAP) and adhere to therapy. AHI, apnea-hypopnea index; HR, hazard ratio; LVEF, left ventricular ejection fraction. (Modified from Oldenburg O, Lamp B, Faber L, et al. Sleep-disordered breathing in patients with symptomatic heart failure: a contemporary study of prevalence in and characteristics of 700 patients. *Eur J Heart Fail* 2007;9:251; and from Javaheri S. Cardiovascular disorders. In Kryger MH, editor. *Atlas of clinical sleep medicine*, Philadelphia, 2010, Elsevier.)

of the small number of patients. In addition, patients with heart failure who exhibited periodic breathing while awake suffered excess mortality.

The author and colleagues<sup>153</sup> monitored 88 patients with heart failure, of whom 56 had CSA (mean AHI = 35/hour) and 32 did not (mean AHI = 2/hour). The median follow-up time was 51 months. After controlling for 24 confounding variables, the investigators found that CSA was associated with excess mortality (hazard ratio = 2.14,  $P = .02$ ). The average length of survival among patients who had heart failure but not CSA was 90 months, in comparison with 45 months among those with CSA (Figure 32-11). The hypothesis that CSA contributes to excess mortality among patients with systolic heart failure is supported by the observation that effective treatment of CSA with CPAP devices improves survival.<sup>152</sup>

## INDICATIONS FOR POLYSOMNOGRAPHY IN HEART FAILURE

The following sections discuss a number of clinical and laboratory findings that, when present in patients with heart failure, should increase clinical suspicion for sleep apnea and prompt the physician to perform a diagnostic sleep study.

### Risk Factors for Obstructive Sleep Apnea

Indications to perform a sleep study for evaluation of OSA in patients without heart failure are equally applicable to patients with heart failure. The protean manifestations and risk factors of OSA in general population include obesity, habitual snoring, witnessed apnea, waking up unrested, excessive daytime sleepiness, and hypertension. However, subjective excessive daytime sleepiness may be absent in patients with heart failure and OSA (see Figure 32-5).

### Nocturnal Angina

Both in general population and in patients with heart failure, with or without known coronary artery disease, nocturnal angina should increase suspicion of sleep apnea.

### Paroxysmal Nocturnal Dyspnea

This symptom may actually be perception of shortness of breath that occurs during the hyperpneic phase of periodic breathing.

### Restless Sleep

This complaint may reflect periodic arousals and movements following episodes of apnea and hypopnea.

### Low Arterial Partial Pressure of Carbon Dioxide

Several studies<sup>10,13,44,159,160</sup> have shown that among patients with heart failure and low arterial  $P_{CO_2}$ , the prevalence of CSA is high. The predictive value of low  $P_{CO_2}$  ( $\leq 35$  mm Hg) is about 80%.<sup>103</sup> However, many patients with heart failure have CSA without daytime hypocapnia.<sup>161</sup>

### Atrioventricular Arrhythmias

Several studies have shown that among patients with heart failure and sleep apnea, the prevalence of atrial fibrillation<sup>10,12,44,162</sup> and ventricular arrhythmias<sup>10,33,163,164</sup> is higher. Presence of these arrhythmias should increase suspicion of the presence of CSA.

### Progressive Left Ventricular Systolic or Diastolic Dysfunction

Patients with heart failure and progressive ventricular dysfunction or those whose status remains New York Heart Association class III or IV in spite of intensive medical therapy should undergo a diagnostic sleep study.

### Pacemaker and Cardioverter Defibrillator

In a European multicenter study<sup>165</sup> of a large number of patients who had received a pacemaker (for sinus node dysfunction, atrioventricular block, or congestive heart failure), 50% were found to have sleep apnea. The results of this study confirmed those of an earlier study<sup>19</sup> showing that 40% of patients with heart failure who received a cardioverter

**FIGURE 32-11** Probability of survival in patients with systolic heart failure (HF) according to the presence or absence of central sleep apnea (CSA). AHI, apnea-hypopnea index. (Modified from Javaheri S, Shukla R, Zeigler H, et al. Central sleep apnea, right ventricular dysfunction, and low diastolic blood pressure are predictors of mortality in systolic heart failure. *J Am Coll Cardiol* 2007;49:2028; and from Javaheri S. Cardiovascular disorders. In Kryger MH, editor. *Atlas of clinical sleep medicine*, Philadelphia, 2010, Elsevier.)

488 defibrillator had sleep apnea and that the rate of mortality was highest in those with CSA. The author and colleagues suggest that patients with implanted pacemakers undergo polysomnography for diagnosis of sleep-related breathing disorders and appropriate therapy.

### Awaiting Cardiac Transplantation

Prevalence of sleep apnea is high among patients awaiting cardiac transplantation, inasmuch as they suffer from severe left ventricular dysfunction.<sup>15</sup> The waiting period for transplantation is long, and a large number of patients die from consequences of heart failure while waiting. Appropriate therapy for sleep apnea could improve survival of these patients and thereby increase their chance of living long enough to undergo cardiac transplantation.

## TREATMENT OF SLEEP APNEA IN HEART FAILURE

### Obstructive Sleep Apnea

Treatment options for OSA in heart failure (Table 32-2) are similar to those in the absence of heart failure. The treatment of choice is CPAP, which has been shown to improve cardiovascular function and survival. Meanwhile, improvement in sleep hygiene and avoidance of both alcoholic beverages and benzodiazepines (both of which may result in relaxation of the muscles of the upper airway) are also recommended. Single-dose administration of sildenafil has also been shown to worsen OSA, and associated desaturation,<sup>166</sup> presumably by vasodilation of the vascular bed in the upper airway, compromising the surface area. We also recommend avoiding use of this and related medications before sleep.

#### Weight Loss

Obesity is the major risk factor for OSA, and both obesity and OSA are associated with heart failure. Both obesity<sup>167</sup> and OSA are also associated with increased mortality, primarily from cardiovascular causes. The author and colleagues therefore recommend weight loss for obese patients with heart failure.

#### Noninvasive Positive Airway Pressure Devices

These devices consist of a nasal (or naso-oral) mask that, through a piece of tubing, is connected to an electrically driven blower that provides an adjustable amount of positive pressure to the airway. Application of the device increases the transmural pressure of the upper airway, preventing closure (pneumatic splint). Online heated humidification is added to prevent upper airway dryness.

There are several forms of these devices. Nasal CPAP devices are programmed to deliver a constant inspiratory and expiratory pressure. For subjects who feel expiratory pressure is excessive, bilevel pressure devices, in which expiratory pressure is set at a lower level than the inspiratory pressure, may be used. There are also devices that provide an expiratory pressure that is lower than inspiratory pressure and variable inspiratory pressure (pressure support servo-ventilation).

The level of pressure necessary to maintain upper airway patency may vary from 5 to 20 cm H<sub>2</sub>O and is determined in a sleep titration study. With the subject asleep and wearing the mask, the pressure of the device is gradually increased till obstructive apnea, hypopnea, desaturation, and snoring are eliminated. The device is set at that pressure, and it is recommended for use any time the subject sleeps, including naps.

These devices have been successfully used to treat OSA both in general population and in patients with heart

TABLE 32-2 Treatment of Obstructive Sleep Apnea in Heart Failure

Improvement in cardiac function
Promotion of sleep hygiene
Cessation of smoking
Weight reduction when applicable
Avoidance of alcoholic beverages, narcotics, benzodiazepines, and sildenafil at bedtime
Treatment of nasal congestion
Positive airway pressure devices (CPAP, bilevel, PSSV)
Mandibular advancement devices
Upper airway procedures
Nocturnal use of supplemental oxygen

CPAP, continuous positive airway pressure; PSSV, pressure support servo-ventilation.

failure.<sup>168-171</sup> Overnight application of nasal CPAP resulted in significant improvement in disordered breathing and arterial oxyhemoglobin desaturation.<sup>168</sup> In four randomized trials,<sup>169-172</sup> all of which included a control group, patients with heart failure and OSA were studied; in three trials,<sup>169-171</sup> long-term use of CPAP improved left ventricular ejection fraction. In the fourth study,<sup>172</sup> ejection fraction did not increase, but compliance with CPAP was less than in the other studies. As noted previously, long-term use of CPAP has been shown to improve survival of patients with heart failure and OSA who use it adequately (see Figure 32-10). For patients who do not comply with CPAP use because of complaints of high expiratory pressure, bilevel mechanical devices are recommended.

#### Other Therapeutic Modalities

Many other modalities, including oral appliances (which advance the mandible to prevent upper airway closure), upper airway surgery (to remove excess pharyngeal soft tissue such as tonsils and the uvula), and nocturnal nasal oxygen (to prevent or minimize desaturation during sleep), are available. However, no long-term systematic studies have been performed. In patients with heart failure, every attempt should be made to treat OSA with positive airway pressure devices, which are invariably effective.

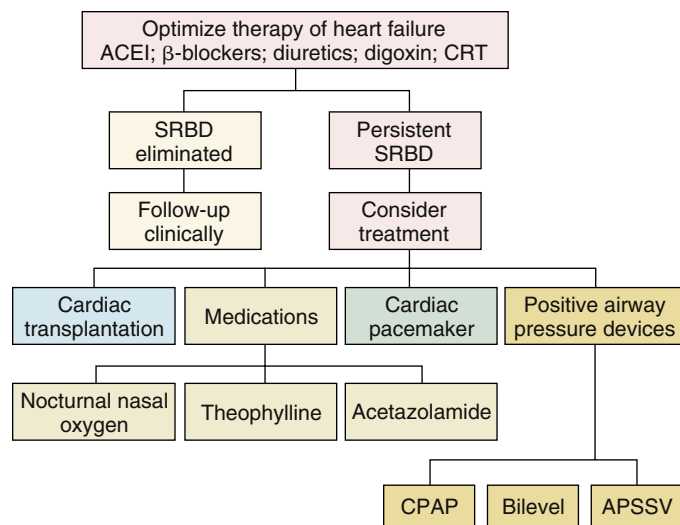

### Central Sleep Apnea

In contrast to OSA, which is easily treated with CPAP, CSA is generally difficult to treat, and response to any given therapy (CPAP, medications) is variable: Some patients respond and some do not. Figure 32-7 depicts the author's current approach to treatment of this disorder in heart failure.

#### Optimization of Cardiopulmonary Function

Optimal therapy for heart failure with diuretics, angiotensin-converting enzyme inhibitors,  $\beta$ -blockers, and cardiac resynchronization therapy (CRT) may improve or eliminate periodic breathing by several mechanisms (for reviews, see Javaheri<sup>173,174</sup> and De Backer and Javaheri<sup>175</sup>). These mechanisms include improved arterial circulation time (as stroke volume increases and cardiopulmonary blood volume decreases), increased Pco<sub>2</sub> reserve (resulting from decreased pulmonary capillary pressure), and increased functional residual capacity (caused by decrease in cardiac size, pleural effusion, and intravascular and extravascular lung water).  $\beta$ -Blockers, by increasing stroke volume and decreasing pulmonary capillary pressure, should be particularly helpful

**FIGURE 32-12** Treatment of central sleep apnea in heart failure. ACEI, angiotensin-converting enzyme inhibitor; APSSV, adaptive pressure support servo-ventilation; CPAP, continuous positive airway pressure; CRT, cardiac resynchronization therapy; SRBD, sleep-related breathing disorder. (Adapted from De Backer W, Javaheri S. Treatment of sleep apnea in heart failure. *Sleep Med Clin* 2007;2:63-638.)

in improving periodic breathing in systolic heart failure. An additional beneficial effect of  $\beta$ -blockers may relate to their counterbalancing of nocturnal sympathetic hyperactivity by decreasing repetitive arousals and desaturation. One particular side effect of  $\beta$ -blockers, however, relates to their effect on melatonin. Melatonin, a sleep-promoting chemical, is secreted through the cyclic adenosine monophosphate-mediated  $\beta$ -receptor signal transduction system, and most  $\beta$ -blockers have been shown to decrease melatonin secretion.<sup>176,177</sup> One of the exceptions is carvedilol.

Several studies have shown that CRT, by improving hemodynamics, improves CSA.<sup>178-181</sup> In one study 77 patients with heart failure who were eligible for CRT were studied before CRT and, on average, 5 months after CRT.<sup>180</sup> In patients with CSA, AHI decreased from 31/hour to 17/hour ( $P < .001$ ). Improvement in CSA occurred only in patients whose hemodynamics improved with CRT. CRT is generally ineffective in OSA.

Atrial overdrive pacing may improve sleep apnea by the same mechanism as CRT but to a lesser extent.

After optimization of cardiopulmonary function, if periodic breathing persists, several approaches are possible (Figure 32-12).

#### Cardiac Transplantation (see also Chapter 54)

After cardiac transplantation,<sup>182-186</sup> CSA is generally eliminated. This observation, along with human studies (reviewed previously) and animal studies,<sup>66</sup> indicate that heart failure is the cause of CSA. Unfortunately, however, OSA may develop a few months after transplantation.<sup>182-186</sup> In the largest study,<sup>186</sup> in which 45 patients underwent polysomnography a few months after cardiac transplantation, 36% had developed moderate to severe OSA, with an AHI of 15 or more per hour. This group of patients, in comparison with those who had no or mild OSA, had gained the most weight after transplantation. OSA was associated with systemic hypertension and poor quality of life. Because of steroid use and improved quality of life, weight gain is common in transplant recipients, and obesity is the major risk factor for OSA. It is therefore important that cardiac transplant recipients be monitored for weight gain and development of OSA.

#### Oxygen

As early as 1908, Pembrey<sup>186</sup> demonstrated that administration of oxygen resulted in improvement in periodic breathing in a few patients with congestive heart failure. Several systematic studies of subjects with systolic heart failure<sup>187-194</sup> have shown that supplemental nasal oxygen administered during sleep ameliorates CSA. Oxygen administration may also decrease arousals and light sleep. In addition, randomized, placebo-controlled, double-blind studies have revealed that short-term (1- to 4-week) administration of supplemental nocturnal oxygen improved maximum exercise capacity<sup>191</sup> and decreased overnight excretion of urinary norepinephrine.<sup>192</sup> The latter finding may be a better indicator of the overall sympathetic activity than serum norepinephrine spot sampling. In addition, investigators in three randomized clinical trials<sup>193-195</sup> (9, 12, and 52 weeks in duration) reported that nocturnal oxygen therapy significantly improved CSA, desaturation, left ventricular ejection fraction, and quality of life in patients with systolic heart failure. In the two longest studies, left ventricular ejection fraction increased by 5% to 6% in oxygen-treated subjects but did not change significantly in the control subjects.

Mechanisms of therapeutic effect of nasal oxygen on CSA are complex<sup>196</sup> and may include increasing the difference between the prevailing  $P_{CO_2}$  and the  $P_{CO_2}$  at the apneic threshold and decreasing ventilatory response to carbon dioxide and increasing body stores (e.g., lung contents) of oxygen, which increases damping. Consequently, breathing during sleep should stabilize (see “Mechanisms of Sleep Apnea in Heart Failure” section).

Although many years of experience and studies have demonstrated beneficial effects of nocturnal oxygen therapy in patients with CSA and heart failure, prospective placebo-controlled, long-term studies have not been performed to determine the potential to decrease mortality among patients with systolic heart failure.

#### Noninvasive Positive Airway Pressure Devices

As noted previously, these devices have been successfully used to treat OSA in patients with heart failure. They have also been used to treat CSA, but efficacy has been variable.

**Continuous Positive Airway Pressure and Bilevel Pressure Devices.** Both these types of devices have been used to treat CSA in patients with heart failure.<sup>152,168,197-204</sup> However, most studies have focused on CPAP.

One-night use of CPAP has been shown to eliminate CSA in 43% of the subjects with systolic heart failure.<sup>168</sup> OSA, in contrast, is invariably eliminated with overnight CPAP titration.

In patients with CSA who have responded to CPAP, the AHI decreased from 36 per hour to 4 per hour, and desaturation was virtually eliminated. CPAP level varied from 5 to 12 cm  $H_2O$ . In these patients, the number of premature ventricular contractions, couplets, and episodes of ventricular tachycardia decreased.<sup>168</sup> This effect was presumed to result from decreased sympathetic activity and improved oxygenation. CPAP had no significant effect on ventricular irritability in patients whose disordered breathing did not improve.

In one study,<sup>168</sup> 53% of CSA patients did not respond to CPAP. Others investigators have also reported negative results.<sup>198-200,202</sup> This observation may explain why CPAP therapy did not improve survival of patients with heart failure and CSA in the Canadian Continuous Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure (CANPAP) trial.<sup>202</sup> In the CANPAP trial, patients with heart failure and CSA were randomly assigned to receive CPAP or no CPAP for a mean duration of 2 years. There was no difference between these groups in the primary endpoint of death or transplantation ( $P = .54$ ), nor was there a significant difference in the frequency of hospitalization between groups.

(0.56 vs. 0.61 hospitalizations per patient year,  $P = .45$ ). The trial was terminated prematurely in part because of excess early mortality in the CPAP recipients in comparison with the control group ( $P = .02$ ). In their analysis, the authors did not categorize patients with heart failure as CPAP responders and nonresponders. In a pro and con discussion<sup>205</sup> about these observations, we suggested that excess mortality occurred primarily in nonresponders. Consequently, the post hoc analysis of the data<sup>152</sup> revealed significant improvement in survival of CPAP responders (Figure 32-13). The reasons why CPAP may have increased mortality are multiple,<sup>205</sup> including adverse hemodynamic effects of increased intrathoracic pressure (decreasing venous return and cardiac output), which is quite deleterious in patients who continue to have persistent CSA while receiving CPAP.

Caution should therefore be exercised with use of nasal CPAP. If CSA persists during an overnight CPAP titration, we recommend a trial with pressure support servo-ventilation devices.

**Pressure Support Servo-Ventilation Devices.** These devices are distinctively different from CPAP and bilevel pressure devices. First, they provide variable (not constant) and proportional amounts of ventilatory support during different phases of periodic breathing. The support is minimal during the hyperpneic phase of periodic breathing and maximal during periods of diminished breathing and central apnea. Like a buffer that keeps the pH of a solution relatively stable, these devices keep ventilation relatively stable (buffer positive airway pressure).

In addition, these devices are equipped with a backup rate that initiates a breath after a short preset time (a few seconds) of no spontaneous breathing.

Several short-term studies provide evidence of the efficacy of these devices in the treatment of heart failure<sup>206-214</sup> and also in the treatment of idiopathic CSA<sup>215</sup> and CSA associated with the use of opioids.<sup>216</sup>

These devices should be used in patients with heart failure who are not responsive to or are noncompliant with

CPAP treatment. Randomized clinical trials are in progress to determine long-term efficacy.

**Acetazolamide.** Acetazolamide acts as a respiratory stimulant and a mild diuretic. It has been used for prevention and treatment of periodic breathing at high altitude and idiopathic CSA.<sup>217,218</sup> In a double-blind, placebo-controlled crossover study<sup>219</sup> in 12 patients with systolic heart failure and severe CSA, patients who received acetazolamide exhibited significantly lower central AHI (34 per hour) than did placebo recipients (57 per hour) after 5 nights. Arterial oxyhemoglobin desaturation also improved significantly in the experimental group. Acetazolamide was administered as a single dose at about 3 mg/kg one half hour before bedtime, in order to minimize the side effects associated with multiple doses, particularly with long-term use. Patients reported improved subjective perception of overall sleep quality, feeling rested on awakening, falling asleep unintentionally, and fatigue. Acetazolamide could have two other advantageous effects when used in patients with heart failure and CSA: acting as a mild diuretic and minimizing alkalemia (caused by loop diuretics), which is commonly present in patients with heart failure. At this dose, the effect on pH is mild. In this study,<sup>219</sup> arterial blood pH decreased from 7.43 before bedtime to 7.37 in the morning.

The mechanism of action of acetazolamide is related to an increase in  $\text{PCO}_2$  reserve, noted previously.<sup>70</sup>

**Theophylline.** Aminophylline and theophylline have long been known to alleviate CSA in premature infants and adults. Open-label studies have demonstrated the efficacy of this drug in the treatment of CSA in patients with heart failure.<sup>3,220</sup> In a double-blind, randomized, placebo-controlled, crossover study of 15 patients with treated, stable systolic heart failure, similar results were reported.<sup>221</sup> Administration of theophylline, twice daily by mouth, at therapeutic plasma concentrations (11  $\mu\text{g/mL}$ ; range, 7 to 15/ $\mu\text{g/mL}$ ) decreased the AHI by about 50% and improved arterial oxyhemoglobin saturation.<sup>221</sup>

The mechanisms of action of theophylline in improving central apnea remain unclear.<sup>221</sup> At therapeutic serum concentrations, theophylline competes with adenosine at some of its receptor sites. In the central nervous system, adenosine is a respiratory depressant, and theophylline stimulates respiration<sup>222,223</sup> by competing with adenosine. It is therefore conceivable that an increase in ventilation by theophylline could decrease central apnea during sleep. Theophylline does not increase ventilatory response to carbon dioxide.<sup>223</sup>

Potential arrhythmogenic effects and phosphodiesterase inhibition are common concerns with long-term use of theophylline in patients with heart failure. Therefore, further controlled studies are necessary to establish its safety. If theophylline is used to treat CSA, frequent and careful follow-up is necessary.

**Benzodiazepines.** It has been hypothesized that by decreasing arousals, benzodiazepines may decrease CSA. However, two studies,<sup>198,224</sup> including a placebo-controlled, double-blind study,<sup>224</sup> failed to show any improvement in CSA in patients with systolic heart failure. Therefore, their use for this purpose is not recommended.

**Inhaled Carbon Dioxide.** Several studies have demonstrated that low-level inhalation of carbon dioxide virtually eliminates CSA.<sup>225-229</sup> However, some of these studies also have also shown that carbon dioxide inhalation increases arousals, which are associated with increased sympathetic and decreased parasympathetic activity. Because of the adverse cardiovascular effects of sympathetic overactivity in heart failure, the use of carbon dioxide to treat CSA is not recommended.

**FIGURE 32-13** Probability of survival in patients with systolic heart failure (HF) comparing continuous positive airway pressure (CPAP) responders to a control group (patients with systolic heart failure and similar apnea-hypopnea index [AHI]) and to CPAP nonresponders. CPAP responders had a significantly increased probability of survival compared to the control group. CPAP nonresponders tended to have a poor survival when compared to the control group, although this was not significant. CSA, central sleep apnea; HR, hazard ratio. (Modified from Artzm. Floras, J. S., Logan, A. G., et al. (2007). Suppression of central sleep apnea by continuous positive airway pressure and transplant free survival in heart failure, *Circulation* 115; 3173-3180 and adapted from Javaheri S, cardiovascular disorders Atlas of clinical Sleep Medicine.)

## CONCLUSIONS

Heart failure is a widespread problem with significant economic effects. Because of the increase in average life span and improvements in therapy for ischemic coronary artery

disease and hypertension, the number of people living with heart failure will remain high.

Heart failure is associated with excess morbidity and mortality, despite recent advances in its treatment. Multiple factors may contribute to the progressively declining course of heart failure. One such cause could be the occurrence of repetitive episodes of apnea, hypopnea, and hyperpnea, which are common in patients with heart failure. Episodes of apnea, hypopnea, and hyperpnea cause sleep disruption, arousals, intermittent hypoxemia, hypercapnia, hypocapnia, and changes in intrathoracic pressure. These pathophysiological consequences of sleep-related breathing disorders have deleterious effects on the cardiovascular system and may be most pronounced in the setting of established heart failure and coronary artery disease. Several studies have revealed that patients with systolic heart failure and sleep apnea, both OSA and CSA, have significantly shorter survival than do patients without sleep apnea. Furthermore, several observational studies have demonstrated that appropriate treatment of sleep-related breathing disorders, both OSA and CSA, improves survival of patients with heart failure.

## Heart Failure in Developing Countries

Gustavo F. Méndez Machado

In the *epidemiological transition*, the basic human needs for water, food, shelter, and medical care are met with a consequent reduction in the burden of infectious, parasitic, nutritional, and perinatal diseases, to the point that life expectancy rises above 50 to 55 years.<sup>1</sup> At this point, the number of deaths from cardiovascular disease (CVD) exceed those from infectious and parasitic diseases, and the population disease pattern has changed to one dominated by chronic diseases.<sup>2</sup>

Currently, CVD accounts for about 25% of all deaths worldwide; as a health burden in developed countries, it accounts for almost 50% of all deaths (see also Chapter 22).<sup>3</sup> The CVD epidemic in developed countries has declined since 1980: CVD-related mortality fell by nearly 50% in Australia, Canada, France, England, Japan, and the United States.<sup>4-6</sup> However, awareness of the possibility that CVD has become an epidemic in developing countries has grown enormously, as a result of (1) the epidemiological transition, (2) the rapid onset of traditional cardiovascular risk factors (smoking and obesity), (3) the rapid rates of population aging, and (4) the process of migration from rural areas.<sup>7,8</sup> This information has encouraged several researchers to study the health effects of CVD in these countries.

Indeed, in 1998, 86% of disability-adjusted life years (DALYs, which is a combination of years of life lost through premature death and years lived with disability) related to CVD occurred in developing countries, and in 1999 alone, CVDs contributed to a third of global deaths, 78% in low- and middle-income countries.<sup>9</sup> According to a report from Columbia University,<sup>10</sup> heart disease and stroke are far more urgent threats to global health in developing countries; CVD in younger people (aged 35 to 64) accounts for almost 40% of all deaths from heart disease. These analyses have encouraged several institutions and organizations worldwide to establish health policy strategies to tackle the problem of CVD in developing countries: assessment of cost-effectiveness interventions, risk assessment of the population, population-based strategies, and tobacco control. The focus is always on primary prevention.<sup>10-12</sup>

Since 1990, heart failure has emerged as a major health problem in developed countries, imposing an escalating burden on their health care systems.<sup>13-15</sup> This burden is reflected by an increase in the number of hospitalizations in nearly all developed countries in Europe and North America.<sup>16</sup> Nowadays, heart failure is the leading cause of admission to hospital with a medical problem in the United States. In the United States alone, approximately 5 million patients have heart failure, and more than 550,000 patients receive diagnoses of heart failure for the first time each year. Heart failure is the main reason for 12 to 15 million office visits and 6.5 million days of hospitalization each year. The number of deaths from heart failure has increased steadily despite advances in treatment, partly because the numbers of patients with heart failure have increased as a result of better treatment of ischemic heart disease and myocardial infarction.<sup>17</sup> Of all patients receiving Medicare, those with heart failure constitute the largest group and more Medicare dollars are spent for the diagnosis and treatment of heart failure than for any other diagnosis. Estimates of the crude incidence of heart failure in the general population in developed countries range from 1 to 5 cases per 1000 per year, with a crude prevalence ranging from 3 to 20 per 1000.<sup>14</sup> Coronary artery disease is the most common cause of heart failure, followed by hypertension, which frequently coexists with coronary artery disease.<sup>18</sup>

Most of the published data on the population features of heart failure is based on work in white populations within developed nations, but some data are available from developing countries. It is possible that heart failure would have a greater effect on the health care systems in those countries, in view of

the enhanced awareness about CVD. This chapter draws this information together to provide a better sense of the epidemiology of heart failure in developing countries.

Méndez and Cowie<sup>19</sup> were unable to find population-based studies of heart failure in developing countries. All the published studies were case series, hospital-based studies, or national surveys of hospitalized patients with the diagnosis of heart failure. The lack of truly population-based studies is presumably related to the difficulty of conducting community epidemiological studies of heart failure. However, the information published does enable very interesting comparisons between different areas within developing countries and between those countries and developed nations.

### AFRICA

CVD is increasingly recognized as a significant cause of morbidity and mortality in most African countries, including sub-Saharan Africa, where it accounts for almost 10% of all medical admissions.<sup>20,21</sup> Sub-Saharan Africa is the only world region where CVD is not the leading cause of death; high mortality rates there are secondary to infectious and nutritional diseases.<sup>2,11</sup>

Cardiomyopathy in Africa has been endemic since the 1940s, primarily in the forms of dilated cardiomyopathy and endomyocardial fibrosis. Dilated cardiomyopathy accounts for 10% to 17% of the diagnoses made in autopsy studies were of patients with heart failure and for 17% to 48% of diagnoses in all patients hospitalized for heart failure.<sup>22</sup> Dilated cardiomyopathy is found in all ages groups and in all regions of Africa; endomyocardial fibrosis, in contrast, is a disease of children and young adults that is confined to tropical and equatorial regions of Africa.<sup>22</sup>

Most cases of dilated cardiomyopathy have been classified as idiopathic; however, the role of infection and myocarditis in the pathogenesis of dilated cardiomyopathy in Africans has revealed striking regional variation. In Nigeria, infection with *Toxoplasma gondii* and coxsackievirus B is thought to play a major role in the pathogenesis of dilated cardiomyopathy. In Kenya,

in contrast, where up to 50% of the cases reported manifest histological signs of myocarditis, no serological evidence of a previous or recent coxsackievirus B infection or other viral infection has been found.<sup>23</sup> In general, it seems that in the African population, the main combination of genetic and environmental factors is present to produce the development of dilated cardiomyopathy and endomyocardial fibrosis.

In 1966, Parry,<sup>23a</sup> in Addis Ababa, Ethiopia, described the main causes of heart failure in young Africans on the basis of clinical symptoms and autopsy studies. He stated that the two most common causes of heart failure in the young adult African were "African cardiomyopathy" (dilated cardiomyopathy) or mitral stenosis resulting from rheumatic heart disease. Other causes of cardiomyopathy have been described in different geographical regions in Africa: for example, left ventricular endomyocardial fibrosis was common in Uganda (especially in a Rwandan-Burundian ethnic group), Zaire, Ghana, and the West Coast Africa but uncommon in Kenya and Tanzania.<sup>24,25</sup> The presence of hypertensive heart failure, peripartum cardiomyopathy, and annular subvalvular aneurysm of the left ventricle were also mentioned, but no exact frequencies were specified.

In a hospital series of 315 patients admitted to the Katsina Hospital in the northern part of Nigeria with the diagnosis of heart failure, 7% of all admissions were medical and pediatric.<sup>26</sup> The cause was determined by clinical assessment and without echocardiography or coronary angiography. In almost half of the patients, the diagnosis was cardiomyopathy, with a congestive pattern in 60% of the cases. Peripartum cardiomyopathy was the main diagnosis in women, which accounted for 29% of all cases of heart failure in women and 16% of all cases in all patients. All of the cases occurred in Hausa women who lived in the Northern part of Nigeria. In contrast, in the southern part of Nigeria, heart failure resulting from peripartum cardiomyopathy was rare (2% of cases); hypertension represented 35% of cases and endomyocardial fibrosis, 17% of cases.

Recently, Stewart and associates published their findings in the Heart of Soweto Study,<sup>27</sup> in which all of the 1960 patients admitted to the Chris Hani Baragwanath Hospital in the township of Soweto with the diagnosis of heart failure underwent diagnostic echocardiography. The probable cause was established by two independent cardiologists. Patients with heart failure had a mean age of 55 years and were predominantly women (57%) and black Africans (88%). The most common diagnoses were hypertensive heart failure (33%), idiopathic dilated cardiomyopathy (28%), and right-sided heart failure (27%); ischemic cardiomyopathy was diagnosed far less often (12%). In another study from Uniben Hospital in Benin City, hypertensive heart failure also was the main cause in 55 patients hospitalized with the diagnosis of heart failure.<sup>28</sup>

In developing areas of the world, acute rheumatic fever and rheumatic heart disease are estimated to affect nearly 20 million people and are the leading causes of cardiovascular death during the first five decades of life.<sup>29</sup> Rheumatic heart disease accounts for 10% of all patients hospitalized with heart failure in Nigeria.<sup>26</sup> Oyoo and Ogola<sup>21</sup> published a hospital-based study of heart failure in 91 patients admitted to the Kenyatta National Hospital in Nairobi, Kenya. Congestive heart failure accounted for 3% of all medical admissions. The main cause of heart failure was rheumatic heart disease (32%); this, dilated cardiomyopathy (25%), and hypertensive heart disease (17%) constituted the majority of causes of admissions for heart failure. The incidence of rheumatic heart disease is known to be very high in Africa; estimates range from fewer than 1 to more than 15 per 1000 per year, representing 30% of all hospital admissions for CVD in Africa.<sup>20,30</sup>

In 2008, Kengne and associates<sup>31</sup> established that even in sub-Saharan Africa, heart failure accounts for more than 30% of all hospital admissions in specialized cardiac units and that

in this population, approximately 11% of all patients with heart failure had type 2 diabetes. As a result of the increase in the prevalence of diabetes, this disease has emerged as a major comorbid condition or cause.

## CENTRAL AND SOUTH AMERICA

Since 1970, Central and South American countries have undergone profound changes in demographic, sociocultural, and epidemiological profiles. Therefore, it is likely that deaths secondary to noncommunicable diseases exceed deaths from communicable diseases for the first time. The change has been swift: The proportion of annual deaths from CVDs has increased from 20% to 27% since 1980.<sup>32</sup> CVD is now the leading cause of death in 31 of the 35 countries in Central and South America that report mortality statistics.<sup>32</sup>

The National Register of Heart Failure in Chile<sup>33</sup> reported 372 patients admitted with the diagnosis of heart failure to 14 hospitals across all nation. The mean age was 69 years, and 59% were men. The major causes were hypertension (35%), ischemic heart disease (32%), valvular heart disease (15%), and idiopathic dilated cardiomyopathy (7%). Patients' medical histories included hypertension (69%), type 2 diabetes (35%), myocardial infarction (22%), and atrial fibrillation (28%). Ejection fraction was less than 40% in 69% of the patients. The mean hospital stay was 11 days, and the in-hospital mortality rate was 5%. In the analysis of patients admitted to the hospital with the diagnosis of heart failure, the same register reported that preserved ejection fraction was defined as exceeding 50%. In these patients, the mean age was 66 years, and 73% were women. The major comorbid conditions were hypertension (76%) and atrial fibrillation (62%). The main limitation of this register is that it did not provide information about the procedure used to identify the main causes, and length of hospital stay varied widely, with no report of mortality from heart failure.

In Argentina in 1999, Amarilla and associates<sup>34</sup> reported a survey of 751 patients admitted with the diagnosis of heart failure to 31 hospitals nationwide. The main causes were ischemic heart disease (30%), hypertension (21%), valvular heart disease (17%), dilated cardiomyopathy (14%), and Chagas' disease (3%). In 2004, Macin and colleagues<sup>35</sup> reported the analysis of 192 patients admitted to the Institute of Cardiology of Corrientes, Argentina, with the diagnosis of heart failure. Of these patients, 73% were male, and the mean age was 65 years. The main causes were ischemic heart disease (45%), hypertension (26%), and valvular heart disease (10%). The mortality rate over 10 months was 39%.

In Mexico, the author and colleagues published the efficacy of a heart failure clinic in the improvement of quality of life of patients with heart failure in a tertiary hospital in Veracruz, Mexico.<sup>36</sup> The main causes were ischemic heart disease (47%) and idiopathic dilated cardiomyopathy (44%). The cause was evaluated by two cardiologists, and in all patients, coronary angiography was performed. The mortality rate at 6 months was 12% (95% confidence interval, 2% to 22%).

In Brazil in 2002, there were 372,604 hospital admissions with a mortality rate of 7%, which represented 3% of all hospital admissions.<sup>37</sup> In 2008, Mangini and associates<sup>38</sup> published an analysis of 212 patients with a diagnosis of decompensated heart failure who were admitted to an emergency department of the Heart Institute (InCor) in Sao Paulo, Brazil. Of these patients, 56% were male, and the mean age was 60 years. The main causes were ischemic heart disease (29%), hypertension (21%), valvular heart disease (15%), and Chagas' disease-related cardiomyopathy (15%). The in-hospital mortality rate was 10%. In 2006, Braga and colleagues<sup>39</sup> reported on a series of 356 patients referred for management of heart failure to the Clinic of the Federal University of Bahia,

**FIGURE 33-1** Distribution of Chagas' disease in Central and South America. (Modified from Acquatella H: Chagas' disease. In Abelmann WH, Braunwald E, editors. *Atlas of heart disease. Cardiomyopathies, myocarditis, and pericardial disease*, Philadelphia, 1995, Current Medicine, pp 8.1-8.18; and Liu PP, Schultheiss HP. Myocarditis. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier, pp 1779.)

Brazil. Of these patients, 53% were male, and the mean age was 54 years. The main causes were Chagas' disease-related cardiomyopathy (48%), hypertension (19%), idiopathic dilated cardiomyopathy (11%), ischemic cardiomyopathy (9%), and valvular heart disease (3%). In previous studies in Brazil,<sup>40</sup> investigators reported causes such as ischemic heart disease (33%), dilated cardiomyopathy (26%), valvular heart disease (22%), and Chagas' disease-related cardiomyopathy (6%). All these investigators acknowledged a high prevalence of Chagas' disease in that it is an endemic cause of dilated cardiomyopathy in this part of the world, with geographical variation within the same country (Figure 33-1).

Chagas' disease<sup>41</sup> is caused by a single-celled flagellate (*Trypanosoma cruzi*) that is transmitted by arthropods. The disease occurs mainly in Latin America, and the resulting cardiac problems are the main cause of morbidity and mortality (Figure 33-2). Accordingly to estimates, the prevalence of *T. cruzi* infestation in Latin American immigrants is 16 per 1000 in Australia, 9 per 1000 in Canada, 25 per 1000 in Spain, and 8 to 50 per 1000 in the United States. The transmission of Chagas' disease is no longer confined to the Americas because it can be transmitted through blood transfusions and organ transplantation. The rate of mortality is higher among patients with Chagas' disease-related cardiomyopathy than among patients with other types of cardiomyopathy; the most common causes of death are fatal arrhythmias, progressive heart failure, and brain embolism. Cases of Chagas' disease have been reported from all over Latin America (Argentina to Mexico).<sup>42,43</sup>

## ASIA

Since 2000, CVD has become the leading cause of death in many Asian countries, such as China,<sup>44</sup> India,<sup>45</sup> Singapore,<sup>46</sup> and Turkey.<sup>47</sup>

Hung and co-authors<sup>48</sup> described a 1997 retrospective study, with a 1-year follow-up period, about the epidemiology of heart failure from 11 hospitals of the Hospital Authority, Hong Kong. All patients admitted with a primary diagnosis of heart failure were identified. Of the cases of heart failure, 4589 (74%) were new and 1614 (26%) were old cases. Of the patients, 56% were female, and the mean age was 77 years. This is the first study in Asia in which incidence and prevalence of heart failure were reported. The incidence of heart failure was 0.7 per 1000 population. The incidences were 20 per 1000 women and 14 per 1000 men older than 85 years; the prevalences among patients older than 85 years was 30 per 1000 women and 20 per 1000 men, and the 1-year mortality rate was 32%. The main limitation of this study was that it provided no information about cause or whether heart failure was systolic or diastolic.

In an early (1999) study from the Prince of Wales Hospital, Hong Kong, Yip and associates<sup>49</sup> showed that the main causes of heart failure were hypertension (50%), coronary artery disease (35%), dilated cardiomyopathy (10%), type 2 diabetes (30%), and rheumatic heart disease (12%); in many patients, more than one factor was implicated. Of patients with coronary artery disease, 69% had hypertension, and of hypertensive patients, 48% had coronary artery disease.

Joshi and coworkers<sup>50</sup> published an analysis of 125 consecutive patients admitted to the Government Medical College in Nagpur, India, with the clinical diagnosis of heart failure. The main causes were rheumatic heart disease (52%) and ischemia or hypertensive heart disease or both (27%). A similar statistic could be found in neighborhood countries; for example, in Pakistan, the current situation regarding rheumatic fever and rheumatic heart disease was almost the same as in India.<sup>51</sup>

In Singapore,<sup>46</sup> congestive heart failure accounted for 4.5% of all hospital admissions and 2.5% of overall mortality in the population aged 65 years and older. A total of 15,774 hospital admissions were identified between 1991 to 1998; cardiovascular deaths occurred in 5.6%. Although analysis of cause was not conducted in all cases, it seems that as a result of the increasing survival of patients with myocardial infarction, ischemic heart disease could be the main cause of heart failure in this country.

Because of their unique geographical situation, Israel and Turkey have showed specific patterns of heart failure. In 2003,<sup>52</sup> the National Heart Failure Survey in Israel reported on 4102 consecutive patients admitted to the 25 public hospital nationwide. Of these patients, 57% were male, and the mean age was 73 years. The most frequent comorbid conditions were coronary artery disease (82%), hypertension (75%), type 2 diabetes (50%), and atrial fibrillation (33%). The in-hospital and 30 day mortality were 5% and 8% respectively. At one year, the mortality rate was 28%. In Turkey,<sup>47</sup> a survey of 16 academic hospitals included 661 consecutive cases of patients admitted with the diagnosis of heart failure. Of these patients, 63% were male, and the mean age was 61 years. Ischemic heart disease was the main cause, followed by hypertension and rheumatic heart disease.

## CONCLUSIONS AND FUTURE DIRECTIONS

Heart failure has imposed a high burden on the health care systems in developed countries since 1980. It is becoming increasingly apparent that the same burden will be reproduced in developing nations as a result of their epidemiological transition. As shown in Figure 33-3, the causes of heart failure in developing countries vary by continent. Unfortunately, there is a dearth of information about how the epidemiological patterns of heart failure are changing in such nations. Moreover, no proper population epidemiological

**FIGURE 33-2** Life cycle of American trypanosome, which causes Chagas' disease. The trypomastigote stage of American trypanosomes is an invasive but nonreplicative form that enters several different cell types; in those cells, the parasite develops into a replicative amastigote form, some of which develop further into invasive trypomastigotes in dying host cells. (1) In taking a blood meal, the triatomine bug passes metacyclic trypomastigotes in its feces; trypomastigotes enter the bite wound or mucosal membranes, such as the conjunctiva. (2) Metacyclic trypomastigotes penetrate various cells at the bite wound site. Inside cells, they transform into amastigotes. (3) Amastigotes multiply by binary fission in cells of infected tissues. Trypomastigotes can infect other cells and transform into intracellular amastigotes in new infection sites. Clinical manifestations can result during this infective stage. (4) Intracellular amastigotes transform into trypomastigotes and then burst out of the cell and enter the bloodstream. (5) The triatomine bug takes a blood meal from the human host, and trypomastigotes are ingested. (6) Epimastigotes develop in the midgut of the triatomine bug. (7) Epimastigotes multiply in the midgut and are transformed into metacyclic trypomastigotes. (8) Metacyclic trypomastigotes move to the bug's hindgut and are passed in feces. (From Blum JA, Zellweger MJ, Burri C, et al. Cardiac involvement in African and American trypanosomiasis. *Lancet Infect Dis* 2008;8:631-641.)

studies have been performed to clarify the changing patterns. Such studies are important from more than only the academic point of view; they would be of value for health policy makers. Up to now, published data are chiefly from hospital-based series and national registers that are subject to selection bias (which may be substantial). Objective confirmation of the clinical diagnosis of heart failure is often lacking; the use of echocardiography and coronary angiography is confined to reports dating only as recently as 2000 from relatively wealthy countries. The determination of cause is another limitation in such studies and is also open to criticism, and any conclusion must be tempered with a considerable degree of caution. Table 33-1 summarizes the available data on the relative importance of the different causes of heart failure. Properly conducted population-based studies in these countries are urgently needed to establish the true size of the problem and the relative importance of the different causes.

Preventive and public health strategies must rely on the specific information obtained from such studies.

In terms of future directions, proper population-based studies on the epidemiological patterns of heart failure must be conducted in developing countries to understand the effects of heart failure in those populations, with special emphasis in the incidence, prevalence, and etiological determinants. The medical community and general population must acknowledge public information about the principal risk factors for the development of heart failure; the main purpose is to tackle the future increase of heart failure in these countries. Finally, developed countries should collaborate with their expertise and economic resources to obtain adequate information about the epidemiological patterns of heart failure in developing economies. Such information will be useful for establishing preventive and public health strategies to diminish the effects of heart failure in those countries.

### Predicting Outcomes in Heart Failure, 507

### The Conversation, 508

In a heart failure clinic, a response to the leading question “What brings you in to see us today?” is often “My doctor told me I have only 6 months to live and I must get a heart transplant.” Most patients come with family, loved ones, or concerned friends and companions. All are anxious and frightened, sometimes to the point of being terrified. This type of encounter is not solely relegated to the heart failure clinic, of course, and the challenge of determining prognosis in any patient is extraordinary and a grave responsibility. The manner in which a clinician determines likelihood of

outcomes, particularly major morbid events, and communicates this information to patients and their attendants, is crucial in long-term management. After all, this information might be life-altering in many patients with serious disease. An accurate prognosis of favorable outcomes that dispels misinformation that suggests imminent bad events is, of course, invaluable therapy for many patients who had been incorrectly informed that they were to die soon. Caregivers’ tasks are to make patients feel better, cure disease when possible, and prevent or attenuate progression to more substantive difficulties. An accurate prognosis is, therefore, essential in designing treatment protocols and judging therapeutic risks and benefits of any intervention to achieve these goals.

The results of the Framingham Heart Study suggested that, over a lifetime, the average resident of Framingham, Massachusetts, had a 20% risk of developing congestive heart failure (see Chapter 22).<sup>1</sup> As a result, innumerable patients have come for evaluation and asked clinicians to determine their prognosis. **Box 34-1** lists several issues important to pursue in prognosticating for the patient with heart failure. This turns out to be a difficult task because no single factor seems the best and most powerful prognosticator.<sup>2-4</sup> It is clearly important to determine whether a patient’s symptoms or clinical findings are indeed related to heart failure. Prognosis is dependent on the clinician’s having made a correct diagnosis. The cause of the difficulty and identification of events precipitating the patient’s presentation affect prognosis and must be enumerated. The nuances of cardiac pump performance, such as presence of diastolic or systolic left ventricular dysfunction, are also critical in predicting outcomes. Obviously, acute and chronic therapeutic interventions, such as treatment with  $\beta$ -blockers or defibrillators, can alter prognosis and must be considered. Guidelines for the evaluation and management of chronic heart failure in the adult are now in use and endorsed by many professional societies.<sup>5-7</sup> All emphasize the importance of treating patients with evidence-based strategies that are based on the severity of disease at presentation and long-term prognosis. End-of-life considerations are an important focus of these guidelines as well, and prognosis is a prime driver in the identification of patients who should be guided toward the hospice and palliative care environment.<sup>8</sup>

**Box 34-2** is a compendium of clinical variables that influence outcomes in patients with heart failure who have participated in clinical trials and registries.<sup>2,3</sup> Once symptomatic heart failure develops, the outlook for patients can be poor, with an average 5-year mortality rate as high as 75% among men and 60% among women; this prognosis is worse than those for many cancers. However, there is a high degree of variability among individual patients. The Rochester Epidemiology Project supervised by the Mayo Clinic group emphasized the adverse prognostic effect of heart failure in the study of all patients who

received an initial diagnosis of congestive heart failure in Olmsted County, Minnesota, in 1991.<sup>9,10</sup> That year, of a population of 106,470 citizens, 216 demonstrated “new-onset congestive heart failure.” Among patients with newly diagnosed heart failure, the 5-year survival rate was 35%. Of the patients in whom ejection fraction was known, 43% had preserved systolic function; in this particular cohort, the survival rate was no different than that among patients with depressed left ventricular systolic function. Further analyses of the incidence of congestive heart failure and prognosis in patients who received diagnoses in 1981, in comparison with those who received diagnoses a decade later, suggested that survival rates of both groups of patients were similar. Levy and colleagues<sup>11</sup> from the Framingham Heart Study demonstrated that since about 1960, the incidence of heart failure has seemingly declined among women but not among men; however, survival after the syndrome onset has improved slightly but is still relatively poor among women. The 5-year mortality rate for newly diagnosed congestive heart failure in the Framingham Cohort was 70% among men who received diagnoses between 1950 and 1969 and almost 60% among men who received diagnoses between 1990 and 1999. The prognosis of heart failure can, in fact be dismal.

According to results of more recent clinical studies of patients hospitalized for all forms of decompensated heart failure, the rate of in-patient hospital mortality is about 4%, the rate of 90-day mortality after discharge is close to 9%, and about 30% of patients require rehospitalization within 90 days.<sup>12,13</sup> Rates of in-hospital mortality for acutely decompensated heart failure can be compared with the rate of mortality among patients with acute myocardial infarction, Killip class I without heart failure or left ventricular dysfunction. Among such patients, the current mortality rate is approximately 3%.<sup>14</sup>

Another contemporary analysis of outcomes was the Heart Failure—A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION), in which, for about 30 months, researchers monitored almost 2500 patients with a mean age of 59 years,

502 who had a median left ventricular ejection fraction of 25%, and of whom one third had New York Heart Association (NYHA) functional class III or IV symptoms; 56% were hospitalized for or died of cardiovascular problems.<sup>14,15</sup> Collectively, these observations emphasize the high variability in

prognosis of patients with heart failure when different populations are analyzed.

The clinical variables in Box 34-2 that are related to outcome in patients with heart failure have been verified, at the least, in univariate analysis; many of them are independently significant when multifactorial analysis techniques are employed. Nonetheless, it is difficult to determine which prognostic variable is most important in predicting an individual patient's outcome either in clinical trials or during day-to-day management. This has been a persistent dilemma for decades, and it is particularly problematic when researchers try to design clinical trials in which event rates determine statistical power and size calculations.<sup>16</sup>

Cowburn and coworkers<sup>17</sup> and Lee and Packer<sup>18</sup> summarized peer-reviewed publications of studies containing more than 200 subjects with chronic, usually congestive, heart failure in which a multivariate analysis of prognostic factors was reported. The original report was subsequently expanded with more observations included.<sup>2,3</sup> The variables listed in Box 34-2 could be ranked with regard to importance and power of predicting outcomes in cohorts of patients with heart failure. In general, the highest ranking variables associated with adverse clinical outcome included hyponatremia,<sup>18,19</sup> The

### BOX 34-1 Determining the Prognosis of a Patient with Heart Failure: Important Questions to Ask

Does the patient actually have heart failure?  
 What is the cause of the heart failure syndrome?  
 What events precipitated presentation or clinical deterioration?  
 What comorbid conditions are present?  
 What are the characteristics of cardiac pump and circulatory (including pulmonary) performance?  
 How compensated, decompensated, or congested is the patient?  
 What acute and chronic therapeutic strategies are in place?  
 What changes in therapeutic strategies can be made to alter prognosis beneficially?

### BOX 34-2 Clinical Variables Relevant to Prognosis of Patients with Heart Failure

#### Demographics

Age  
 Gender  
 Race

#### Cause of Heart Failure

Alcohol use  
 Amyloidosis  
 Anthracycline  
 Coronary artery disease  
 Genetic factors  
 Hemochromatosis  
 Idiopathic dilated cardiomyopathy  
 Myocarditis  
 Valvular heart disease  
 Ventricular hypertrophy

#### Comorbid Conditions

Anemia  
 Chronic lung disease  
 Diabetes mellitus  
 Hepatic abnormalities  
 Hyperthyroidism or hypothyroidism  
 Obesity/cachexia (body mass)  
 Pulmonary hypertension  
 Renal insufficiency  
 Sleep apnea

#### Symptoms

Angina pectoris  
 Depression  
 Dyspnea syndromes  
 Edematous states  
 NYHA class  
 Syncope

#### Hemodynamics

Cardiac index  
 Exercise PuAP  
 Left ventricular ejection fraction  
 PCWP  
 PuAP  
 PuAP-PCWP  
 Right ventricular ejection fraction

#### Findings in Exercise Testing

Anaerobic threshold  
 Blood pressure response  
 Development of arrhythmias  
 Heart rate response (including recovery)  
 Ischemic electrocardiographic response  
 O<sub>2</sub> uptake slope  
 Peak/maximal Vo<sub>2</sub>  
 Six-minute walk time  
 VE/VCO<sub>2</sub>

#### Metabolic Findings

Acidosis or alkalosis  
 Azotemia  
 Hepatic dysfunction  
 Serum sodium level

#### Chest Radiographic Findings

Congestion  
 Cardiac-thoracic ratio

#### Electrocardiographic Findings

Heart rate variability  
 Width of QRS interval  
 QT interval  
 Rhythm  
 T-wave alternans  
 Voltage

#### Cytokines

Pro-inflammatory/antiinflammatory ratio  
 Sedimentation rate  
 TNF- $\alpha$ ; IL-1, IL-6, IL-10

#### Hormones

Aldosterone  
 B-natriuretic peptide  
 Epinephrine  
 Norepinephrine

#### Endomyocardial Biopsy Findings

Degree of cellular disarray  
 Degree of fibrosis  
 Infiltrative processes  
 Inflammation

presence of coronary artery disease,<sup>20-22</sup> severely depressed left ventricular ejection fraction,<sup>23</sup> and elevated levels of neuro-hormones such as epinephrine, norepinephrine, plasma renin, and natriuretic peptides.<sup>24,25</sup> NYHA functional classification,<sup>26</sup> left ventricular end-systolic volume,<sup>27,28</sup> stroke work index,<sup>29</sup> persistent atrial fibrillation, left ventricular internal dimension,<sup>28</sup> peak oxygen consumption on metabolic exercise treadmill testing,<sup>29,30</sup> pulmonary capillary wedge pressure,<sup>29</sup> hepatic dysfunction,<sup>31</sup> evidence of diastolic filling abnormalities on Doppler echocardiography, hypertension, hypotension, age, and chest radiographic cardiothoracic ratio were also frequent, but less consistently present, as independent markers of adverse outcome in the population with heart failure.<sup>2,3,18</sup> The number of variables associated with poor outcome is dizzying. In general, patients who have the greatest perturbation of cardiac and circulatory systems had the poorest outcomes. This is not surprising. Fairly consistent was the fact that patients with coronary artery disease seemed to have worse prognoses; another trend, although not as consistent, was that patients with systolic left ventricular dysfunction had adverse outcomes more often than did patients with congestive heart failure but reasonably normal ejection fraction. Gender is a controversial issue with regard to prognosis; some reports have suggested that women have worse outcomes, whereas others have indicated that being male is predictive of greater morbidity.<sup>32,33</sup>

The observation that few variables are consistently predictive of adverse outcome is disturbing, and this makes clinicians' conversations with patients more difficult. Indeed, clinicians must realize that heart failure is an extraordinarily complicated and heterogeneous syndrome. **Box 34-3** summarizes the variability that exists in identifying specific parameters that are consistently predictive of morbid events. The power of any population-based multivariable analysis to identify factors depends on sample size: Larger clinical cohorts with diverse representation are more likely to reveal factors predictive of adverse outcomes. Heterogeneity of observations also results from the fact that demographics (age, gender, race, and heart failure cause) are highly variable. For example, when attempting to identify adverse prognostic factors in the setting of heart failure with coronary artery disease, researchers must not contaminate the population with individuals who do not have this diagnosis. However, this happens in many clinical trials. An adverse prognostic variable for an individual with idiopathic dilated cardiomyopathy is quite different from that for patients with hypertension and heart failure caused primarily by diastolic dysfunction.<sup>12</sup>

The varying stages of presentation of heart failure also probably affect the ability to identify adverse outcomes. For example, an individual presenting with new-onset and untreated heart failure probably has adverse prognostic

variables that are different from those in a stable patient who does not have congestion and has been taking a  $\beta$ -blocker and an angiotensin-converting enzyme (ACE) inhibitor for many years.<sup>12,13</sup> The presence of a defibrillator or cardiac resynchronization device can have an even more extraordinary effect and improve outcomes when used according to guidelines in specific populations.<sup>5</sup> The time at which information is obtained is highly variable in reports. For example, some studies have relied on initial hemodynamic characterization of patients, which usually occurs at a time when congestive states are at their worst; pulmonary capillary wedge pressure may be more or less important at hospital admission than at discharge. Similarly, determination of exercise tolerance and, in particular, measurement of peak oxygen consumption are complicated by this issue. Many patients can improve their exercise capacity and hemodynamics with aggressive therapeutics. The time the measurement is made in the course of the illness should, therefore, be critical, but little information is available about the prognostic effect of changing observations over time and during short- and long-term follow-up.<sup>4</sup> Furthermore, does an increase in myocardial oxygen consumption at peak exercise after treatment mean that a patient has a better prognosis? Should researchers instead determine how ill the patient is at his or her best?

Particularly contentious, and noted in **Box 34-3**, is the fact that, for variables studied in large clinical trials, there is great ascertainment bias in the study population; in many heart failure studies, cohorts do not represent patients in community-based clinics.<sup>1,9,10</sup> Some trials, for example, have focused solely on male veterans, who, for the most part, are younger than cohorts identified in community settings and may represent an entirely different socioeconomic group.<sup>34</sup> Selective inclusion of clinical information also creates difficulties. Only when hemodynamics or exercise capacity is measured, for example, are these variables included in any multivariable analysis and have a chance of demonstrating predictive value. Many variables are interrelated and therefore, from a mathematical standpoint, compete in prognostic models, so that one or more variables are eliminated as an independent predictor of outcome. Peak oxygen consumption and treadmill exercise time or exercise hemodynamics are examples of this problem. The astuteness of clinicians and the skill of technicians determine the quality of certain testing procedures, particularly echocardiography, radionuclide ventriculography, hemodynamic measurement, and determination of peak myocardial oxygen uptake. The variables identified in compulsively performed clinical trials to determine prognosis might not have the same power when studied in a rudimentary manner during clinical practice. Introduction of therapies during patient follow-up can be variable and might also account for why different prognostic tests yield significant results in one patient but not in another. If the entry criteria for a study are narrow, bias of ascertainment can limit the power of any specific observation. For example, congestive heart failure is defined as a clinical syndrome in patients with both normal and low ejection fraction. This measure is usually an independent predictor of mortality. However, if the cohort includes only patients with ejection fractions of less than 20%, and a narrow standard deviation for this measure exists in the cohort, ejection fraction, per se, is usually not identified as an adverse prognostic factor.<sup>16</sup>

### BOX 34-3 Difficulties with Identification of Specific Prognostic Factors in Heart Failure Trials, Registries, and Populations

- Small cohort sizes
- Heterogeneity of population studied
- Narrow entry criteria (bias of ascertainment)
- Selective data acquisition
- Variable duration of follow-up
- Measurements with high variability
- Variables that are often interrelated and compete in mathematical model
- Flawed techniques from mathematical and statistical point of view

## PROGNOSTIC VARIABLES

### Demographic Variables

Race, sex, and age are frequently implicated as important variables in the determination of a patient's prognosis in the setting of heart failure. The Framingham database suggested that

female patients have a better prognosis than do male patients and that women might have higher ejection fraction than do male counterparts with comparable symptoms, but the latter suggestion is a matter of contention (see Chapter 22).<sup>11,26,32-35</sup> The Studies Of Left Ventricular Dysfunction (SOLVD) demonstrated an interesting disparity when its registry database was compared with the two SOLVD clinical trials with regard to gender-related outcomes. SOLVD clinical trials excluded patients with an ejection fraction greater than 35% with the “treatment” and “prevention” programs, and the results suggested that women actually had worse outcomes than did men.<sup>34,36,37</sup> The SOLVD registry, however, did not require depressed left ventricular ejection fraction for entry and did not suggest that women did any worse than did their male counterparts. Also important is the fact that when heart failure is due to coronary artery disease, little difference in outcomes was noted when men were compared to women. Perhaps outcomes are more adversely affected by the cause of heart failure and other factors than by the gender of the patient.

Controversy has also arisen with regard to the effect of race on heart failure outcome. African Americans have been observed to have a worse prognosis than do white Americans. Differences in causes of heart failure, however, might once again explain some of these observations, as might socioeconomic status and access to health care. According to the SOLVD registry, coronary artery disease was a cause of heart failure syndrome in 73% of white Americans but in only 36% of African American participants.<sup>37</sup> Conversely, hypertension was a primary cause of chronic heart failure in 32% of African Americans in the SOLVD registry but in only 4% of the white patients. As with gender in the SOLVD registry, rates of cardiovascular-related mortality and total rates of mortality were no different when African American and white cohorts were compared, but the African American cohort was younger and had a higher proportion of women than the white cohort.

One of the more consistent and forceful predictors of adverse outcome in heart failure is age.<sup>38,39</sup> This seems intuitive. As has been repeatedly demonstrated, the incidence and prevalence of chronic heart failure increase with age. When studies exclude patients older than 75 years, age may not be an independent predictor of mortality, as was the case in the Vasodilator and Heart Failure Trial (V-HeFT).<sup>40</sup> In the older cohort of V-HeFT patients, however, the risk of death or hospital readmission for worsening congestive heart failure over a 12-month period approached 50%.

## Causes of Heart Failure

Patients in whom coronary artery disease is the cause of chronic heart failure generally fare worse than do patients with dilated cardiomyopathy.<sup>20-22</sup> A few exceptions have been noted. In the treatment trial of SOLVD, a difference in prognosis could not be demonstrated when patients with ischemic and nonischemic heart disease were compared.<sup>41</sup> However, many patients who did not enter the SOLVD trial with the diagnosis of ischemic heart disease suffered subsequent myocardial infarction; therefore, just because coronary artery disease is not diagnosed at trial onset does not indicate that coronary anatomy is normal.

Valvular heart disease carries unique implications with regard to prognosis once heart failure is diagnosed (see Chapter 29).<sup>42</sup> For example, in a cohort of patients undergoing percutaneous coronary interventions for atherosclerotic obstructions, the presence of residual mitral regurgitation was linked to a higher rate of long-term mortality. This was particularly pronounced when left ventricular ejection fraction was less than 40%; among patients with grade 3 or 4+ mitral regurgitation, the 36-month survival rate was less than 50%.<sup>43</sup> When significant aortic stenosis was present and if the valve was not repaired or replaced, length of survival was only 1

or 2 years.<sup>44</sup> In the past, there has been reluctance to operate on patients with aortic stenosis when left ventricular systolic dysfunction was present because of the added risk of adverse surgical outcome. In patients with substantial mitral stenosis, symptoms of congestive heart failure appear frequently despite preservation of left ventricular systolic function. In aortic regurgitation, earlier and more aggressive intervention with vasodilator drugs appears to alter the clinical course.

Despite the fact that viral infections probably cause a significant number of “idiopathic” cardiomyopathies, it is difficult to demonstrate lymphocyte myocarditis on endomyocardial biopsy (see Chapter 31).<sup>45-47</sup> However, no survival difference was noted between patients in whom myocarditis was diagnosed by Dallas criteria at the time of endomyocardial biopsy and patients with idiopathic dilated cardiomyopathy but without this biopsy finding.<sup>45</sup> Anecdotal reports do suggest that patients with acute, fulminant lymphocytic myocarditis have higher mortality rates. Also, giant cell myocarditis, a difficulty of unknown origin, appears to be particularly problematic, with extremely high acute fatality rates.<sup>47</sup> In autopsy series of patients who died with acquired immunodeficiency syndrome (AIDS), lymphocytic myocarditis was noted frequently. In the patients with myocarditis, approximately half had had symptoms of heart failure before death. Nonetheless, endomyocardial biopsy is not routinely indicated to determine prognosis in most patients with heart failure.<sup>5-7</sup>

Although the assumption is under contention, peripartum cardiomyopathy (see Chapter 24) has been thought to be an autoimmune or inflammatory type of myocarditis and has several prognostic subsets. Many patients with peripartum cardiomyopathy improve within several months of diagnosis, and biopsies in those patients usually yield negative findings (myocardial tissue does not demonstrate lymphocytic infiltration).<sup>48</sup>

Patients with hypertrophic cardiomyopathy (see Chapter 25) have historically been particularly plagued by sudden cardiac death. Patients with nonsustained ventricular tachycardia have a higher risk of lethal events in this setting. In patients with a family history of the combination of hypertrophic cardiomyopathy and sudden cardiac death, the degree of left ventricular hypertrophy seems important with regard to predicting adverse outcome in this syndrome.<sup>49</sup>

Alcoholic cardiomyopathy has been suggested to be a powerful predictor of mortality in some cases (see Chapter 24). There may be a genetic predisposition to the development of cardiomyopathy with heavy alcohol use, and women, who rarely develop hepatic cirrhosis, seem less susceptible than men.<sup>50</sup> Of interest is that varying degrees of alcohol consumption have been noted to have a relationship to left ventricular dysfunction. In some people, even modest levels of alcohol consumption causes difficulties. Arrhythmias associated with ethanol consumption (particularly atrial fibrillation) can worsen prognosis as well.

Cardiomyopathy caused by chemotherapy for malignancy is most often related to anthracycline administration (see Chapter 58).<sup>51</sup> Anthracycline-related cardiomyopathy is linked to dosage and, depending on the aggressiveness of cancer treatment, can arise in 5% to 20% of patients who receive these agents. Individuals who develop acute anthracycline-related cardiomyopathy usually have very malignant courses with poor responses to general medical therapies for heart failure. This manifestation can result in death within a few months. Mild to moderate heart failure after anthracycline exposure is more heterogeneous with regard to prognosis. In these cases, it is more difficult to predict adverse outcomes, and the course of illness may be related as much to the presence of additional risk factors for cardiomyopathy, such as concomitant radiation therapy, preexisting cardiac dysfunction from hypertension or coronary artery disease, and valvular abnormalities. All things considered, patients with

anthracycline-related cardiomyopathy appear to have worse rates of survival than do comparatively managed patients with idiopathic dilated cardiomyopathy.

Infiltrative processes that cause cardiomyopathy in heart failure, such as amyloidosis and hemachromatosis, can be diagnosed through endomyocardial biopsy. Among patients with these conditions, the actuarial survival rate is poor; response to standard therapies is generally unsatisfactory. Among patients in whom these diagnoses are made in a setting of frank congestive heart failure, it is rare to live beyond 2 years.<sup>52</sup>

Some forms of idiopathic dilated cardiomyopathy appear to have worse prognosis when all other factors are considered equal. Familial dilated cardiomyopathy, for example, appears to be associated with increased risk of mortality in comparison with sporadically appearing forms of idiopathic dilated cardiomyopathy. The reasons of this are unknown.<sup>53</sup>

## Comorbid Conditions that Affect Outcome of Heart Failure

Comorbid conditions that affect the outcomes of heart failure include hypertension, diabetes mellitus, pulmonary hypertension, and renal insufficiency. Although hypertension increases the risk of developing heart failure significantly, only minimal evidence suggests that hypertension is an independent outcome risk predictor once heart failure is present. In fact, patients with lower blood pressures seem to have worse outcomes and prognosis.<sup>23</sup> Hypertension is certainly related to symptomatic deterioration in acutely decompensated congestive heart failure, and it prompts many visits to emergency departments and many hospital admissions.<sup>54</sup> Diabetes is another prominent risk factor for the development of heart failure and, interestingly, is a stronger risk factor in women than in men.<sup>55</sup> The combination of hypertension and diabetes seems particularly problematic; the risk of developing heart failure is quintupled. Pulmonary hypertension, whether secondary to left ventricular dysfunction or other primary pulmonary vascular problems, affects survival by causing right ventricular dysfunction with failure and precipitating malignant arrhythmias.<sup>56</sup> Attention has been focused on sleep apnea in heart failure because nocturnal desaturation associated with periodic respirations promotes pulmonary hypertension, right ventricular dysfunction, and worsening heart failure with increased neurohormonal levels.<sup>57</sup>

Renal insufficiency might result from low cardiac output and medication administration, as well as from underlying diseases such as diabetes and hypertension. Renal dysfunction can therefore be associated with worse outcomes in patients with heart failure.<sup>58</sup> Hepatic dysfunction can present because of worsening passive congestion of the liver. Sometimes this difficulty can be severe enough to cause cirrhosis of the liver, hence the term *cardiac cirrhosis*.<sup>31</sup>

Diseases that already shorten life expectancy, such as chronic obstructive pulmonary disease or metastatic malignancy, are, when combined with heart failure, associated with increased rates of mortality. However, most clinical trials and registries of patients with heart failure have excluded individuals with significant lung disease or other chronic illnesses, and so the precise effect of these diseases on ventricular dysfunction and its complications is largely unknown.

## Clinical Manifestation (see Chapter 35)

Severe congestive states in the heart failure syndrome have been consistent predictors of adverse outcomes in most clinical trials. Even when extremely gross assessments of symptomatic severity (such as NYHA functional classification) are used, mortality rates appear higher in more symptomatic patients. Quality-of-life score, classification of daily activities, and motion meters have all provided some degree

of prognostic information. Patients in whom depression or mood-altering disorders are diagnosed are at increased risk of death and decompensation. The presence of peripheral or pulmonary edema is associated with worse outcomes. Longer duration of symptoms is predictive of high mortality and a lower likelihood that depressed ejection fraction will improve. Syncope, whether associated with an arrhythmia or not, portends adverse outcomes, as does angina pectoris or recent myocardial infarction.

As noted, although this issue is under contention, the relationship of congestive symptoms to systolic and diastolic dysfunction may be important with regard to predicting morbid events. Congestive heart failure in individuals who have normal and near-normal ejection fraction is being observed more frequently. Sudden decompensated heart failure with acute symptoms caused by predominantly diastolic dysfunction can be seen in the setting of acute myocardial infarction or severe hypertension.

Prognosis in patients with primarily left ventricular diastolic dysfunction and a congestive state may be different than in patients with left ventricular systolic dysfunction. When clinicians try to determine outcomes in patients with diastolic dysfunction and congestive heart failure, it is more important to determine the cause of the diastolic dysfunction. Infiltrative processes such as amyloidosis and hemachromatosis cause much worse outcomes. When diastolic dysfunction complicates systolic dysfunction, chances of survival may also be worse.

## Ventricular Performance and Hemodynamics

Systolic left ventricular function has been repeatedly one of the most powerful independent predictors of morbidity in patients with heart failure who enter clinical trials (see Chapter 13). In general, an ejection fraction less than 25% is predictive of major adverse outcomes in comparison with ejection fractions greater than 35%. However, left ventricular ejection fraction should be used alone only with caution to determine prognosis. Many other variables play a role. A noncongested, active, mesomorphic individual with well-controlled blood pressure and an ejection fraction of 20% can do quite well for many years by taking  $\beta$ -blockers and ACE inhibitors or vasodilators. Nonetheless, most practitioners rely on left ventricular ejection fraction, by one method or another, to differentiate between systolic and diastolic dysfunction and to get some idea about severity of disease and likelihood of an adverse outcome. Some information suggests that a serial yearly decrease in ejection fraction is associated with increased risk of mortality, but guidelines do not recommend regular measurement of ejection fraction in patients with heart failure. Of most importance is that clinicians not use ejection fraction exclusively to determine a patient's prognosis.

Right ventricular ejection fraction is much more difficult to determine accurately than is left ventricular ejection fraction. Nonetheless, right ventricular ejection fraction of more than 35% at rest or during exercise was associated with higher survival in patients with heart failure than was oxygen consumption at peak exercise in one study.<sup>59</sup>

Hemodynamics has been used to assess the severity of heart failure when heart transplantation is considered.<sup>60</sup> Particularly important is the presence of the degree of congestion, manifesting as high right atrial pressures and pulmonary hypertension; "irreversible" pulmonary hypertension is predictive of adverse outcome in general and after cardiac transplantation. However, resting hemodynamics have turned out not to correspond directly with symptoms, physical findings, or exercise capacity more generally. Assessing risk by resting hemodynamic profile has therefore yielded disappointing results. This seems particularly true when patients are admitted to the hospital with decompensated heart failure.<sup>61</sup>

The routine referral of a patient for right-sided heart hemodynamic measurement did not improve outcomes in one large multicenter clinical trial.<sup>61</sup> Right ventricular hemodynamics should be measured only in complicated cases in which specific details of management need to be addressed. When hemodynamic measurements have been used, however, cardiac index of less than 2 L/min/m<sup>2</sup> and pulmonary resistance higher than 2.5 Wood units were predictive of substantially higher mortality rates.

## Exercise Testing (see also Chapter 57)

Functional status and cardiac reserve of patients with chronic heart failure can be objectively characterized by determining exercise tolerance.<sup>29,30</sup> Particularly important is the precise measurement of peak oxygen consumption. It has become probably the most important test to determine whether ambulatory patients are ill enough to list for cardiac transplantation.<sup>60</sup> Patients who have a peak oxygen uptake of less than 10 mL/kg/min at a respiratory exchange rate greater than 1.10—which suggest that the patient has reached anaerobic threshold and peak exercise capability—is associated with a 1-year mortality risk that can be as high as 77%, in comparison with 21% when the peak oxygen uptake is in the range of 10 to 18 mL/kg/min. Mancini and colleagues used this particular finding to determine optimal timing for cardiac transplantation; they suggested that patients with a peak oxygen uptake below 14 mL/kg/min were mostly likely to benefit from cardiac transplantation, and this number has become an important guideline for transplantation programs.<sup>29,30</sup>

Peak oxygen uptake can, however, be affected by age, gender, muscle mass, aerobic conditioning, and medication therapy. Thus, some individuals with peak oxygen uptake of less than 14 mL/kg/min do well despite the presence of significant left ventricular dysfunction. Some authors have used percentage of predictive peak oxygen uptake rather than the absolute value to stratify risk. In multivariate analysis, 50% or 55% of predicted peak oxygen uptake (when the respiratory exchange ratio is greater than 1.10) has generally been selected as the most significant predictor of cardiac death.<sup>60</sup> Adjustments have to be made if the patient is taking a  $\beta$ -blocker.<sup>62</sup>

Attempts have been made to enhance the predictive power of peak oxygen uptake during exercise by coupling this measure to other data such as central hemodynamics, presence or absence of T-wave alternans, abnormal heart rate recovery, and ratio of ventilation to ventilatory carbon dioxide uptake ( $\dot{V}_E/\dot{V}_{CO_2}$ ). Additional findings that may help classify patients into more serious heart failure categories include peak exercise heart rate, systolic blood pressure, minute ventilation, and anaerobic threshold. These observations have played a role in creating outcome prediction formulas or algorithms, discussed subsequently.

Although metabolic exercise testing to determine ventilatory responses in heart failure is quite important, specialized equipment and highly trained personnel are needed to accurately perform. Conversely, a simple 6-minute walking test also provides valuable prognostic information.<sup>63</sup> Many clinical trials have now used the 6-minute walk test to classify patients with heart failure into syndrome severity categories. A significant correlation between distance walked during 6 minutes and survival is noted. A total distance walked of less than about 300 meters in the SOLVD study carried an annual mortality risk of 11%, in contrast to 4% among patients who could walk more than about 450 meters.<sup>63</sup>

## Metabolic Parameters

Many metabolic perturbations occur as heart failure alters flow to the central nervous system and mesentery. In patients with severe congestive heart failure, the serum sodium

measurement probably reflects the degree of neurohormonal perturbation and intensity of diuretic therapy. Low serum sodium is associated with high morbidity rates. Elevated uric acid level is probably a result of renal perfusion abnormalities and also is associated with adverse outcomes. Liver enzyme levels can be elevated as a result of hepatic congestion. Hypothyroidism and hyperthyroidism frequently coexist with heart failure, can worsen symptoms, and may affect survival.

## Chest Radiography

Routine chest radiography has been criticized as a tool to establish prognosis in heart failure; however, critical review of this simple, relatively inexpensive, and easy test has revealed pertinent findings that might be helpful.<sup>28</sup> Cardiothoracic ratio has been noted to be an independent predictor of survival. There is, however, a poor correlation between cardiothoracic ratio and left ventricular ejection fraction. Nonetheless, volume overload, manifesting as either pleural effusions or pulmonary parenchymal congestion, has been noted to be an independent predictor of mortality in some multivariate analyses.

## Electrocardiography

In view of studies demonstrating the beneficial effects of cardiac resynchronization in patients with QRS intervals longer than 120 msec and with depressed ejection fraction, electrocardiography has had a resurgence in use during evaluation of patients with heart failure.<sup>64</sup> The combination of first-degree atrial ventricular block with intraventricular conduction delay can be particularly problematic, and now that cardiac resynchronization devices are available, clinicians must quite carefully evaluate a routine 12-lead surface electrocardiogram, particularly for QRS prolongation. Of course, the presence of arrhythmias such as atrial fibrillation, nonsustained ventricular tachycardia, and simply frequent premature ventricular contractions is important.

Support for signal average electrocardiography has waxed and waned with regard to stratifying risk for patients with dilated and ischemic cardiomyopathies.<sup>65,66</sup> Some investigators have noted that this technique is predictive of adverse outcome, but the sensitivity of signal average electrocardiographic parameters appears low overall, and the use of this technique remains controversial. QT dispersion has been used to stratify risk for patients with heart failure as well.<sup>67,68</sup> Patients who have atrial fibrillation and demonstrate complete left bundle branch block, however, present challenges to analysis of QT dispersion. In contrast, heart rate variability, a surrogate index of cardiac autonomic balance, appears to be, in some studies, a more powerful predictor of mortality and morbidity.<sup>69,70</sup> Electrocardiographic measurement of baroreflex sensitivity, an indirect measure of cardiac autonomic disruption, has also been used to stratify risk for patients with heart failure, but this technique has not been often used in the author's experience. Routine electrophysiological studies in patients with congestive heart failure have demonstrated that the inducing of ventricular tachycardia by programmed ventricular stimulation does not appear to be predictive of adverse outcome in nonselected patient populations.<sup>71</sup> However, in patients with heart failure who have a history of sudden cardiac death, syncope, or coronary artery disease, inducible ventricular tachycardia does seem to be associated with high morbidity rates. Of interesting is that electrophysiological study data do not often drive decision making regarding insertion of defibrillator devices in large practices. Rather, the general clinical characteristics of a patient with heart failure drive decisions to insert a defibrillator according to practice guidelines.

## Inflammatory Markers of Heart Failure (see also Chapter 11)

Cytokines are small protein molecules that are produced not by specialized glands, as are hormones, but rather by many different tissues and individual cells. Unlike hormones, cytokines are not liberated continuously but are upregulated and downregulated in response to specific stimuli. Cytokines exert their effect in a paracrine manner on adjacent cells or in an autocrine manner on the producing cell itself. Major systemic effects may not be obvious with cytokine upregulation. Interest has emerged in cytokine analysis in the setting of heart failure because of the link between heart failure pathogenesis and inflammation more generally.<sup>72-74</sup> However, the routine measurement of cytokines has not proved useful for individual patients.<sup>74</sup> Nonetheless, cytokines can produce left ventricular dysfunction, precipitate pulmonary edema, cause cardiomyopathy, and induce ventricular remodeling (causing hypertrophy). Cytokines are also linked to anorexia and cachexia in patients with very severe heart failure (tumor necrosis factor, for example, is also called *cachectin*). In general, proinflammatory cytokines have been the ones associated with adverse outcome (tumor necrosis factor and interleukins-1 and -6, for example).

The erythrocyte sedimentation rate, a nonspecific index of inflammation, can be correlated with severity of illness of patients with heart failure.<sup>75,76</sup> Indeed, Paul Wood observed in 1936 that sedimentation rates were low in patients with pulmonary congestion and peripheral edema.<sup>75</sup> More recently, the erythrocyte sedimentation rate has been shown to vary in these patients, depending on individual patients' presentation. Patients with low or normal sedimentation rates in the setting of heart failure generally had more severe hemodynamic abnormalities than have patients with elevated sedimentation rates.

## Neuroendocrine Activation

One of the most important insights into heart failure pathophysiology is that neuroendocrine activation appears early in the syndrome and can be subtle; several classic studies documented that renin-angiotensin-aldosterone abnormalities were associated with poor prognosis in the absence of treatment with neurohormonal modulating agents (ACE inhibitors, angiotensin receptor-blocking drugs, aldosterone antagonists, and  $\beta$ -blockers).<sup>77</sup> More recently, elevated levels of C- and N-terminal atrial and brain natriuretic peptide indicate worse outcomes in patients with heart failure.<sup>78</sup> These natriuretic peptide measurements can be used to both diagnose heart failure and guide clinicians during prognostication and treatment. It is not clear whether routine measurements of neurohormones other than natriuretic peptides will add further prognostic information in individuals.

Plasma endothelin has been recognized as an independent, significant prognostic marker in congestive heart failure as well.<sup>79</sup> Endothelin is an extremely potent vasoconstricting, endogenous hormone that causes pulmonary hypertension. Big endothelin-1 is the biologically inactive precursor of endothelin-1 and has been shown to be associated with short-term mortality from heart failure.

## Endomyocardial Biopsy

The routine performance of endomyocardial biopsy in patients with heart failure, as previously mentioned, is not now endorsed as a routinely applied method to help with prognostication.<sup>5</sup> In some cases, however, the procedure can be useful. Adverse outcomes are associated with certain biopsy findings, including the presence of inflammation, particularly giant cell myocarditis, as discussed. Morphometric

analysis of biopsy specimens that focuses on the degree of fibrosis and hypertrophy has been considered, but, again, it is not routinely used. Because endomyocardial biopsy is important for diagnosing doxorubicin (Adriamycin)-induced cardiomyopathy and for differentiating this difficulty from other infiltrative disease processes such as amyloidosis and hemochromatosis, endomyocardial biopsy cannot be completely dismissed, even though it should not be routinely performed.

## PREDICTING OUTCOMES IN HEART FAILURE

In prognosticating during day-to-day management of individuals with heart failure, the clinician should focus attention on readily available clinical information that includes symptom severity (usually NYHA functional classification), left ventricular ejection fraction, cause of the difficulty, routine biochemical markers (particularly serum sodium, creatinine, blood urea nitrogen, and uric acid levels; liver function tests), and select hormones such as natriuretic peptides.<sup>80-90</sup>

Several algorithms have been tested to assist clinicians in determining which patients might benefit from cardiac transplantation, pharmacotherapeutic prescriptions, and device interventions.<sup>81,85</sup> Aaronson and colleagues<sup>81</sup> proposed a non-invasive risk-stratification model that was based on clinical findings during determination of peak oxygen uptake. This particular model contains seven variables: whether ischemia is present, resting heart rate, left ventricular ejection fraction, presence of a QRS duration longer than 200 msec, mean resting blood pressure, peak oxygen uptake, and serum sodium level. A heart failure score can be developed and related to subsequent morbidity and mortality. Adding invasively obtained data to this formula, including mean pulmonary capillary wedge pressure, improved predictive power of this approach somewhat. This model defines low-, medium-, and high-risk groups: 1-year event-free survival rates are 93%, 72%, and 43%, respectively.

Campana and coworkers<sup>88</sup> also tested a prognosticating model with similar but not the same factors. This model included cause of heart failure, functional class, presence of an S3 gallop, cardiac output, mean arterial pressure, and either pulmonary artery diastolic pressure or pulmonary capillary wedge pressure. This model obviously requires invasive measurements of hemodynamics. According to the risk score generated, patients were stratified into low-, intermediate-, and high-risk groups, whose 1-year event-free survival rates were 95%, 75%, and 40%, respectively, which were quite similar to those of the Aaronson model.

The model that is perhaps most elegant and easy to use and that has been a subject of great interest is the Seattle Heart Failure Prognostication Model.<sup>86,88</sup> Previous heart failure risk models, such as the ones described previously, stratify patients into group ranges without a specific and individualized risk assignment. The Seattle Heart Failure risk prediction tool produces an individualized estimate of survival and is based on readily available clinical characteristics and not invasive measurements of hemodynamics. Levy and colleagues<sup>86</sup> at the University of Washington Health Sciences Center derived the model by retrospectively investigating predictors of outcome among 1125 patients with heart failure who had been entered into randomized clinical trials whose entry criteria required symptomatic NYHA class III or IV, an ejection fraction of less than 30%, and medication with an ACE inhibitor and diuretics. A stepwise Cox proportional hazard model was used to create a multivariate risk model that identified age, gender, ischemic cause, functional classification, ejection fraction, systolic blood pressure, potassium-sparing diuretic use, statin use, allopurinol use, hemoglobin, percent lymphocyte count, uric acid level, serum sodium level, total

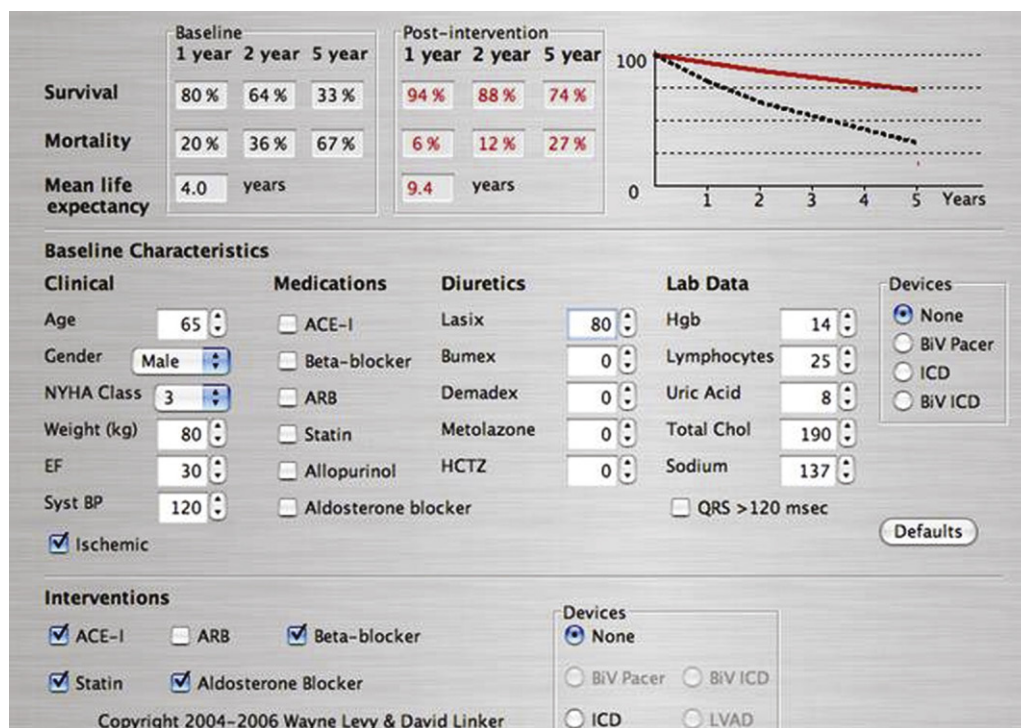

cholesterol level, and diuretic dose as significant predictors of death. The model was then prospectively validated in five additional cohorts totaling almost 10,000 patients and 17,000 person-years of follow-up. The model provided an accurate estimate of 1-, 2-, and 3-year survival with the use of easily obtained clinical characteristics. Particularly attractive is the fact that the model can be freely accessed at <http://depts.washington.edu/shfm> (accessed February 6, 2010) and individual patient characteristics entered to determine the effects of various interventions. Figure 34-1 demonstrates that for a 65-year-old man with class III symptoms and an ejection fraction of 30% with a normal blood pressure, no anemia, and preserved serum sodium level, starting “guideline-driven, evidence-based” drug therapy will improve the chance of 5-year survival from 33% to 74%. Another advantage is that the likelihood of improving outcomes with interventions in appropriate patients with defibrillators and resynchronization pacing can be assessed.

Of course, these prediction models have limitations. Nonetheless, the use of mathematical models to help predict outcome in heart failure cohorts helps physicians determine which patients might be appropriate candidates for particular therapies.

## THE CONVERSATION

Prognostication in a patient with heart failure is critical in patient management, and patients deserve careful, thoughtful, and compassionate analysis of the data and then information that will guide them through the important challenges of self-care. Fortunately, most patients with heart failure have a reasonable prognosis. Nonetheless, bad news is often given, and cardiologists do not have adequate training in the delivery of this information. It is stressful to the clinician and, unlike physicians in the fields of oncology and neurology, cardiologists have paid less attention to this challenge.

One strategy used by some authorities is summarized by the mnemonic SPIKES.<sup>91</sup> “S” stands for “setting up the conversation”; the clinician has a strategy regarding the discussion before entering the room with the patient and family or attendants. The clinician should anticipate that the patient and the family are experiencing anxiety, and although the clinician might wish to avoid the conversation entirely, the conversation must take place. “P” represents “perception”: What does the patient know about the disease and multiple issues that might be complicating the clinical situation? Does the patient know the facts, or does the patient have misperceptions that have been conveyed by less educated caregivers? The clinician must educate the patient. If the prognosis is not that bad, that point should be highlighted, but the clinician should not be excessively optimistic. “I” represents “invitation,” which means that the clinician must determine how much information the patient desires. “K” is for “knowledge”: The clinician should educate the patient by using a discussion format that the patient can understand. “E” means “empathy”: The clinician should give the patient a few minutes to let the information and discussion resonate and then use empathetic statements to react to the patient’s emotions. The clinician should not be patronizing or paternalistic. The clinician should be sensitive to the wishes of the patient. Forceful persuasion should not be used in discussing therapeutic options. The final “S” stands for “summarize and strategize”: Make sure that the patient understands what has been discussed and, in particular, what the next steps are. A few common barriers to these discussions include the clinician’s feeling responsible for buoying a patient’s hope, ignoring the clinician’s own feelings, making assumptions (that are often quite wrong) about the knowledge level and sophistication of the patient, assuming that all patients want “everything possible” done and that cure is the goal, and talking more than listening.<sup>92</sup> These insights could be helpful during difficult conversations with some patients with heart failure.

**FIGURE 34-1** Seattle Heart Failure Prognostication Model. This online model for predicting risk in heart failure is easily accessed (<http://depts.washington.edu/shfm>; accessed November 1, 2009) and can help with determining mathematical survival likelihood with a variety of interventions. In this example, the predicted 1-year survival rate increased from 80% to 94% when an angiotensin-converting enzyme inhibitor, a  $\beta$ -blocker, an aldosterone antagonist, and a “statin” were added to the medication treatment protocol of a 65-year-old man with normal blood pressure, narrow QRS interval, coronary artery disease, and an ejection fraction of 30%. Genetic Evaluation, 523

## Future Directions, 523

Heart failure is a clinical syndrome that manifests in different stages with a wide spectrum of bedside observations. Hence, the evaluation of the patient with heart failure may vary, but it is a critically important task. The physician must use clinical acumen and laboratory resources properly and skillfully. Heart failure is much like fever or anemia, in that it should not be considered as a “stand-alone” diagnosis but should be described with its associated cause (or causes), such as coronary artery disease, hypertension, valvular heart disease, or arrhythmia. This evaluation is clearly not to be a “one-time” occurrence but rather an ongoing process, and it may evolve according to how the clinical course unfolds. Additional diagnostic information may be necessary to support the diagnosis and to determine the precise mechanism of the symptoms, the severity of the problem, the natural history of the disorder, and the prognosis for an individual patient.

Historically, the clinical concept of heart failure has been descriptive of volume overload (which may explain the common use of the term “congestive heart failure”). Today the availability of hemodynamic and imaging measures, ability to quantify the degree of cardiac insufficiency, and description of morphological abnormalities are increasingly becoming part of the process of bedside clinical evaluation. With the adap-

tation of the staging system that extends beyond the presentation of signs and symptoms of heart failure, the evaluation process requires the implementation of a combination of complex clinical and laboratory skills. In particular, patients with “preclinical” heart failure can be identified only by careful imaging or other techniques that reveal underlying structural abnormalities. Thus, the departure from a purely symptomatic evaluation and management in favor of a notion of a process of disease progression allows for the opportunity to explore how to best evaluate patients afflicted by this condition.

This chapter provides a broad framework of clinical evaluation across the spectrum of heart failure to gain an appreciation of how the heart failure began, how the signs and symptoms develop over time, and the pace at which the signs and symptoms appear. Such information is critical for determining prognosis and devising precise management strategies, specific therapies, and interventions, including pharmacological treatment, percutaneous coronary intervention, surgery, and use of mechanical devices.

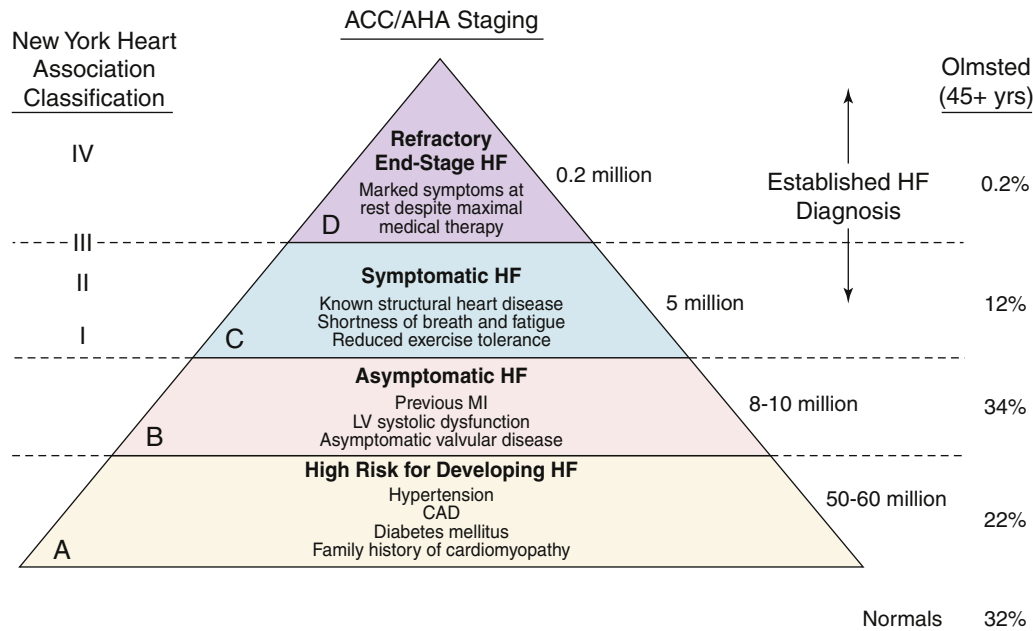

failure are often nonspecific. Despite these ambiguities, a series of questions should be addressed to every patient in order to understand the contributors and trajectory of disease progression: When did the symptoms start? Are the symptoms stable or are they getting worse? Are symptoms provoked, or do they occur at rest? Are there accompanying symptoms (such as chest pain or calf claudication, palpitations, and dizziness)? How do the symptoms affect everyday activities? Illness narratives are particularly important, and sometimes patients may provide some clues as to how their conditions evolved, even though many of these questions may not yield immediate answers (and sometimes the answers may be elicited from significant others or family members). Sometimes, several rounds of interviewing are necessary. It can be a time-consuming process, and the person taking the history must be patient.

It is important to determine the stage in which the patient might be in the natural history of the disorder. Risk factors for the development of heart failure must be identified in order to anticipate heart failure (so-called stage A heart failure, according to the heart failure guidelines of Hunt and associates<sup>1</sup>) (Figure 35-1). Such risk factors include hypertension, coronary artery disease, diabetes mellitus, valvular heart disease, history of myocardial infarction, family history of cardiomyopathy, or exposure to cardiotoxins (such as excessive use of alcohol, use of anthracycline, occupational exposure, use of ephedra-containing supplements, or use of illicit drugs). Table 35-1 lists the prevalence and population attributable risk of some of these risk factors. Figure 35-2 illustrates a risk scoring system that may be used to predict the risk of developing heart failure, on the basis of common clinical variables.<sup>2</sup> Some of these risk factors may not be apparent, and it is commonly necessary for patients to trace back their past exposures or their family histories in order to provide clues to possible underlying causes, particularly in those with nonischemic causes.

Even in the absence of symptoms, some patients may have structural and functional abnormalities of the heart and circulation that antedate the onset of symptoms (so-called stage B heart failure<sup>1</sup>). These structural abnormalities include left ventricular

## CLINICAL EVALUATION OF PRESENTING SYMPTOMS: THE MEDICAL HISTORY

One of the first principles of the clinical evaluation of heart failure is to determine whether the patient is indeed presenting with heart failure. Although this may sound obvious and self-fulfilling, presenting signs and symptoms of heart

**FIGURE 35-1** Heart failure (HF) staging and prevalence of stages in the Olmstead County Epidemiology Study. ACC, American College of Cardiology; AHA, American Heart Association; CAD, coronary artery disease; LV, left ventricular; MI, myocardial infarction. (Data on the right side of the figure is from Ammar KA, Jacobsen SJ, Mahoney DW, et al. Prevalence and prognostic significance of heart failure stages: application of the American College of Cardiology/American Heart Association heart failure staging criteria in the community. *Circulation* 2007;115:1563-1570.)

hypertrophy, asymptomatic left ventricular dysfunction, asymptomatic valvular dysfunction, or wall-motion abnormalities from prior myocardial infarction. Because heart failure will probably develop in these early stages in some patients, preventive therapy or risk factor modification should be instituted, as well as early use of neurohormonal antagonists, including angiotensin-converting enzyme (ACE) inhibitors and, in selected cases,  $\beta$ -blockers and statin therapy.

Symptoms of heart failure may be well controlled with outpatient medical therapy (stage C<sup>1</sup>) or may become refractory to conventional therapy (stage D<sup>1</sup>). After the physician establishes that symptoms may be caused by the syndrome of heart failure, ongoing review of the patient's clinical status is crucial for the appropriate selection and monitoring of therapy. It is traditional to classify patients by extent of disability according to the New York Heart Association (NYHA) functional classification (see Figure 35-1).<sup>3</sup> Although this classification system is notoriously subjective, it has stood the test of time and continues to be widely applied to patients with heart failure. Several other clinical scoring systems have been developed to define heart failure in population-based studies (Table 35-2).<sup>4</sup> There is an important distinction between staging and functional classification assessment: The NYHA functional classification applies only to patients with overt heart failure (stages C and D), and whereas a patient's NYHA class can improve or worsen, heart failure staging can only advance forward. In other words, once a patient's condition reaches stage C, even if the patient becomes asymptomatic with treatment, the condition would not be restaged B because symptoms have already manifested themselves.

The pace at which heart failure develops and progresses can be highly variable, and sometimes it is difficult to distinguish stage C from stage D. The timing and need for various diagnostic assessments therefore depend on decisions regarding the appropriateness and timing of specialized interventions (such as revascularization and heart transplantation). For example, a young woman with decompensated heart failure resulting from acute inflammatory myocarditis may require full diagnostic workup and mechanical circulatory support to maximize the chances of recovery. In contrast, an

**TABLE 35-1** Prevalence and Population Attributable Risk Factors for Developing Heart Failure

surgical interventions, as well as their clinical consequences. This is particularly important in patients with advanced heart failure, whose choices may be limited to improving the quality versus length of life.<sup>5</sup>

When a patient first presents with new heart failure or decompensated heart failure, identification and correction of a *precipitating cause* is very important (Box 35-1). In some cases, this is obvious (such as dietary indiscretion), but in other cases, it may be far more subtle. A prospective substudy of a large clinical trial demonstrated that the most common acute precipitants of heart failure exacerbations were non-compliance with salt restriction (22%), pulmonary infections (15%), and arrhythmias (13%). More alarming is the prevalence of iatrogenic causes of decompensation, such as use of antiarrhythmic agents (15%) or calcium channel blockers (13%), or inappropriate reductions in medications for heart failure (10%).<sup>6</sup> Furthermore, different precipitating factors may also have different implications. For example, 60- to 90-day outcomes are poorer for heart failure decompensation caused by ischemia or worsening renal function than for that caused by poor blood pressure control or arrhythmia (because the latter are more likely to be reversible with appropriate treatment).<sup>7</sup>

Much effort has been made to develop objective assessment of health-related quality of life in heart failure, such as the Minnesota Living with Heart Failure questionnaire<sup>8</sup>

(Box 35-2) or the Kansas City Cardiomyopathy Questionnaire<sup>9</sup> (Table 35-3). These disease-specific instruments have been developed to improve the measurement of health status and quality of life; the findings would help physicians gain insight into disease severity or to quantify changes over time. Many of these have been used in substudies of clinical trials and are now beginning to be incorporated into standardized registries as part of patient assessment tools and performance measures.

The cardinal symptoms of heart failure are dyspnea (shortness of breath) and fatigue that occur either at rest or with exertion, or in both situations. Some patients may attribute their dyspnea to being “out of shape” or even to “old age.” Many patients may have lived with it for so long that they do not even notice the degree of slow but steady deterioration. Conversely, some patients present initially with severe acute pulmonary edema that can be rarely mistaken for any other condition. Most patients manifest heart failure somewhere between these two extremes, and the most recent guideline updates have emphasized that the clinical manifestation can be congestion, lack of congestion, or lack of symptoms.<sup>1</sup> As in the eliciting of any medical history, many of the answers may be apparent only to experts, and most arise in casual conversations regarding activities of daily living. A good example is when patients are asked about their fluid status and dietary salt intake. Most patients insist that they have

NHANES, National Health and Nutrition Examination Survey.

made every effort to reduce sodium intake. However, careful review of their dietary habits may reveal otherwise or simply clear ignorance of salt-laden food intake. Probing into specifics often helps physicians better understand patients' conditions and their immediate environment. Patients may also be focused on any abnormal signs and symptoms that may be attributable to heart failure or its treatment side effects. Good rapport with patients and their families is vital in eliciting information regarding adherence to medical advice and reviewing abilities to provide appropriate self-care.

## Dyspnea

Dyspnea is the uncomfortable awareness of breathing. When it occurs at rest or at a level of physical activity at which it is not expected, it is abnormal. Dyspnea is a nonspecific symptom that occurs with a wide variety of cardiac, pulmonary, and chest wall disorders. For example, it can also result from acute anxiety, acute coronary insufficiency, and anemia.

Patients with heart failure may manifest various types of dyspnea, including exertional dyspnea, orthopnea, paroxysmal nocturnal dyspnea, dyspnea at rest, and, with acute pulmonary edema, respiratory distress. An increase in respiratory rate (usually > 16 breaths/minute) usually accompanies dyspnea and may signal the onset of acute decompensation of stable heart failure.

The mechanisms of dyspnea, fatigue, and exercise intolerance in patients with heart failure are still not well understood, inasmuch as they are not simply a result of increased pulmonary capillary wedge pressure and decreased cardiac output.<sup>10-14</sup> There is little correlation between pulmonary capillary wedge pressure and exertional dyspnea in individual patients with heart failure, unless frank pulmonary is present.<sup>15</sup> It is well known that in auscultation, the lungs may sound clear in a substantial proportion of patients with shortness of breath and heart failure.<sup>16</sup>

All patients with heart failure should be carefully queried regarding the threshold of dyspnea onset during exercise.

### BOX 35-1 Factors That May Precipitate the Worsening of Heart Failure

Myocardial ischemia or infarction  
 Excess dietary sodium or excess fluid intake  
 Medication noncompliance  
 Iatrogenic volume overload  
 Uncontrolled hypertension  
 Arrhythmia

- Atrial fibrillation or flutter
- Ventricular tachyarrhythmias
- Bradyarrhythmias

Comorbid conditions

- Fever, infections, or sepsis
- Thyroid dysfunction
- Anemia
- Renal insufficiency
- Nutritional deficiencies (such as thiamine deficiency)
- Pulmonary diseases (chronic obstructive pulmonary disease, pulmonary embolism, hypoxemia)

Inappropriate reduction of medications for heart failure  
 Adverse drug effects

- Alcohol
- Overzealous administration of negative inotropic agents (such as  $\beta$ -blockers, calcium channel blockers, antiarrhythmic agents)
- Nonsteroidal antiinflammatory drugs
- Thiazolidinediones and other medications that can cause fluid retention
- Corticosteroids

### BOX 35-2 Minnesota Living With Heart Failure Questionnaire

Did your heart failure prevent you from living as you wanted during the last month by:

1. causing swelling in your ankles, legs, etc.?
2. making you sit or lie down to rest during the day?
3. making your walking about or climbing stairs difficult?
4. making your working around the house or yard difficult?
5. making your going places away from home difficult?
6. making your sleep at night difficult?
7. making your relating to or doing things with your friends and family difficult?
8. making your working to earn a living difficult?
9. making your recreational pastimes, sports, or hobbies difficult?
10. making your sexual activities difficult?
11. making you eat less of the foods you like?
12. making you short of breath?
13. making you tired, fatigued, or low on energy?
14. making you stay in a hospital?
15. costing you money for medical care?
16. giving you side effects from medicine?
17. making you feel you are a burden to your family or friends?
18. making you feel a loss of self-control in your life?
19. making you worry?
20. making it difficult for you to concentrate or remember things?
21. making you feel depressed?

**TABLE 35-3 Kansas City Cardiomyopathy Questionnaire**

1. Please indicate how much you are limited by *heart failure* (shortness of breath or fatigue) in your ability to do the following activities *over the past 2 weeks*? (extremely limited, quite a bit limited, moderately limited, slightly limited, not at all limited, or limited for other reasons or did not do the activity)
  - Dress yourself
  - Showering/bathing
  - Walking 1 block on level ground
  - Doing yard work, housework, or carrying groceries
  - Climbing a flight of stairs without stopping
  - Hurrying or jogging (as if to catch a bus)
2. Compared with 2 weeks ago, have your symptoms of *heart failure* (shortness of breath, fatigue, or ankle swelling) changed? (much worse, slightly worse, not changed, slightly better, much better, I've had no symptoms over the last 2 weeks)
3. Over the *past 2 weeks*, how much have the following signs/symptoms bothered you? (extremely, quite a bit, moderately, slightly, not at all bothersome; no such signs/symptoms)
  - Swelling in your feet, ankles, or legs
  - Fatigue
  - Shortness of breath
4. Over the *past 2 weeks*, how many times did you have *swelling* in your feet, ankles, or legs when you woke up in the morning? (every morning, 3 or more times a week but not every day, 1–2 times a week, less than once a week, never over the past 2 weeks)
5. Over the *past 2 weeks*, on average, how many times has *fatigue* limited your ability to do what you want? (all the time, several times/day, at least once/day, 3 or more times/week but not every day, 1–2 times/week, less than once/week, never over the past 2 weeks)
6. Over the *past 2 weeks*, on average, how many times have you been forced to sleep sitting up in a chair or with at least 3 pillows to prop you up because of *shortness of breath*? (every night, 3 or more times/week but not every day, 1–2 times/week, less than once/week, never over the past 2 weeks)
7. *Heart failure* symptoms can worsen for a number of reasons. How sure are you that you know what to do, or whom to call, if your *heart failure* gets worse? (not at all sure, not very sure, somewhat sure, mostly sure, completely sure)
8. How well do you understand what things you are able to do to keep your *heart failure* symptoms from getting worse (for example, weighing yourself, eating a low salt diet, etc.)? (Do not understand at all, do not understand very well, somewhat understand, mostly understand, completely understand)
9. Over the *past 2 weeks*, how much has your *heart failure* limited your enjoyment of life? (extremely, quite a bit, moderately, slightly, not limited)
10. If you had to spend the rest of your life with your *heart failure* the way it is *right now*, how would you feel about this? (not at all satisfied, mostly dissatisfied, somewhat satisfied, mostly satisfied, completely satisfied)
11. Over the *past 2 weeks*, how often have you felt discouraged or down in the dumps because of your *heart failure*? (all the time, most of the time, occasionally, rarely, never)
12. How much does your *heart failure* affect your lifestyle? Please indicate how your *heart failure* may have limited your participation in the following activities *over the past 2 weeks*. (severe limited, limited quite a bit, moderately limited, slightly limited, did not limit at all, does not apply or did not do for other reasons)
  - Hobbies, recreational activities
  - Working or doing household chores
  - Visiting family or friends out of your home
  - Intimate relationships with loved ones

From Green, C.P., Porter, C.B., Bresnahan, D.R., et al. Development and evaluation of the Kansas City Cardiomyopathy Questionnaire: a new health status measure for heart failure. *J Am Coll Cardiol* 2000; 35:1245-1255.

Specific examples of how and when the dyspnea occurs should be sought. The mechanism of dyspnea should be considered. Shortness of breath may be caused by concomitant pulmonary disease or respiratory muscle dysfunction.<sup>17</sup> Increased ventilatory drive or exercise hyperventilation is believed to be a common cause of dyspnea in patients with heart failure,<sup>18-21</sup> but the precise mechanism of dyspnea has not been pinpointed. The mechanism of increased ventilatory drive in patients with heart failure is multifactorial and incompletely understood, but it may be related to increased peripheral chemosensitivity in the skeletal muscles and accumulation of lactic acid. Both of these may lead to exercise hyperpnea,<sup>22,23</sup> which tires the patient out at increasingly earlier points in exercise. This concept is consistent with the “muscle hypothesis,” according to which dyspnea in patients with heart failure actually begins in the skeletal muscles.<sup>22,23</sup> Exertional dyspnea can also occur when there is markedly elevated left ventricular filling pressure.

Multiple, complex mechanisms are operative in the production of exertional dyspnea in patients with heart failure, and probably no single mechanism is dominant. Nevertheless, the augmented ventilatory response to exercise in heart failure (such as increased breathing rate in relation to the amount of exercise) is correlated with hemodynamic alterations,<sup>24</sup> whereas peak ventilatory oxygen uptake ( $\dot{V}O_2$ ) is not. According to the dominant theory of increased exercise ventilatory response of heart failure, increases in carbon dioxide output in relation to peak oxygen consumption lead to bicarbonate buffering and accumulation of lactic acid.<sup>23</sup> Lactic acid builds up at relative low levels in patients with heart failure and acts as an additional stimulus to breathing. This buildup may also contribute to the sensation of dyspnea. In some patients, there is also an increase in airway dead space because of reduced perfusion of ventilated lung tissue, which leads to inefficient gas exchange. Despite this, arterial carbon dioxide concentration is driven to low levels during peak exercise in most patients with heart failure. According to the “muscle hypothesis” of exertional dyspnea, peripheral (i.e., skeletal muscle) chemoreceptors are stimulated by higher levels of arterial oxygen and carbon dioxide concentrations in heart failure, which leads to overactivation of ergoreflexes.<sup>25</sup> This overactivation increases both ventilatory drive and sympathetic nervous system activity through the activation of a central mechanism. Physical training in patients with heart failure may reduce exaggerated ergoreflex activity and thereby improve the response to exercise.<sup>26</sup> Clearly, exertional dyspnea in patients with heart failure is complex, multifactorial, and not simply a result of increased filling pressures. Reflex control mechanisms involving the heart, lungs, brain, and skeletal muscles and a buildup of lactic acid in the working muscles are probably involved; they would lead to an increased ventilatory response to exercise.

## Fatigue

As with dyspnea, the mechanism of fatigue in patients with heart failure is uncertain. Cardiac fatigue was widely assumed to be simply a result of low cardiac output, but since 2000, it has become clear that abnormalities of skeletal muscles and other noncardiac comorbid conditions such as anemia may contribute to fatigue. Abnormalities of high-energy phosphates in the skeletal muscles of patients with heart failure are well documented (see also Chapter 19),<sup>27-31</sup> even in the presence of normal regional blood flow.<sup>29</sup> Muscle fatigue is related to abnormal phosphocreatine depletion, acidosis, or both in the working muscle. The anaerobic regeneration of adenosine triphosphate (ATP) is impaired in the skeletal muscles of patients with heart failure. There is also a shift in fiber distribution: The percentage of the fast-twitch, glycolytic, easily fatigable type IIb fibers is increased.<sup>27</sup> Patients with heart

failure have major histological alterations in skeletal muscle and biochemical alterations,<sup>32</sup> including the development of skeletal muscle atrophy.<sup>33</sup> Significant ultrastructural abnormalities<sup>34</sup> lead to diminished oxidative capacity of working muscle.<sup>35,36</sup> Chronic fatigue begets further inactivity, which leads to further deconditioning and a greater extent of disability. In the late stages of heart failure, low cardiac output and anemia related to chronic disease probably also contribute to fatigue. Patients who are ambulatory with heart failure should be encouraged to stay physically active,<sup>37,38</sup> and participation in a structured exercise training program can improve exercise tolerance.<sup>39-41</sup>

## Other Symptoms of Heart Failure

An occasional patient with heart failure presents with palpitations, lightheadedness, or even frank syncope. In the authors' experience, this is unusual. However, heart block, arrhythmias with circulatory collapse, or even atrial fibrillation or premature beats may be a presenting feature of heart failure, which is especially common in specific conditions such as acute myocarditis, sarcoid cardiomyopathy, or Chagas' disease. Right upper quadrant pain caused by acute liver congestion or early satiety may be another presenting symptom. Additional presenting symptoms might include nocturnal angina, weight loss (weight gain is more common), and cough. Other signs and symptoms of heart failure are usually present. Sometimes symptoms of heart failure are more subtle and are often mistakenly misdiagnosed as “bronchitis” (dry productive cough), “asthma” (wheezing due to cardiac asthma), or “insomnia” (Hunter-Cheyne-Stokes respiration). Many endocrine abnormalities can be associated with heart failure and may be treatable. In asymptomatic people it is not uncommon for cardiomegaly to be diagnosed on a routine chest radiograph or for left bundle branch block or arrhythmia to be detected on an electrocardiogram; both situations are forerunners to the development of heart failure and cardiac dysfunction.

## CLINICAL EVALUATION OF PRESENTING SIGNS: PHYSICAL EXAMINATION

A careful physical examination is always warranted in the evaluation of patients with heart failure. The purpose of the examination is to help determine the cause and severity of the heart failure. Obtaining additional information about the hemodynamic profile, documenting the response to therapy, and determining the prognosis are important additional goals of the physical examination.

### General Inspection of the Patient

The diagnosis of heart failure is relatively straightforward by simple medical history and physical examination. It is not unusual for an experienced physician to sense the severity of the heart failure syndrome within the first few minutes of walking into the examination room, meeting the patient, and observing the patient carefully. Hospitalized patients often have labored or uncomfortable breathing. They may not be able to finish a sentence because of shortness of breath. Lying down may be difficult because of orthopnea. Altered respiratory signs such as coughing, Hunter-Cheyne-Stokes respiration, and cyanosis are sometimes observed. Peripheral cyanosis, which is limited to exposed skin, usually indicates inadequate perfusion or low cardiac output. In contrast, central cyanosis is uncommon, but when it occurs, it is found predominantly in the tongue, uvula, and buccal mucosa; its presence indicates intracardiac or intrapulmonary shunting. Some patients demonstrate cachexia, a particularly poor

prognostic sign. The presence of severe peripheral edema and ascites are obvious in visual inspection.

Examination of the arterial pulse is very important. The absence of pulses should be noted, as should the character of the pulse detected. Pulsus alternans (a strong beat alternating with a weak beat), although unusual, is virtually diagnostic for severe advanced heart failure. Pulsus paradoxus (a substantial diminishment in the amplitude of the arterial pulse during inspiration) is found in pericardial tamponade. It is usually confirmed by measuring blood pressure carefully during the phases of inspiration and expiration. Pulsus paradoxus is also seen in an occasional patient with severe asthma, pulmonary embolism, pregnancy, or marked obesity and in patients with superior vena cava syndrome. Patients with aortic stenosis may have diminished upstroke of the carotid pulse, whereas patients with severe, chronic aortic regurgitation manifest accentuated pulses and a series of findings related to a large stroke volume. Peripheral pulses may be absent in patients with coarctation of the aorta. Therefore, a thorough assessment of the pulses is always warranted.

### Assessment of the Volume Status of the Patient

Pertinent features of the cardiac physical examination, such as jugular venous distention and tissue congestion, are especially important in the accurate assessment of the patient with heart failure. It can be useful to dichotomize the signs of heart failure as those of volume overload and those of low cardiac output (see Figure 35-3).<sup>42</sup> Signs of volume overload include increased jugular venous distention, prominent V waves, gallop heart rhythm (or third heart sound [S3]), rales and pleural effusion, anasarca, ascites, and peripheral edema. On occasion, specific organomegaly is present; examples include enlarged and sometimes tender liver, enlarged spleen (rare), and cardiomegaly. According to the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial,<sup>43</sup> the presence of orthopnea and increased jugular venous distention may be useful for detecting increased intracardiac filling pressures, whereas a global assessment of inadequate perfusion ("cold profile") may be useful for detecting reduced cardiac index.

Despite the historical use of the term *congestive heart failure*, it is not unusual for patients with advanced heart failure to consistently demonstrate no evidence of volume overload.<sup>16</sup> For reasons that are unclear, such patients do not

seem to retain significant amounts of salt and water; hence, they are subject to overdiuresis, which leads in some cases to *prerenal azotemia*. Patients should be examined while they are lying down, with the head tilted at 45 degrees. The physician should examine a patient from the patient's right side (oslerian tradition). The most important assessment of volume status is careful examination of the jugular venous pressure; unfortunately, this is somewhat of a lost art.<sup>16,44,45</sup> It is important to understand that jugular venous pressure often reflects left- and right-sided filling pressures but that a substantial number of patients with heart failure have relatively normal intracardiac filling pressures and no distended neck veins. In patients with mild heart failure, the jugular venous pressure may be normal when the patient is lying with the head tilted at 45 degrees, but it rises to abnormal levels with compression to the right upper quadrant. This is referred to as *hepatojugular reflux*. To elicit this sign, the right upper quadrant should be compressed firmly, gradually, and continuously for 1 minute while the neck veins are observed. The presence of hepatojugular reflux that very slowly dissipates on release of hand pressure is a sign that intracardiac filling pressures are abnormally increased.<sup>46</sup>

Despite the common lack of abdominal complaints, some patients do accumulate fluid in the form of ascites or visceral edema. Examination of the abdomen should be performed to determine the presence of ascites, hepatosplenomegaly, or pulsatile, tender liver. Splenomegaly is rare in heart failure. However, hepatomegaly is common, and acute congestion can lead to rather severe right upper quadrant tenderness that mimics cholecystitis. On occasion, patients with acute decompensation and severe right upper quadrant pain may even go to the operating room for cholecystectomy with the suspicion of acute cholecystitis, where the actual problem is found to be acute hepatic congestion. Liver transaminase levels are often elevated during acute passive congestion, and in severe right-sided heart failure, levels of clotting factors and total bilirubin may be increased. Raised intra-abdominal pressures have been recognized in patients with congestion and decompensated heart failure, which further illustrates the evidence and hemodynamic impact of abdominal congestion.<sup>47</sup>

Normal, hyperdynamic, or sustained precordial pulsations may be present. Cardiomegaly tends to displace the point of maximal impulse, which is also sustained in cases of severe left ventricular hypertrophy. Physical examination of the precordial pulsation, however, is inadequate for assessing

		NO	Yes	<b>Signs/Symptoms of Congestion:</b> <hr/> Orthopnea/PND Jugular venous distension Hepatomegaly Edema Rales (rare in chronic heart failure) Elevated est. PASys Valsalva square wave Abdominal-jugular reflux

#### Possible Evidence of Low Perfusion:

Narrow pulse pressure	Cool extremities
Sleepy/obtunded	Hypotension with ACE inhibitor
Low serum sodium	Renal dysfunction

**FIGURE 35-3** Clinical presentation of acute heart failure syndrome based on congestion and perfusion. (From Nohria, A., Lewis E., Stevenson, L. W. (2002). Medical management of advanced heart failure. JAMA, 287, 628-640.)

the degree of left ventricular dysfunction. In some patients, a third heart sound is audible and palpable at the apex. Patients with enlarged or hypertrophied right ventricles may have a sustained and prolonged left parasternal impulse that extends throughout systole.

A third heart sound (or gallop rhythm) is most commonly present in patients with volume overload who have tachycardia and tachypnea. It may be absent in many patients with advanced heart failure, but the presence of a third heart sound can signify severe hemodynamic compromise.<sup>48</sup> The murmurs of mitral and tricuspid regurgitation are frequently present in patients with advanced heart failure, although severe regurgitation is frequently present in the absence of an audible murmur. The presence of jugular venous distention and a third heart sound imply a poor prognosis<sup>49</sup> and disease progression<sup>50</sup> and should always be sought and recorded in the notes.

Of interest is that signs of pulmonary congestion (such as rales, pulmonary edema, and elevated jugular venous pressure) are frequently absent even in patients with raised pulmonary capillary wedge pressure.<sup>16</sup> Similar to patients with long-standing mitral stenosis, patients with chronic, severe heart failure tend to have robust lymphatic drainage of the pulmonary interstitial spaces. The absence of rales does not preclude impending pulmonary edema, and direct hemodynamic measurements may sometimes be necessary. Instead, tachypnea (and in some extreme cases, hypoxia) is often associated with significant pulmonary congestion.

An increase in circulating volume is often associated with evidence of excessive adrenergic activity. This evidence includes diaphoresis, tachycardia, pallor, and coldness of the extremities. The adrenergic nervous system is similarly activated during low cardiac output. Relief of congestion is always an important primary goal in the management of patients with chronic heart failure; thus, the identification of the volume overload state is a critical step in the physical examination.<sup>51</sup>

### Signs of Low Cardiac Output

Patients in a low-output state may exhibit a wide variety of clinical signs (from cool, dry skin, pallor, or peripheral cyanosis to normal color, warmth, and appearance). In some cases, pulses may be diminished and blood pressure may be low with a narrow pulse pressure. Some patients demonstrate virtually no signs of inadequate blood flow despite a low cardiac output. They may be alert and cognitively responsive despite extreme diminishment in cardiac index (i.e.,  $<1.5$  L/min/m<sup>2</sup>). This finding is probably related to the body's remarkable ability to redistribute flow to vital organs (including the brain) in the presence of very diminished cardiac output. In contrast, with acute cardiogenic shock (e.g., acute myocardial infarction), patients may develop cool skin, pallor, changes in mental status or cognitive deficits, oliguria, peripheral cyanosis, and hypothermia. Pulsus alternans, if present, is virtually pathognomonic of a low-output state<sup>52</sup> but is more often seen in terminally ill patients. Compensatory tachycardia (especially in young patients) and low blood pressures are more common in the setting of profound signs and symptoms of heart failure, and they are of concern in low-output states. Clinical assessment of inadequate perfusion can yield reasonably accurate findings.<sup>43</sup>

### Signs of Cachexia (see also Chapter 21)

The importance of cachexia in patients with severe end-stage heart failure is currently the subject of intense research.<sup>53,54</sup> It is believed that unintentional weight loss and cachexia portend a very poor prognosis. Although the mechanism of cachexia is not entirely understood, it may be related to various cytokines, including tumor necrosis factor  $\alpha$ , whose levels are known to be increased in patients with heart failure with poor prognosis.<sup>55</sup>

## LABORATORY EVALUATION OF THE PATIENT WITH HEART FAILURE

As shown in Tables 35-4 and 35-5, the diagnostic sensitivity and specificity of the clinical history and physical examination for diagnosing patients with heart failure are relatively poor. For this reason, laboratory testing has assumed a progressively greater role in establishing the diagnosis of heart failure.

### Biochemical Evaluation: Biomarker Testing (see also Chapter 37)

It is recommended that patients with new-onset heart failure undergo a battery of routine laboratory tests when the condition is first diagnosed. This is also recommended for patients with chronic heart failure and acute decompensation, when there is a change in therapeutic intervention, or in periodic monitoring for clinical stability. Very often, a basic metabolic panel that includes measurement of electrolytes and renal markers is useful, sometimes with additional thyroid or liver function tests or measurement of markers of glycemic or lipid control.<sup>56,57</sup> The recognition of anemia in patients with heart failure who have a poor prognosis has also prompted periodic evaluation of hemoglobin levels and iron profiles, but some patients may have reversible abnormalities.<sup>58</sup>

Several cardiac biomarkers may provide incremental diagnostic and prognostic information, such as B-type (brain) natriuretic peptide (BNP) and cardiac troponin.<sup>59</sup> BNP and its amino-terminal fragment (NT-proBNP) in particular have provided important diagnostic utility for heart failure in the acute clinical setting (Figure 35-4). There are still ongoing clinical studies to determine the appropriateness of their uses in guiding therapy, because clinical trials supporting the drugs and devices received their approval *before* broad adoption of biomarker testing. Testing for markers for inflammation (such as erythrocyte sedimentation rate, C-reactive protein, or other specific rheumatological disease markers) can sometimes be helpful in unmasking myocarditis or other inflammatory causes, but routine measurements are yet to be adopted.<sup>59</sup> Viral antibody titers have also found to yield little information and are rarely indicated, inasmuch as the appropriate treatment with positive viral antibody titers remains unclear at this point. Other commonly measured biomarkers indicate renal function (blood urea nitrogen and serum creatinine levels), electrolyte balance (sodium and potassium levels), oxidative process (uric acid level), liver function (total bilirubin level, aminotransferase levels, prothrombin time), and hematological status (hemoglobin, red blood cell distribution width); the majority of them are important prognostic indicators of disease severity. The use of cardiac biomarker evaluation in heart failure is discussed further in Chapter 37.

### Electrocardiographic Evaluation: Electrocardiography

Electrocardiographic evaluation remains a valuable and broadly available laboratory test for patients with heart failure. An electrocardiogram should be routinely obtained and studied for evidence of underlying structural alterations (e.g., left ventricular hypertrophy, prior myocardial infarctions), for rhythm abnormalities as a cause or consequence of heart failure decompensation (e.g., atrial fibrillation, frequent ectopic beats, or other sustained arrhythmias), and for the presence of conduction abnormalities (such as bundle branch block or intraventricular conduction delays) that may lead to electrical dyssynchrony. Frequently, Holter monitoring or event monitoring can assist with the detection of such abnormalities.

The QT interval should be noted because many types of therapy can further prolong the QT interval and provoke lethal arrhythmias. In patients who have undergone cardiac resynchronization therapy (CRT), acute changes in the QRS complex or structure may also signify underlying pacing or programming alterations (although such changes may or may not result in reversal of cardiac remodeling, and they are not a prerequisite for symptomatic improvement). The presence of ectopic beats, although benign in most cases, may also lead to cardiac insufficiency when the burden is high.

### Morphological Evaluation: Chest Radiography, Echocardiography, and Magnetic Resonance Imaging (see also Chapter 36)

The authors believe that chest radiography remains important in the assessment of patients with heart failure. Radiographic evidence of pulmonary congestion may precede the presence of rales. Careful examination of the cardiac size and shape, as well as the pulmonary vasculature, remains part of routine evaluation of all patients with heart failure. In recipients of CRT implantation, posteroanterior and lateral views of chest radiographs may help determine inappropriate left

ventricular lead positioning that may contribute to persistent symptoms (Figure 35-5).

Echocardiographic evaluation remains an essential diagnostic tool for assessing cardiac structure and function. The focus has traditionally been on left ventricular ejection fraction, and the degree of underlying chamber dilation (or hypertrophy) can be overlooked. In fact, it is seldom recognized that the estimation of effective stroke volume (i.e., the ejection fraction relative to the left ventricular end-diastolic volume) is more appropriate in determining whether the signs and symptoms can be explained by cardiac causes. Therefore, chamber size is an important indicator of compensatory progression of disease, and the propensity for long-term recovery. Other aspects of chamber dilation can lead to valvular regurgitation (from annular dilation) or mechanical dyssynchrony from prolonged interventricular and intraventricular conduction delays. Doppler study estimates of right ventricular or pulmonary artery systolic pressure are helpful surrogates for measurements of pulmonary hypertension. Doppler patterns of mitral, tricuspid, and pulmonary vein flow can provide estimates of intracardiac pressures and diastolic staging, and tissue Doppler indices can characterize the myocardial abnormalities related to diastolic dysfunction and restrictive physiology.

The clinical utility of mechanical dyssynchrony assessment remains debated. Left atrial enlargement and left ventricular hypertrophy are common findings in diastolic heart failure, whereas left ventricular outflow tract obstruction (at rest or provoked by amyl nitrite), caused by asymmetrical septal hypertrophy or systolic anterior motion of the mitral leaflet, may occur in the setting of hypertrophic cardiomyopathy. The presence of thrombus in the left ventricular appendage or the left atrium or left atrial appendage can be a surrogate indicator of low cardiac output status, and should warrant aggressive evaluation. The presence of wall motion abnormalities or abnormalities of cardiac structure and performance are obvious hallmarks of stage B heart failure. This topic is further discussed in Chapter 36.

Magnetic resonance imaging (MRI) has been considerably useful in the morphological and functional assessment of the heart. At present, however, this technology is used mainly to gain additional information. Cardiac MRI, like echocardiography, requires viewing in multiple oblique planes of the heart. The imaging techniques are designed to render blood dark or bright and to depict various aspects of motion, flow, and perfusion (Figure 35-6). Different techniques have been used for assessing cardiac function with MRI. New magnetic

resonance sequences enable the study of cardiac motion (myocardial tagging, blood flow velocity (phase contrast method), and myocardial scarring (late enhancement technique), and specific patterns may indicate the presence of infiltrative diseases (such as amyloidosis, sarcoidosis, hemachromatosis) or myocarditis (see also Chapter 36).

**Ischemic Evaluation: Myocardial Viability and Coronary Anatomy (see Chapters 23 and 36)**

Coronary artery disease is the cause of heart failure in about two thirds of patients with left ventricular systolic dysfunction, and up to one third of patients with nonischemic cardio-

myopathy experience chest pain that mimics angina (see also Chapter 23).<sup>56,60</sup> Researchers have also pointed out that underdiagnosis or misdiagnosis of ischemic heart disease among patients with heart failure is common if angiographic evaluation was not undertaken as part of the heart failure workup.<sup>61,62</sup> Patients with systolic heart failure and severe coronary artery disease have, by definition, ischemic cardiomyopathy, and in some cases this reduction in myocardial function may be improved with percutaneous coronary intervention (PCI) or surgical revascularization. Most patients with heart failure should be considered candidates for diagnostic coronary angiography to determine whether significant coronary artery disease is present, especially in patients for

**FIGURE 35-6** Cardiac magnetic resonance imaging (MRI) assessment of myocardial viability with cine-imaging (*top left*), myocardial tagging imaging (*top right*), TurboFlash perfusion imaging with gadolinium (*bottom left*), and delay-enhanced imaging with gadolinium (*bottom right*).

whom revascularization is often very beneficial. This clearly remains highly controversial because such an invasive procedure may not be needed in most patients with a good clinical history and in whom clinical suspicion of heart failure is low because of the lack of cardiovascular risk factors. However, coronary artery disease may not be easily predicted from the medical history, physical examination findings, and echocardiogram.<sup>63</sup> For a patient who has angina pectoris and heart failure, an even more compelling argument can be made for performing diagnostic coronary angiography. On the other hand, severe coronary artery disease and reduced left ventricular function are present but anginal symptoms are minimal, demonstration of myocardial viability is of paramount importance (and is discussed in Chapter 37). Also, diagnostic evaluation for coronary artery disease provides only a “snapshot” at the time of evaluation, and atherosclerotic diseases may progress over time, leading to progressive ischemia.

In the case of cardiac MRI, assessment of myocardial viability is of utmost importance to detect ischemic but viable myocardium for potential therapeutic interventions. In patients with heart failure, of whom 60% to 70% suffer from coronary artery disease, these techniques are helpful for therapeutic and prognostic stratification. Late-enhancement MRI has become a tool for determining lesion size in patients with myocardial infarction. The spatial and temporal relationship measured through differential uptake and release of contrast material in the viable tissue versus scar tissue can provide the location as well as extent of the scar.

### Functional Evaluation: Cardiopulmonary Exercise Testing (see Chapter 57)

For many activities of daily living, a fundamental requirement is the ability to perform aerobic work. Functional capacity is usually measured in metabolic equivalents (METs) where 1 MET represents 3.5 mL of O<sub>2</sub>/kg/min. Exercise testing is a valuable tool in the diagnosis and assessment of patients with heart failure<sup>38</sup> (Table 35-6). It has long been recognized that the simple history and physical examination, as well as various subjective functional classification systems, can be too nonspecific and relatively insensitive. Therefore, exercise

testing can add substantial precision in the initial evaluation of the patient with heart failure. This is particularly true when heart transplantation is a consideration or when quantitative information on assessing an individual patient’s disability is necessary.

The primary goal of metabolic exercise testing is to determine the functional status and prognosis of the patient objectively (see also Chapter 57). Exercise testing in patients with heart failure was first widely applied in the late 1970s to test the response of patients to various drug therapies.<sup>13</sup> Although it has become apparent that response of exercise to short-term drug therapy is not predictive of long-term drug efficacy,<sup>64</sup> useful information regarding how to gauge the degree of disability more precisely has emerged from these studies. More recently, exercise testing has been used to assess the severity of heart failure and to help determine the prognosis for individual patients. In retrospect, it has become clear that measurements of the peak V<sub>O<sub>2</sub></sub> and the slope of the ratio of ventilation (V<sub>E</sub>) to carbon dioxide production (V<sub>CO<sub>2</sub></sub>) (V<sub>E</sub>/V<sub>CO<sub>2</sub></sub>) are powerful predictors of prognosis. Serial improvement in peak V<sub>O<sub>2</sub></sub>, either in response to therapy or occurring spontaneously, has also been demonstrated to have prognostic value.<sup>65</sup> However, the V<sub>E</sub>/V<sub>CO<sub>2</sub></sub> slope remains the strongest predictor of prognosis, better even than peak V<sub>O<sub>2</sub></sub>.<sup>66</sup> The usefulness of cardiac output estimation during standard metabolic exercise testing is under intense investigation.<sup>67</sup>

Metabolic exercise testing is of value in determining whether the heart or lungs are causing the dyspnea. Increased ventilation (V<sub>E</sub>) with regard to carbon dioxide production is a hallmark finding of patients with heart failure<sup>66,68</sup> (Figure 35-7). The slope of the V<sub>E</sub>/V<sub>CO<sub>2</sub></sub> ratio offers important prognostic information, perhaps even more than V<sub>O<sub>2</sub></sub>.<sup>68,69</sup> However, the increase in V<sub>E</sub>/V<sub>CO<sub>2</sub></sub> slope observed in patients with heart failure is nonspecific<sup>70</sup>; it can also be abnormally steep in patients with primary lung disease.<sup>71</sup>

Assessment of functional capacity is typically performed on a motorized treadmill or a stationary bicycle ergometer. The functional capacity can be estimated or measured directly by gas exchange methods (V<sub>O<sub>2</sub></sub>) from the highest work level achieved. Estimates of functional capacity such as exercise duration are less reliable than direct measurements of gas exchange. Peak V<sub>O<sub>2</sub></sub> and anaerobic ventilatory threshold are

**TABLE 35–6 Weber Classification of Functional Impairment in Aerobic Capacity and Anaerobic Threshold as Measured during Incremental Exercise Testing**

Class	Degree of Impairment	Vo <sub>2</sub> Max (mL/min/kg)	Anaerobic Threshold (mL/min/kg)
A	None to mild	>20	> 14
B	Mild to moderate	16–20	11–14
C	Moderate to severe	10–16	8–11
D	Severe	6–10	5–8
E	Very severe	<6	≤4

Vo<sub>2</sub>, ventilatory oxygen uptake.

highly reproducible and therefore recommended for evaluation of patients with heart failure.<sup>38</sup> The peak Vo<sub>2</sub> is currently the standard used by most laboratories. However, maximal exercise testing has well-known limitations in the setting of heart failure.<sup>72</sup> Because patients generally have a reduced level of physical activity, peak Vo<sub>2</sub> may not be a relevant indicator of everyday exercise capacity. The 6-minute walk or shuttle-walk tests, on the other hand, are simpler and do not require special equipment.<sup>73,74</sup> Simply assessing exercise duration can also provide important prognostic information. However, it is controversial whether these submaximal exercise tests are accurate predictors of prognosis,<sup>75,76</sup> inasmuch as the results may depend on the patient's motivation and the operator's enthusiasm. The point of aerobic threshold is, however, insensitive to patient motivation. In this regard, submaximal exercise testing may be an ideal test of everyday activity capacity, but there is no uniform agreement on how to best perform it. A prime use of metabolic exercise testing is in the evaluation of patients for heart transplantation. A peak Vo<sub>2</sub> of more than 14 mL/kg/min is considered “too well” for transplantation in many centers.<sup>77</sup> Because this information was derived from a relatively aged population before the widespread use of β-adrenergic blockers, this criterion has posed some problems with younger individuals, in whom extremely poor functional capacity is not below this cutoff range. In the most recent guidelines about advanced heart failure,<sup>78</sup> the criteria have therefore been refined to include an age- and gender-predicted comparison, and a peak Vo<sub>2</sub> of more than 50% of predicted normal is now often considered as being impaired to the point at which heart transplantation might be considered.

Additional information from the exercise test includes the chronotropic response to exercise, which is indicative of abnormal parasympathetic activation, a well-described feature of heart failure.<sup>79</sup> Abnormal return of parasympathetic activity after exercise (that is, reduction in heart rate to 12 beats or less 1 minute after cessation of exercise) is also abnormal in many patients with heart failure.

**Hemodynamic Evaluation: Cardiac Catheterization**

In certain individual circumstances, it may be prudent to consider invasive hemodynamic evaluation and monitoring as part of the clinical evaluation of patients with heart failure. This was the predominant mode of quantifying disease during the development of neurohormonal antagonists. The main shift in practice occurred as a result of both fading interest in using intravenous vasoactive therapies and increasing concerns regarding the lack of incremental long-term benefit (or even harm) in using such strategies.

The results of the ESCAPE trial have clarified the usefulness of invasive monitoring to some degree.<sup>80</sup> Currently,

**FIGURE 35–7** Plot of minute ventilation (Ve) versus the rate of carbon dioxide production (Vco<sub>2</sub>) in patients with different degrees of severity of chronic heart failure (CHF). (From Coats AJ. Heart failure: What causes the symptoms of heart failure? *Heart* 2001;86:574-578.)

patients who are doing poorly with severe congestion, ascites, anasarca, or obvious signs and symptoms of low cardiac output might be considered for hospitalization with hemodynamic monitoring. When constrictive physiology or restrictive cardiomyopathy is suspected, right-sided heart catheterization should also be considered. With improved imaging techniques, the role of right-sided heart catheterization is diminishing, although it is still useful as a confirmatory test in patients with complex or unusual forms of heart failure. Most right-sided heart catheterizations performed in patients with heart failure today are used to help guide therapy rather than to make a specific diagnosis. Clearly, it is no longer a routine diagnostic component of the evaluation algorithm.

**Histological Evaluation: Endomyocardial Biopsy**

The role of diagnostic endomyocardial biopsy in patients with heart failure has diminished,<sup>81</sup> because of the results from the Myocarditis Treatment Trial, which implied a sense of futility regarding various treatment strategies for acute myocarditis.<sup>82</sup> It is unclear whether certain forms of cardiomyopathy and myocarditis can be managed better with the aid of diagnostic endomyocardial biopsy,<sup>82</sup> especially with some recent support for immunosuppression and immunosuppression in the setting of chronic persistent myocarditis without viral persistence. If acute inflammatory myocarditis is suspected, endomyocardial biopsy should still be considered, especially with the current availability of newer molecular markers.<sup>83</sup> Selected patients may in fact respond to various immunosuppressant therapies, but success cannot be predicted reliably.<sup>84</sup>

Although the role of endomyocardial biopsy is diminishing in the evaluation of patients with heart failure, it is important that clinicians keep in mind that specific entities can be diagnosed through only this technique. Endomyocardial biopsy is a requirement for the diagnosis of acute myocarditis, inasmuch as the clinical diagnosis of this entity is notoriously insensitive. Some types of heart failure, including fulminant myocarditis, giant-cell myocarditis, sarcoidosis, and amyloid heart disease, are quite distinct and are variably responsive to different management strategies. For example, amyloid heart disease is usually refractory to both conventional therapy and heart transplantation. Patients with fulminant myocarditis may recover spontaneously after aggressive hemodynamic support.<sup>85</sup> Patients with giant-cell myocarditis often have a rapid downhill course and may be eligible

for immunosuppressive protocols or heart transplantation.<sup>86</sup> Therefore, although its use is now more limited, endomyocardial biopsy clearly has a role when specific types of cardiomyopathy are suggested on clinical grounds, and the biopsy information may be quite helpful in planning therapy. Table 35-7 outlines the 14 clinical scenarios in which endomyocardial biopsy should be considered, as recommended by a published consensus statement.<sup>84</sup>

## Genetic Evaluation (see Chapter 27)

Clinical genetic testing for monogenetic mutations of sarcomeric and metabolic genes in inherited cardiomyopathies has become available in commercial testing laboratories. Many of the inherited cardiomyopathies have been extensively reviewed in Chapter 27. Several important hurdles facing routine genetic testing remain. First, mapping specific gene mutations can be highly complex, and some of the affected genes are large, which can translate into labor-intensive and expensive ventures. Second, despite the association between a family history of heart failure and underlying genetic predispositions, only a small proportion of mutations are known to lead to inherited cardiomyopathies. This means that a negative result of a test for unexplained cardiomyopathies cannot provide the confidence to rule out any underlying genetic mutations. Third, treatment options have yet to catch up with the availability of genetic information to help clinicians to tailor their management strategies. For now, the most efficient use of genetic testing remains identification of at risk individuals for inherited cardiomyopathies who then require careful evaluation and close monitoring, particularly in the case of hypertrophic cardiomyopathy and arrhythmogenic right ventricular dysplasia.<sup>87</sup> For specific diseases such as Fabry's disease or transthyretin amyloidosis, genetic tests are available for confirmatory purposes also. Nevertheless, pharmacogenomic-guided therapy is still under intensive clinical investigations. Some of the challenges of pharmacogenetics are discussed in Chapter 42.

## FUTURE DIRECTIONS

The current approach to clinical evaluation of heart failure is still confined to the traditional patient-doctor encounter, including the elicitation of the medical history for suspect symptoms, bedside examinations to detect clinical signs of congestion and perfusion, and the decision to conduct confirmatory or monitored testing in search for therapeutic interventions. These require the patient's physical presence and may capture only a "snapshot" of the clinical picture. Simple longitudinal information such as daily weighings, self-reports of health status, and vital sign measurements have been widely used but are often plagued with nonadherence, subjectivity, and selectivity in self-reporting. The next step in clinical evaluation relies on the ability of technological advances to quantify disease severity both at the time of clinical encounter and at home. Some of these advances are already available as implantable devices that yield adjunctive parameters; others have linked disease management with home care programs. Examples of information yielded by this technology include arrhythmia detection and management, intracardiac impedance monitoring, and even detection of intracardiac filling pressures. External devices, both stand-alone and portable versions, are also becoming increasingly available to measure physiological and electrocardiographic information. When the appropriate configurations and methods are established, such "ambulatory" insight can provide insight and clarity into the clinical profile, which could transform the way physicians evaluate (and ultimately manage) patients with heart failure.

**TABLE 35-7** Indications for Endomyocardial Biopsy: 14 Clinical Scenarios

Scenario	Recommendation (Strength/Level)
1. New-onset heart failure of <2 weeks' duration associated with a normal-sized or dilated left ventricle and hemodynamic compromise	I/B
2. New-onset heart failure of 2 weeks' to 3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1–2 weeks	I/B
3. Heart failure of ≥3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 1–2 weeks	IIa/C
4. Heart failure associated with a dilated cardiomyopathy of any duration associated with suspected allergic reaction and/or eosinophilia	IIa/C
5. Heart failure associated with suspected anthracycline cardiomyopathy	IIa/C
6. Heart failure associated with unexplained restrictive cardiomyopathy	IIa/C
7. Suspected cardiac tumors	IIa/C
8. Unexplained cardiomyopathy in children	IIa/C
9. New-onset heart failure of 2 weeks' to 3 months' duration associated with a dilated left ventricle, without new ventricular arrhythmias or second- or third-degree heart block, that responds to usual care within 1–2 weeks	IIb/B
10. Heart failure of >3 months' duration associated with a dilated left ventricle, without new ventricular arrhythmias or second- or third-degree heart block, that responds to usual care within 1–2 weeks	IIb/C
11. Heart failure associated with unexplained hypertrophic cardiomyopathy	IIb/C
12. Suspected arrhythmogenic right ventricular dysplasia	IIb/C
13. Unexplained ventricular arrhythmias	IIb/C
14. Unexplained atrial fibrillation	III/C

## Use of Cardiac Imaging in the Evaluation of Heart Failure

Hisham Dokainish, Matthias Friedrich, Maria C. Ziadi, and Rob S. Beanlands

Noninvasive cardiac imaging plays a critical initial role in the diagnosis and subsequent management of patients with heart failure. Echocardiography, cardiac magnetic resonance (CMR) imaging, and nuclear cardiac imaging are all noninvasive tests commonly used in patients with heart failure. This chapter describes the utility of these noninvasive cardiac imaging techniques in the diagnosis and management of patients with both systolic and diastolic heart failure, including sections on assessing heart failure with a depressed and preserved ejection fraction, assessment of right ventricular (RV) function, the role of imaging with regard to implanting cardiac devices, and future directions for cardiac imaging in heart failure.

### ASSESSMENT OF THE LEFT VENTRICLE: VOLUMES, EJECTION FRACTION

#### Echocardiography

In the clinical setting, 2-dimensional echocardiography is the noninvasive imaging test most commonly used to assess left ventricular (LV) volume, as well as calculating LV ejection fraction (LVEF); these measurements are necessary for determining the proper management of patients with heart failure.<sup>1-4</sup> Although M-mode measurements can be used, more accurate measurements of LV systolic and diastolic volumes are obtained by biplane Simpson's method or the area-length method used in the apical two- and four-chamber views (Figure 36-1).<sup>5</sup> The use of harmonic imaging has greatly improved endocardial-blood border differentiation in technically difficult studies, and the use of intravenous contrast material further increases the accuracy of assessing LV echocardiographic

Spectral Doppler imaging can also be used to determine cardiac output in patients with heart failure, and pulsed-wave Doppler imaging is used in the left ventricular outflow tract to determine stroke volume (Figure 36-2).

#### Cardiac Magnetic Resonance Imaging

CMR imaging has emerged as an important imaging technique with regard to the morphological and functional assessment of patients with heart failure. CMR imaging requires acquisition of multiple oblique planes in relation to the heart (Figure 36-3). The imaging techniques are designed to render blood dark or bright and to depict various aspects of cardiac motion, blood flow, and myocardial perfusion. CMR imaging is considered the reference standard for the quantitative assessment of systolic function.<sup>10</sup> If CMR imaging is used strictly for the assessment of LV function, the acquisition time of a scan usually does not exceed 10 minutes. The accurate quantification of volumes can be used to calculate LVEF, stroke volume, and cardiac index. This is of particular importance in patients with heart failure and a normal ejection fraction (e.g., in restrictive cardiomyopathy or cardiac amyloidosis), in whom low-output states can be determined even if the ejection fraction is normal. Different techniques have been used for assessing cardiac function with magnetic resonance imaging (MRI). New magnetic resonance sequences allow for the assessment of 3-dimensional cardiac motion by labeling ("tagging") specific myocardial regions (Figure 36-4). The rotational and translational motion of the left ventricle can be determined by following the motion of the tags, which has been likened to the wringing of a wet towel. During systole, there is clockwise twisting motion at the base and a counterclockwise rotation at the apex (Figure 36-5). The untwisting motion occurs very early in diastole and is directly related to myocardial relaxation. The rate of untwisting may be used as a measure of the rate and completeness of

volumes.<sup>6</sup> Although 2-dimensional echocardiography is relatively well correlated with LV volumes that are obtained by CMR imaging, the correlation with CMR imaging is better in 3-dimensional echocardiography.<sup>7-9</sup> Once LV systolic and diastolic volumes are measured, LV stroke volume can be readily calculated as LV end-diastolic volume – LV end-systolic volume.<sup>5</sup> The LVEF is calculated as the ratio of stroke volume to LV end-diastolic volume.<sup>5</sup>

relaxation and may serve as an estimate of early diastolic filling. Despite the strengths of CMR imaging for assessing cardiac structure and function in patients with heart failure, the applicability of this technique is currently limited, insofar as patients with implantable cardioverter-defibrillators

or biventricular pacemakers, or both, cannot be placed within the electromagnetic waves of the magnet, which may interfere with function of the intracardiac defibrillators or biventricular pacemakers. However, CMR imaging-compatible pacemakers are now available in Europe (Advisa MRI SureScan pacemaker), which suggests that this problem may be ameliorated in the future.

## Nuclear Imaging

### Radionuclide Angiography

Radionuclide angiography is a highly reproducible for measuring LV function when performed either by *first-pass* or by *multiple-gated acquisition techniques*.<sup>11,12</sup> Technetium-99m (<sup>99m</sup>Tc)-labeled red blood cells are used to define the blood pool. First-pass techniques yield a high target-to-background ratio, more distinct visualization of the separate cardiac chambers, and rapid imaging. In contrast, the multiple-gated technique enables repeated assessment of cardiac function, high count density, and acquisition of images in multiple projections, and it is therefore best for the assessment of LVEF.

### Echocardiography-Gated SPECT with Myocardial Perfusion Imaging

Although gated single photon emission computed tomography (SPECT) with <sup>99m</sup>Tc or thallium-201 (<sup>201</sup>Tl) has been validated against other techniques for assessing LV function,<sup>13,14</sup> SPECT is generally viewed as less accurate than radionuclide angiography because of its greater variability. The best use for this technique has been the determination of wall motion to determine whether a perfusion defect represents scar or attenuation artefact.<sup>15</sup>

### Echocardiography-Gated PET with Myocardial Perfusion Imaging

This method enables better tissue characterization of perfusion, metabolism, and function.<sup>16</sup> Because the timing of image acquisition is immediately after stress, rubidium-82 (<sup>82</sup>Rb)-labeled positron emission tomography (PET) is better able to estimate LVEF and volumes at peak stress than is SPECT, and it also yields additional diagnostic information about disease severity.<sup>16,17</sup>

**FIGURE 36-1** Calculation of left ventricular (LV) stroke volume and ejection fraction by method of discs in a patient with ischemic cardiomyopathy. The LV end-diastolic volume was 275 mL (*top*), and the LV end-systolic volume was 181 mL (*bottom*). Therefore, LV stroke volume was 94 mL, and the LV ejection fraction was 34%. Note the implantable cardiac defibrillator wire in the right ventricle (*yellow arrow*) with a pacemaker lead visualized in the right atrium (*blue arrow*).

**FIGURE 36-2** Use of spectral Doppler imaging for the calculation of cardiac output in a patient with advanced non-ischemic cardiomyopathy. With the use of pulsed-wave Doppler imaging in the apical five-chamber view, the sample volume is placed in the left ventricular outflow tract (LVOT). Integrating the LVOT spectral tracing (*blue lines*) yields a velocity time integral (VTI). After the LVOT area is calculated as the square of the diameter of the LVOT  $\times 0.785$ , the stroke volume can be determined as LVOT area  $\times$  LVOT VTI. The cardiac output (L/minute) can then be calculated as the heart rate  $\times$  stroke volume. In the example in this figure, the calculated cardiac output was 2.2 L/min, which is depressed.

**FIGURE 36-3** Example of short-axis stack in cardiac magnetic resonance imaging in a patient with heart failure and depressed left ventricular ejection fraction.

**FIGURE 36-4** Series of magnetic resonance images in a control patient with normal left ventricular function (temporal resolution 35 msec). The horizontal and vertical lines (myocardial tags) are superimposed on the conventional magnetic resonance image. From the movement of the grid crossing points, the contraction and relaxation behavior of the left ventricle can be determined. During isovolumic contraction, there is a counterclockwise rotation at the apex, followed by systolic shortening. During isovolumic relaxation, there is a clockwise rotation (“untwisting”), followed by diastolic lengthening. This systolic-diastolic contraction-relaxation behavior is altered in patients with diastolic dysfunction, with prolongation of diastolic back-rotation. (From Mandinov L, Eberli F, Seiler C, et al: Diastolic heart failure. *Cardiovasc Res* 2000;45:813-825.)

## DETECTION OF MYOCARDIAL ISCHEMIA AND MYOCARDIAL INFARCTION

### Echocardiography

Identification of ischemia as the cause of heart failure is of great importance in patients with systolic dysfunction, insofar as revascularization can improve LV function and the patient's functional status. Echocardiography can demonstrate the presence of previous ischemic injury, most typically myocardial infarction, which can be visualized as thin

(<6 mm in diameter), echo-dense (“bright”) LV walls that contract poorly in relation to other normal LV myocardial segments. The absence of segmental wall motion abnormalities (e.g., global hypokinesis) does not necessarily preclude an ischemic cause of heart failure. Similarly, segmental abnormalities do not necessarily preclude a nonischemic cause. For example, patients with dilated cardiomyopathy from sarcoidosis may have regional myocardial disease.<sup>4,18,19</sup>

Stress echocardiography, conducted either with exercise treadmill or bicycle or pharmacologically (with dobutamine), has been shown to help accurately identify ischemic and

**FIGURE 36-5** Ejection phase of the left ventricle at the base (A) and at the apex (B) of a healthy subject. End-systolic acquisitions are overlaid with corresponding local trajectories. There is a clockwise rotation at the base and a counterclockwise rotation at the apex. This motion pattern has been described as a systolic wringing motion, and its analysis provides a more sophisticated approach to quantifying regional left ventricular systolic function than do the traditional methods of analyzing endocardial shortening and simple wall thickening. (From Stuber M, Scheidegger MB, Fischer SE, et al: Alterations in the local myocardial motion pattern in patients suffering from pressure overload due to aortic stenosis. *Circulation* 1999;100:361-368.)

**FIGURE 36-6** A-D, Cardiac MRIs in patients with dilated cardiomyopathy (DCM). A, DCM is evident without gadolinium enhancement. B, In a patient with known previous myocardial infarction that resulted in heart failure, late gadolinium enhancement is seen throughout the subendocardium, causing thinning particularly in the septum and inferolateral wall. C, In a patient with the presumed clinical diagnosis of coronary angiography, late gadolinium-enhanced CMR imaging clearly shows an inferolateral infarction despite the normal coronary arteries; the patient's heart failure is probably related to coronary disease and not to DCM. D, In a patient with DCM, the midwall of the septum in the ventricular circumferential fibers is enhanced by late gadolinium. This pattern of fibrosis is recognized by pathologists but had not been previously visualized in vivo. E, Kaplan-Meier survival curves of the occurrence of major cardiac events in patients with proven DCM according to the presence of intramural fibrosis. Fibrosis was a powerful predictor of outcome, which was poorer in relation to worsening cardiac volumes and ejection fraction. (A to D, From McCrohon JA, Moon JC, Prasad SK, et al: Differentiation of heart failure related to dilated cardiomyopathy and coronary artery disease using gadolinium-enhanced cardiovascular magnetic resonance. *Circulation* 2003;108:54. E, From Assomull RG, Prasad SK, Lyne J, et al: Cardiovascular magnetic resonance, fibrosis, and prognosis in dilated cardiomyopathy. *J Am Coll Cardiol* 2006;48:1977.)

infarcted myocardial segments, and the findings are correlated with patient's prognosis.<sup>20-22</sup> For evaluating suspected ischemic heart disease, the advantages of stress echocardiography include relatively low cost, rapid performance and availability of results, relative ease of performing the study (because of low technological requirements), and lack of radiation exposure.<sup>20,21</sup> Disadvantages include the need for expert readers to minimize erroneous interpretation and technical difficulties in scanning certain patients, particularly those with significant lung disease or morbid obesity.<sup>20,21</sup>

### Cardiac Magnetic Resonance Imaging

Late gadolinium enhancement can be used to reliably differentiate patients with ischemic cardiomyopathy from patients with nonischemic cardiomyopathy<sup>23</sup> without the need for stress perfusion imaging (Figure 36-6). Gadolinium, an agent used for extracellular imaging, normally does not enter the myocardium because cardiac muscle is packed tightly. After

myocardial infarction, however, the extracellular space is expanded because of cellular rupture, which allows for a distribution of the gadolinium within the myocardial scar. The optimal time for gadolinium imaging for late enhancement is after 10 to 15 minutes. The myocardial scar secondary to myocardial ischemia invariably involves the subendocardial layer because of the transmural perfusion pressure gradient, whereas myocardial scars that are secondary to nonischemic injury typically demonstrate a regional distribution that is fairly distinct from that seen with myocardial ischemia or infarction.<sup>24</sup> Specific patterns have been associated with several myocardial diseases such as myocarditis (see Chapter 31),<sup>25</sup> dilated cardiomyopathy (see Chapter 24),<sup>23</sup> and hypertrophic cardiomyopathy (see Chapter 25).<sup>26</sup> With cardiac sarcoidosis,<sup>27</sup> there is evidence of a transmural myocardial scar; however, the distribution of this myocardial scarring does not necessarily reflect coronary artery anatomy. Gadolinium should be used cautiously in some patients with heart failure and reduced renal function, insofar as gadolinium-induced

**FIGURE 36-7** Perfusion cardiovascular magnetic resonance (CMR) images and parametric maps in a patient with stenosis of the right coronary and left anterior descending arteries (arrows in **G** and **H**). A single slice (**A** through **F**) shows delayed wash of gadolinium in the inferior wall during the first pass (arrowheads). In the parametric map (**I**), this abnormality is shown in blue. Image **J** is a segmental display of perfusion in a bull's eye plot (32-segment model). In the polar map (**K**), areas of abnormal perfusion are shown in blue, and both the inferoseptal and anteroseptal abnormal areas, corresponding to right coronary and left anterior descending artery stenoses, respectively, are apparent. (From Schwitter J, Nanz D, Kneifel S, et al: Assessment of myocardial perfusion in coronary artery disease by magnetic resonance: a comparison with positron emission tomography and coronary angiography. *Circulation* 2001;103:2230-2235.)

nephrotoxicity has been reported. However, it should be emphasized that the deleterious effects of gadolinium on renal function remain controversial.

Both dobutamine and adenosine stress testing can be used with CMR imaging in order to detect clinically significant coronary artery disease. A fast intravenous bolus of gadolinium is administered by power injector, and the changes in the myocardial signal during the first pass are measured at rest and during stress. Low-signal areas of perfusion can be readily detected during stress (Figure 36-7A to F). Dobutamine infusions in conjunction with CMR imaging have been shown to yield very reproducible results,<sup>28,29</sup> and these studies are especially useful in patients with suboptimal echocardiographic image quality.<sup>30</sup> CMR imaging with stress perfusion has the potential for significant widespread use because of the combination of enhanced resolution with no ionizing radiation. The sensitivity may be increased by the use of myocardial tagging (see Figure 36-4).<sup>31</sup> Adenosine can be used with CMR imaging for assessing myocardial perfusion. Studies have shown that the prognostic utility of CMR imaging with adenosine stress is similar to that of CMR imaging with dobutamine stress.<sup>32</sup> The clinical evaluation of myocardial blood flow is often qualitative; however, with experience, the degree of diagnostic accuracy may exceed that obtained with SPECT.<sup>33</sup> Practical and accurate algorithms for a quantitative analysis of CMR imaging with myocardial perfusion have been developed (see Figure 36-7K) and offer high degrees of diagnostic accuracy<sup>34-36</sup> and reproducibility.<sup>37</sup> Furthermore, imaging of myocardial perfusion under stress can be combined with late gadolinium enhancement to delineate areas of nonviability.

### Nuclear Imaging

Myocardial perfusion imaging (MPI) is used to identify and predict the functional consequences of coronary artery disease.<sup>17</sup> Moreover, MPI can be used to differentiate between myocardial scar and ischemia (Figure 36-8), as well as distinguish at-risk individuals who are the most likely to benefit

from interventional therapies in comparison with medical therapy alone (Figure 36-9).<sup>38,39</sup> Myocardial perfusion defects that appear reversible on at-rest images are indicative of stress-induced ischemia, whereas myocardial perfusion defects that are irreversible, or “fixed,” on at-rest images are indicative of myocardial scarring. Findings on SPECT that imply high risk include a large myocardial perfusion defect, multiple myocardial perfusion defects in more than one coronary territory, abnormal at-rest LVEF, transient RV visualization, transient ischemic LV dilation, increased lung uptake, and post-stress LV dysfunction with a normal at-rest LVEF.<sup>40</sup> In the setting of chronic stable coronary artery disease, basing intervention decisions on coronary anatomy alone is often problematic and does not necessarily lead to improved outcomes.<sup>38,39,41</sup> Hachamovitch and colleagues<sup>39</sup> demonstrated that the magnitude of inducible myocardial ischemia<sup>38</sup> is predictive of a survival benefit with revascularization. Thus, the clinical decision to perform coronary artery revascularization in patients with heart failure hinges on the severity of symptoms and the magnitude of inducible myocardial ischemia (see Figure 23-13).<sup>38</sup>

### ASSESSMENT OF VIABILITY IN PATIENTS WITH ISCHEMIC CARDIOMYOPATHY

The myocardium has several acute and chronic ways of adapting to temporary or sustained reductions in myocardial blood flow (Figure 36-10), known as stunning, hibernation, and ischemic preconditioning (see also Chapter 23) is understood as an increased tolerance toward ischemia, caused by brief, preceding episode of ischemia. *Myocardial stunning* has been defined as reversible myocardial contractile dysfunction in the presence of normal resting myocardial blood flow.<sup>42</sup> Recovery of function occurs spontaneously. *Myocardial hibernation* is defined as reversible myocardial contractile dysfunction in the presence of myocardial hypoperfusion. *Ischemic preconditioning* is understood as an increased tolerance toward ischemia, caused by

**FIGURE 36-8** Myocardial perfusion images. Single photon emission computed tomography (SPECT) images at rest (*lower panels*) and during stress (*upper panels*), revealing a mixture of nontransmural scar and moderate ischemia involving the apex and middle to distal anterior wall (*arrows*), which are consistent with coronary artery disease in the left anterior artery distribution. The images also reveal a moderate to severe fixed perfusion defect in the inferior and inferolateral walls, which is suggestive of nontransmural scar of the right coronary artery and left circumflex arterial distribution (*arrowhead*). Transient ischemic dilation (1.88) was identified with the stress images. Gated images demonstrated a moderately dilated left ventricle (end-diastolic volume = 209 mL; end-systolic volume = 137 mL) with a drop in left ventricular ejection fraction (LVEF) on the post-stress images (at rest, LVEF = 50%; after stress, LVEF = 35%).

**FIGURE 36-9** Role of myocardial perfusion imaging in risk stratifying patients with coronary artery disease. As shown, Cox proportional hazards modeling suggests that hazard ratios for both medical therapy and for revascularization increase as a function of increasing area of ischemic myocardium; however, the relative risk is significantly lower for patients who underwent revascularization. (From Hachamovitch R, Rozanski A, Hayes SW, et al. Predicting therapeutic benefit from myocardial revascularization procedures: are measurements of both resting left ventricular ejection fraction and stress-induced myocardial ischemia necessary? *J Nucl Cardiol* 2006;13:768-778.)

brief, preceding episodes of ischemia. Recovery of function occurs only with restoration of myocardial blood flow. The goal of assessing viability is to optimize selection of patients with heart failure whose symptoms may improve after revascularization. Echocardiography, CMR imaging, and nuclear imaging can be used to demonstrate myocardial viability.

### Echocardiography

In patients with heart failure and a depressed ejection fraction secondary to myocardial ischemia, the identification of myocardial viability is important, insofar as such patients may have hibernating myocardium and may benefit from myocardial revascularization.<sup>43,44</sup> Three typical patterns are seen during dobutamine stress echocardiography. Patients with ischemic cardiomyopathy and viable myocardium commonly manifest a typical “biphasic response” to dobutamine stress: that is, segmental function in viable segments improves with low-dose dobutamine (typically 5 to 10  $\mu\text{g}/\text{kg}/\text{min}$ ) and deteriorates with higher doses (20 to 40  $\mu\text{g}/\text{kg}/\text{min}$ ), as the viable segments become ischemic.<sup>20-22</sup> A second possible response is one of continuing improvement in segmental function and global LVEF with increasing doses of dobutamine (“contractile reserve”), wherein viable segments do not become ischemic at high doses of dobutamine. This response can occur in patients with nonischemic cardiomyopathy, with or without concomitant mild coronary artery disease. A third common finding is no change in global LVEF or segmental function (i.e., a “flat response”), or a worsening of LV function with dobutamine. In general, patients with a

Comparison of noninvasive imaging techniques for assessment of myocardial viability in patients with heart failure. Although stress echocardiography with dobutamine, cardiac magnetic resonance (CMR) imaging, cardiac single photon emission computed tomography (SPECT), and cardiac positron emission tomography (PET) with computed tomography (CT) all are helpful and validated techniques for assessment of myocardial viability, each has its particular advantages and disadvantages.

FDG, fluorodeoxyglucose.

(From Camici PG, Prasad SK, Rimoldi OE. Stunning, hibernation, and assessment of myocardial viability. *Circulation* 2008;117:103-114.)

biphasic response demonstrate the best response to revascularization, followed by those with evidence of contractile reserve.<sup>43,44</sup> Patients with a flat or worsening response to dobutamine typically do not benefit from or fare poorly with revascularization and are often advised to continue medical management. When LV recovery after revascularization is assessed segmentally, SPECT and PET demonstrate excellent sensitivity, whereas echocardiography and CMR imaging with dobutamine stress have superior specificity and positive predictive value (Table 36-1).<sup>45</sup>

### Cardiac Magnetic Resonance Imaging

CMR imaging is an established technique for assessing myocardial viability, as well as predicting the potential for recovery of LV function after myocardial revascularization (see also Chapter 23). Prior studies have shown that an LV end-diastolic wall thickness of less than 5 to 6 mm depicted on a resting cine MRI is a marker of transmural myocardial infarction and virtually precludes the presence of viable myocardium. In the event of poorly contracting LV myocardium with preserved end-diastolic wall thickness ( $\geq 6$  mm), detection of contractile reserve during low-dose dobutamine infusion confirms the presence of viable myocardium.<sup>46,47</sup> This approach is considered very specific and is thus very helpful for therapeutic decision making for patients with suspected ischemia-induced chronic contractile dysfunction. Because CMR imaging can visualize both viable and nonviable tissue, side by side with cine loops of ventricular contraction, late gadolinium enhancement (discussed previously; see Figure 36-6) is useful in assessing myocardial viability. Gadolinium accumulation accurately reflects irreversible myocardial injury,<sup>48</sup> and late enhancement imaging accurately visualizes scars in acute and in chronic infarction<sup>49,50</sup> and is predictive of the functional recovery of dysfunctional segments after myocardial revascularization.<sup>51</sup> In some patients, the late enhancement

series can be combined with a low-dose dobutamine infusion in the same session.<sup>29</sup>

### Nuclear Imaging

MPI is the imaging method most widely used for assessing myocardial viability in patients with heart failure. After injection of a selected radiotracer (e.g., <sup>201</sup>Tl), the isotope is extracted from the blood by viable myocytes and is retained within the myocytes for some time. For a dysfunctional segment or territory, the probability of functional recovery after revascularization is directly related to the magnitude of tracer uptake. The magnitude of global LV functional recovery after revascularization is dependent on the extent of viable myocardial tissue. In a clinical trial of patients with heart failure, of whom only a minority had angina, hibernation, stress-induced ischemia, or both (angina and hibernation or ischemia), were demonstrated in approximately 70% of the patients by SPECT; this finding suggests a significant population of patients with heart failure may benefit from viability testing.

#### SPECT Imaging with Thallium-201

After intravenous injection of <sup>201</sup>Tl, the extent of its initial myocardial uptake is proportional to regional blood flow. The peak myocardial concentration of <sup>201</sup>Tl within the myocardium occurs within 5 minutes after injection, with rapid clearance from the intravenous compartment. Although the initial uptake and distribution of <sup>201</sup>Tl are primarily a function of myocardial blood flow, the subsequent distribution of <sup>201</sup>Tl is a function of the concentration gradient between the level of <sup>201</sup>Tl in the blood and the level in cardiac myocytes. The presence of <sup>201</sup>Tl after redistribution is indicative of myocyte cellular viability. However, because the absence of <sup>201</sup>Tl uptake on the redistribution images does not necessarily preclude myocyte viability, a number of imaging protocols

**FIGURE 36-11** Use of positron emission tomography (PET) to determine myocardial viability. Myocardial uptake of perfusion with rubidium-82 ( $^{82}\text{Rb}$ ) is depicted in the upper panels, whereas myocardial uptake of perfusion with 2-[fluorine-18]-fluoro-2-deoxy-D-glucose ( $^{18}\text{FDG}$ ) is depicted in the lower panels. There is large area of decreased perfusion with preserved FDG metabolism (perfusion-metabolic mismatch) involving the apex (arrows), the septum, and the entire anterior and anteroseptal walls, which is consistent with hibernating myocardium in the distribution of the left anterior descending artery.

have been developed to increase the sensitivity and specificity of this technique for detecting viability. At present, stress-redistribution-reinjection imaging and late rest-redistribution imaging are the two protocols most commonly applied for viability assessment.<sup>52</sup> With rest-redistribution  $^{201}\text{Tl}$  imaging, images are obtained after tracer reinjection at rest, and images are obtained 3 to 4 hours after redistribution. With late redistribution  $^{201}\text{Tl}$  imaging,  $^{201}\text{Tl}$  injection 24 to 48 hours after the initial stress allows for more time for redistribution to occur. However, image quality may be suboptimal with this technique. For defining viable tissue, tracer uptake on redistribution-reinjection images or on late rest-redistribution imaging must exceed 50% to determine viability.<sup>52</sup>

#### **SPECT Imaging with Technetium 99m-Labeled Agents**

As with  $^{201}\text{Tl}$  imaging, stress-induced perfusion abnormalities and resting isotope uptake of 50% to 60% are predictive of functional recovery.<sup>53</sup> Sestamibi SPECT has been performed after the administration of nitrates, which improves specificity and sensitivity.<sup>52,54</sup> In comparison with PET, SPECT underestimates viability.<sup>55,56</sup>

#### **PET with 2-[Fluorine-18]-Fluoro-2-Deoxy-D-Glucose**

2-[Fluorine-18]-fluoro-2-deoxy-D-glucose ( $^{18}\text{FDG}$ ) can be used for the assessment of glucose metabolism in the heart, and this method is very sensitive in detecting myocardial viability.<sup>45,54,57,58</sup> When at-rest perfusion is integrated with measurement of myocardial glucose metabolism and LV function, the pattern of reduced perfusion with preserved metabolism (*perfusion-metabolism mismatch*) is considered essential for myocardial hibernation<sup>59</sup> and is predictive of improved functional outcomes and survival outcomes (Figure 36-11).<sup>57,60</sup> Although patients with severe ventricular dysfunction and coronary disease may benefit from revascularization,<sup>61,62</sup>

perioperative morbidity and mortality rates are significant. The prospective PET and Recovery Following Revascularization (PARR-2) trial showed that among patients with severe LV dysfunction, those who underwent  $^{18}\text{FDG}$  PET to detect viable myocardium and guide therapy tended to have better 1-year outcomes than did those who received standard care.<sup>63</sup>

Figure 36-12 depicts the outcome of medical management in comparison with revascularization in patients with or without myocardial viability, as determined by dobutamine echocardiography or FDG PET. As shown, the outcomes with revascularization were superior to those with medical treatment in this observational study.

## **ASSESSMENT OF VALVE FUNCTION IN PATIENTS WITH HEART FAILURE**

### **Echocardiography**

Doppler echocardiography plays a pivotal role in determining the primary or secondary relation of valve function or dysfunction to cardiac performance and hemodynamics. Mitral valve disease can be a primary cause of cardiac dysfunction in settings such as myxomatous mitral valve disease, rheumatic mitral valve disease, endocarditis, congenital mitral valve disease, or ischemic mitral valve dysfunction.<sup>64</sup> In general, a mitral valve regurgitation lesion that is more than “moderate” in severity (regurgitant volume > 50 mL) can result in LV remodeling and lead to heart failure (“primary mitral regurgitation”).<sup>65,66</sup> Mitral valve regurgitation can also be secondary to the LV dilation that occurs with advancing heart failure. Two-dimensional echocardiography can readily distinguish the cause of mitral valve dysfunction—whether

**FIGURE 36-12** Role of myocardial viability testing using dobutamine echocardiography and positron emission tomography (PET). Mortality rates were lower among patients who underwent revascularization than among those who received medical therapy when myocardial viability was present, determined either by dobutamine echocardiography (1645 patients) or 2-[fluorine-18] fluoro-2-deoxy-D-glucose (<sup>18</sup>FDG) PET (1002 patients). (Adapted from Schnikel AFL, Bax JJ, Poldermans D, et al. Hibernating myocardium: diagnosis and patient outcomes. *Curr Prob Cardiol* 2007;32:375-410.)

primary or secondary, myxomatous or ischemic—and Doppler analysis, including spectral and color imaging, can accurately calculate regurgitant volumes.<sup>65,66</sup> For significant primary mitral valve regurgitation, surgical correction is appropriate if the patient is symptomatic, if LV dilation (LV end-systolic dimension > 4.0 cm) is present, or if the LVEF exceeds 60%.<sup>65</sup> However, if the LV is severely dysfunctional (LVEF < 30%) or if the mitral valve regurgitation is secondary to LV dilation, the results of surgical mitral valve correction are often suboptimal, and medical management may be more appropriate.<sup>65</sup>

Severe and chronic aortic valve disease (stenosis or regurgitation) can result in significant LV systolic dysfunction. Two-dimensional echocardiography can readily reveal the cause of aortic valve disease (degenerative, rheumatic, congenital or bicuspid, or secondary to aortic root disease), and Doppler imaging can accurately reflect the severity of aortic valve disease.<sup>65-67</sup> In general, in the setting of significant aortic valve stenosis or regurgitation (more than moderately severe), if a patient is symptomatic or has signs of LV dilation or systolic dysfunction, surgery is warranted.<sup>65</sup> In asymptomatic severe aortic valve stenosis or regurgitation, echocardiography can be helpful for determining surgical timing.<sup>65-67</sup> For patients with low-gradient aortic stenosis (moderate stenosis with LVEF < 35%), low-dose dobutamine stress echocardiography can be helpful for distinguishing true, severe aortic stenosis from “pseudo”-aortic stenosis and for demonstrating the presence of LV contractile reserve.<sup>65,68,69</sup> In general, patients

## Cardiac Magnetic Resonance Imaging

Although echocardiography typically provides comprehensive information for diagnostic and therapeutic decision making in valvular disease, CMR imaging may be a useful alternative in patients with limited image quality in ultrasound studies. CMR imaging may also be helpful by providing a “third opinion” in patients with conflicting or inconclusive findings. Sometimes, additional information such as tissue characteristics may help physicians make informed therapeutic decisions. Whereas regurgitant and stenotic jets may be readily apparent in cine images, the assessment of valvular disease requires a quantitative evaluation of flow or flow velocity data, or both. The accuracy of flow quantification by CMR imaging has been previously validated.<sup>70,71</sup>

In regurgitant valvular heart disease, regurgitant volume and fraction can be measured by comparing left ventricular stroke volume with systolic aortic flow. CMR imaging allows for measuring effective cardiac output and can therefore provide an important objective parameter of heart failure related to low output. In stenotic valvular disease, flow quantification can be used to identify increased transvalvular flow velocity and calculate pressure gradients.<sup>72</sup> A planimetric quantification of the aortic valve area provides reliable results and avoids the limitations introduced by irregularly turbulent jets and varying pressure gradients.<sup>73-75</sup> This may be of special importance in patients with associated heart failure, inasmuch as the pressure gradient is often unreliable in low-output states.

## HEART FAILURE WITH A DEPRESSED EJECTION FRACTION (see Chapters 14 and 48)

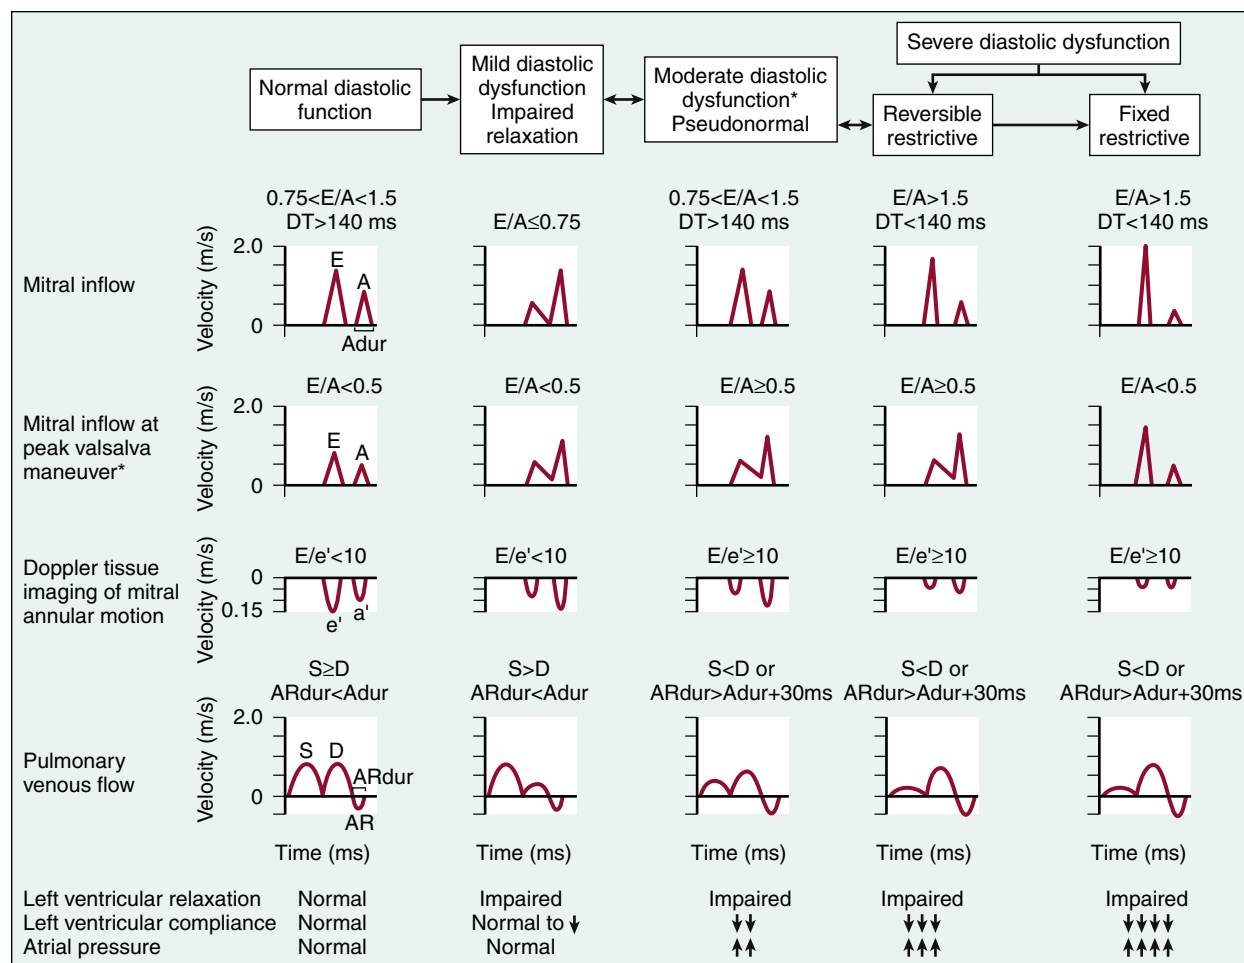

### Echocardiography

#### Assessment of Left Ventricular Mass and Left Atrial Size

In diastolic heart failure, also referred to as heart failure with a preserved ejection fraction (LV > 46% to 50%), elevated left atrial pressures (which reflect LV filling pressures in the absence of obstructive mitral valve disease) lead to increased pulmonary venous pressures and dyspnea at rest or during exertion.<sup>76-80</sup> In order for left atrial (LA) pressures to be elevated in the absence of significantly depressed LVEF, LV relaxation and compliance generally are impaired (see Chapter 14).<sup>76,77,80</sup> Therefore, increased LV mass (≥90 g/m<sup>2</sup> for women and ≥115 g/m<sup>2</sup> for men; i.e., LV hypertrophy) is common in patients with diastolic heart failure.<sup>5,76,80</sup> Because LA pressures are elevated in this scenario, LA enlargement (≥30 mL/m<sup>2</sup>) is usually observed.<sup>76-81</sup> In previous studies, increasing degrees of LV mass have been correlated with increasing LV diastolic dysfunction and filling pressures.<sup>82</sup> Similarly, increasing LA size is correlated with increasing LV filling pressures and worse outcome in patients with diastolic heart failure.<sup>81,83</sup> In cases of ischemic or infiltrative heart disease, significant LV hypertrophy may be absent, and yet LA volumes are often enlarged.<sup>77,84</sup>

#### Identification of Diastolic Dysfunction and Elevated Left Ventricular Filling Pressures

Clinically, diastolic dysfunction secondary to impaired LV relaxation and increased LV stiffness is usually demonstrated by Doppler echocardiography.<sup>76-81</sup> The best correlate of symptoms and survival in diastolic heart failure is elevation of left atrial (or left ventricular filling) pressure, readily estimated through comprehensive echocardiography with Doppler measurement.<sup>76,77</sup> Pulsed Doppler interrogation of transmitral and

**FIGURE 36-13** The proposed progression of diastolic function abnormalities, as assessed through comprehensive Doppler echocardiography with correlation of invasively measured diastolic properties. A comprehensive Doppler assessment, as illustrated in this figure, can yield important information regarding relaxation, filling pressures, and (indirectly) diastolic stiffness in most patients, but careful data acquisition and informed interpretation are required. (From Redfield MM. Heart failure with a normal ejection fraction. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier, pp 641-656.)

pulmonary venous flows is crucial for the assessment of LV filling pressures. Figure 36-13 depicts the grades of diastolic dysfunction that have clinical and prognostic utility. Markedly elevated LV filling pressure are represented by “restrictive filling” in echocardiography (Figure 36-14).<sup>78-80</sup> The Doppler ratio of early transmitral velocity to early mitral diastolic tissue velocity ( $E/E_a$ ) has been validated as a reasonably reliable noninvasive indicator of LV filling pressure in patients with preserved or depressed LVEF.<sup>85-88</sup> When obtained from the septal annulus, an  $E/E_a$  ratio exceeding 15 indicates a pulmonary capillary wedge pressure of 20 mm Hg or more. When the  $E/E_a$  ratio is less than 8, the pulmonary capillary wedge pressure is usually normal. An  $E/E_a$  ratio between 8 and 15 is usually inconclusive, and other information is needed in order to estimate pulmonary capillary wedge pressure. One useful formula that has been suggested is LV end-diastolic pressure (in millimeters of mercury) =  $1.3 (E/E_a) + 2$ . Secondary echocardiographic markers of significant diastolic dysfunction include an enlarged LA volume ( $>30$  mL/m<sup>2</sup>) and evidence of elevated pulmonary artery pressures ( $>30$  mm Hg).<sup>78-81</sup>

## Cardiac Magnetic Resonance Imaging

### Assessment of LV Mass and LA Size

CMR calculation of LV mass is highly accurate<sup>89,90</sup> and reproducible,<sup>91</sup> even in irregularly shaped ventricles.<sup>92</sup> Atrial volumes may have prognostic significance<sup>93</sup> and can

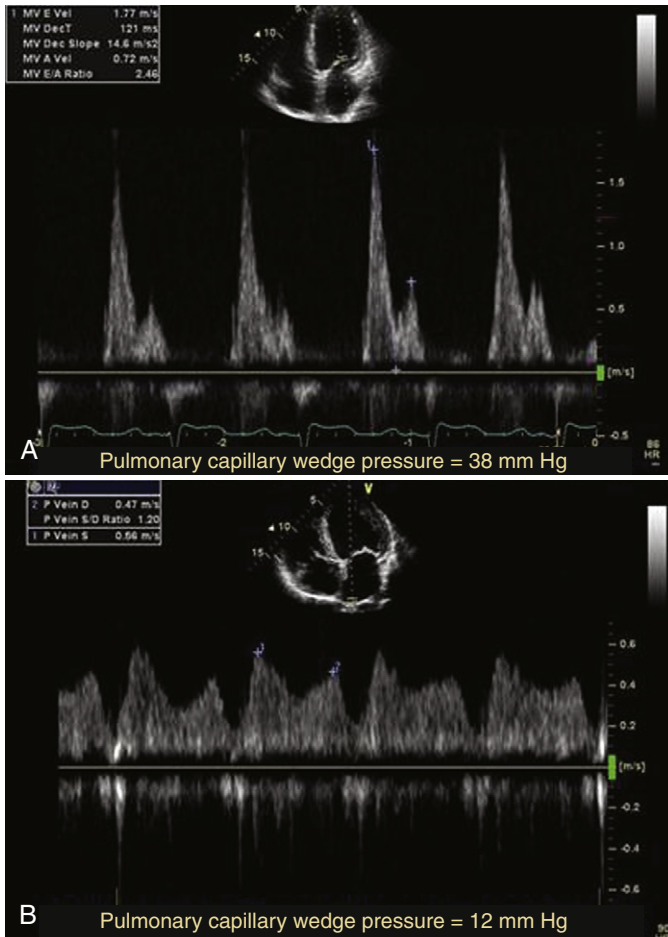

be monitored in clinical scenarios such as atrial fibrillation.<sup>94</sup> Volumes can be calculated on the basis of geometrical assumptions and multislice volumetric methods.<sup>95</sup>

### Identification of Diastolic Dysfunction and Demonstration of Elevated LV Filling Pressures

Parameters of diastolic function that are assessed in CMR imaging include transmitral and pulmonary venous flow and myocardial annular motion.<sup>96,97</sup> Rates of time to peak filling,<sup>98</sup> peak left atrial filling,<sup>99</sup> and left ventricular filling<sup>100</sup> can also be assessed; the latter can be combined with measurements of early diastolic tissue velocity on the basis of concepts developed in echocardiography.<sup>101</sup> Like echocardiography, phase-contrast CMR flow sequences can be used to assess filling pressures by quantification of the  $E/E_a$  ratio as part of a comprehensive protocol in a patient with heart failure.<sup>101</sup>

In myocardial tagging, prepulses are used to selectively saturate spins within the field of view to produce a grid or set of stripes with transiently nullified tissue. The deformation of these patterns during the cardiac cycle allows for analyzing contraction, relaxation, or both patterns of the myocardium (see Figures 36-4 and 36-5). This has been used for 2-dimensional<sup>102</sup> and 3-dimensional<sup>103</sup> strain analysis, including strain analysis of diastolic dysfunction in LV hypertrophy.<sup>104</sup> A large population-based study demonstrated adequate reproducibility of strain analysis.<sup>105</sup> Markers for early diastolic

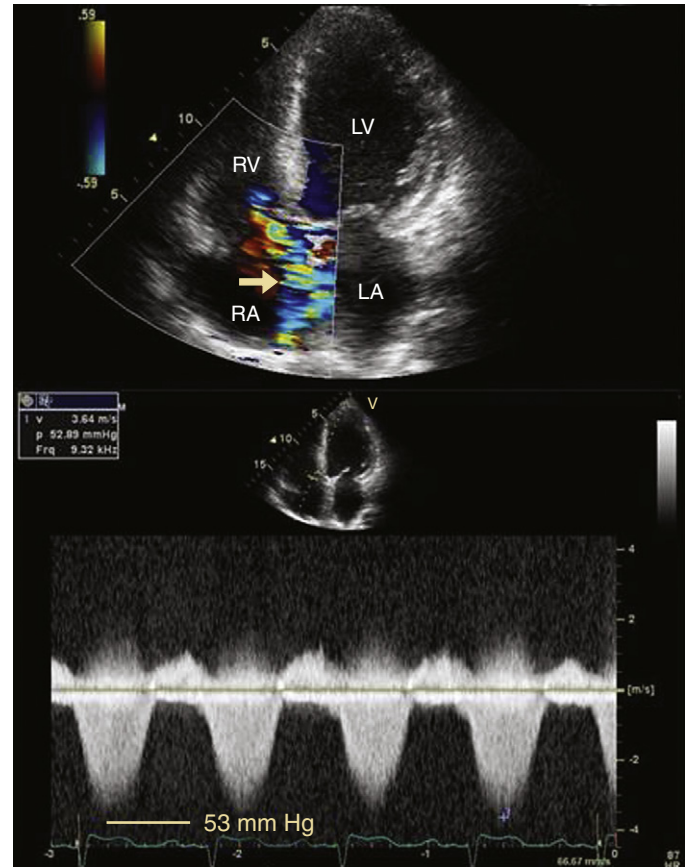

**FIGURE 36-14** Utility of Doppler estimates of left ventricular (LV) filling pressures, derived from examinations of mitral valve (MV) inflow velocities (**A**) and pulmonary (*P*) vein flow velocities (**B**). **A**, A patient with known depressed LV ejection fraction presented with acute dyspnea. Transmitral Doppler imaging revealed an early (*E*) mitral valve velocity of 1.77 m/sec, a late (*A*) mitral valve velocity of 0.72 m/sec, with an *E/A* ratio of 2.46. The mitral deceleration time (*DecT*) was 121 msec. Together, these parameters are indicators of a restrictive filling pattern, which is predictive of a pulmonary capillary wedge pressure of 25 mm Hg or higher. In this patient, the right-sided heart catheterization study revealed a pulmonary capillary wedge pressure of 38 mm Hg. **B**, A patient with dilated cardiomyopathy and a depressed ejection fraction presented with dyspnea. Pulmonary venous Doppler imaging revealed a systolic (*S*) wave velocity of 0.56 m/sec, a diastolic (*D*) wave velocity of 0.47 m/sec, and an *S/D* ratio of 1.2, all consistent with normal LV filling pressure. Subsequent right-sided heart catheterization study revealed a pulmonary capillary wedge pressure of 12 mm Hg. A pulmonary embolus was subsequently diagnosed as the cause of dyspnea.

untwisting motion of the basal and apical segments have been used to assess diastolic function<sup>106,107</sup> and were shown to be independent of preload.<sup>108</sup>

### Nuclear Imaging

Although 2-dimensional echocardiography is most commonly used, radionuclide angiography or gated SPECT and PET can provide information as well. Equilibrium radionuclide angiography techniques<sup>109</sup> can be used to assess LV diastolic filling properties; such assessment relies on analysis of the LV time-activity curve, which represents relative volume changes throughout the cardiac cycle. This method yields results that are well correlated with those of Doppler echocardiography.<sup>110</sup>

**FIGURE 36-15** Use of Doppler velocity of tricuspid valve regurgitation in the estimation of pulmonary artery systolic pressure. In a patient with ischemic cardiomyopathy and marked dyspnea, color Doppler echocardiography (*top*) revealed moderately severe, eccentric tricuspid valve regurgitation (*yellow arrow*). Continuous wave Doppler echocardiography (*bottom*) revealed a peak tricuspid valve regurgitation velocity of 3.64 m/sec, or 53 mm Hg by modified Bernoulli equation. When this was added to a right atrial pressure estimate of 10 mm Hg, the estimated pulmonary artery systolic pressure was 63 mm Hg, which was consistent with moderate pulmonary hypertension secondary to left-sided heart failure. *Freq*, frequency; *LA*, left atrium; *LV*, left ventricle; *P*, pressure; *RA*, right atrium; *RV*, right ventricle; *V*, velocity.

## ASSESSMENT OF RIGHT VENTRICULAR FUNCTION

### Echocardiography

Echocardiography is a noninvasive method commonly used for assessing RV function and dysfunction. Variables for assessment of the right ventricle include RV transverse diameter (normal value < 3.8 cm in the apical four-chamber view),<sup>5</sup> assessment of RV fractional area change (normal  $\geq 40\%$ ), tricuspid annular longitudinal displacement by M-mode echocardiography (normal > 1.5 cm),<sup>111</sup> Doppler systolic annular velocity of tricuspid tissue (normal > 9 cm/sec),<sup>112,113</sup> and RV systolic strain and strain rate (normal > 16% and > 1.1 m/sec, respectively).<sup>114</sup> In the setting of RV failure, several secondary echocardiographic phenomena can be observed: right atrial dilation (>30 mL/m<sup>2</sup>), evidence of elevated RA pressure by dilated hepatic veins and a dilated inferior vena cava, the presence of pulmonary artery hypertension, tricuspid valve regurgitation (*Figure 36-15*), dilation of the pulmonary artery, and pulmonary valve insufficiency.<sup>111,115</sup> Doppler echocardiography has proven invaluable for estimating pulmonary artery pressures. The velocity of tricuspid valve regurgitation reflects the difference in systolic pressure between the right

ventricle and the right atrium. As shown in Figure 36-15, the peak velocity of the tricuspid valve regurgitant jet can be obtained and converted to an estimated pressure by means of the modified Bernoulli equation ( $4 \times [\text{tricuspid valve regurgitation peak velocity}]^2$ ). When the calculated pressure is added to an estimated right atrial pressure of 10 mm Hg, it is possible to obtain reliable estimates of pulmonary artery systolic pressures.

Echocardiography is particularly useful for differentiation between secondary RV failure (caused by left-sided heart dysfunction, in which LA pressures are elevated), cor pulmonale (in which pulmonary artery pressure is elevated but the left heart chambers are normal), and primary RV failure (in which case there is no evidence of left-sided heart disease or significant parenchymal pulmonary disease).<sup>115</sup> Both in secondary RV failure and in cor pulmonale, pulmonary artery hypertension results in increased RV diameter, and depressed Doppler systolic annular velocity of tissue and RV strain have been shown to be adverse prognosticators.<sup>111-115</sup>

### Cardiac Magnetic Resonance Imaging

Because it is often difficult to obtain echocardiographic imaging of the right ventricle, CMR imaging has become a pivotal imaging tool for determining RV structure and function.<sup>116</sup> With regard to heart failure, this is often of critical importance for planning surgical repair<sup>117</sup> in congenital heart disease, as well as follow-up after surgery.<sup>118,119</sup> Because of the irregular shape of the right ventricle, the assessment of RV mass is more difficult than the assessment of LV mass, which has ellipsoidal geometry.<sup>120</sup> However, reasonable estimates of RV structure have been obtained with CMR imaging in axial views.<sup>121</sup> Reference values obtained with state-of-the-art CMR sequences are available,<sup>100,122,123</sup> including data for various ethnic backgrounds.<sup>124</sup> In RV heart failure (e.g., chronic pulmonary hypertension), ventricular interaction is an important contributor to the impairment of cardiac output. The underlying mechanism entails a leftward shift of the interventricular septum that leads to underfilling of the left ventricle, which can easily be identified by CMR studies<sup>125,126</sup> and whose detection is often helpful for diagnosing pulmonary hypertension. As in echocardiography, retrograde flow velocity of a tricuspid valve regurgitant jet can be measured in CMR flow studies and can be used to estimate systolic RV pressure. This measurement, however, not widely performed.

### Nuclear Imaging

Equilibrium gated radionuclide angiography is used with <sup>99m</sup>Tc-labeled red blood cells. Right ventricular ejection fraction (RVEF) can be abnormally decreased in patients with pulmonary hypertension. Patients with lesions in the proximal right coronary artery may exhibit decreases in RVEF during exercise.<sup>11</sup> With SPECT, RV uptake may be qualitatively assessed with the raw projection data and with the reconstructed data. The intensity of the RV uptake is 50% of peak intensity of LV uptake.<sup>15</sup> RV uptake increases in the presence of RV hypertrophy.<sup>11</sup> As on radionuclide angiography, reduced RV uptake evident on SPECT may be a sign of coronary artery disease in the distribution of the right coronary artery.<sup>15</sup> In the setting of chronic obstructive pulmonary disease, smoking, and severe LVEF impairment, sequestration of nitrogen-13-labeled ammonia (<sup>13</sup>NH<sub>3</sub>) in the lungs can be increased on PET, for which it would be necessary to delay the time between radiotracer injection and image acquisition to enhance image quality. This is an indirect marker of RV and LV performance that may provide additional data.<sup>16</sup>

## ROLE OF CARDIAC IMAGING IN IMPLANTABLE CARDIAC DEVICES (see also Chapter 47)

### Echocardiography

The role of echocardiography in the selection of patients for, and the optimization of, cardiac resynchronization therapy (CRT) has been extensively investigated.<sup>127</sup> LV septal-posterior wall systolic delay, demonstrated in M-mode echocardiography, was one of the first echocardiographic parameters shown to indicate significant LV dyssynchrony.<sup>128</sup> Doppler tissue imaging has been of value in demonstrating different time to peak systolic velocity in opposing walls (>65 msec being evidence of significant dyssynchrony) or in the maximum delay of any of six walls in the apical views (>100 msec being significant).<sup>129,130</sup> The standard deviation of time to opposing wall delay of more than 33 msec, on the 12 segments visible in the three apical views, has also been shown to denote significant intraventricular dyssynchrony and to be predictive of response to therapy.<sup>131</sup> Newer modalities involving speckle-based LV strain in systole, as well as 3-dimensional echocardiography, have also been employed to identify significant dyssynchrony.<sup>132</sup> The PROSPECT trial has highlighted reproducibility challenges in the measurement of these echocardiographic indicators of LV dyssynchrony.<sup>133</sup> For implantable cardioverter-defibrillator therapy, echocardiography is commonly used for demonstrating depressed LVEF (<30%), which is an indication for implantation of the defibrillator for the primary prevention of sudden cardiac death in patients with ischemic cardiomyopathy.<sup>134</sup>

### Cardiac Magnetic Resonance Imaging

Data derived from CMR studies may provide important information for planning interventional therapy. Among several parameters,<sup>135</sup> strain analysis with tagged images may be particularly useful in mapping conduction abnormalities in three dimensions, which would significantly increase the success rate of CRT.<sup>136</sup> Furthermore, CMR imaging has been successfully used to predict outcome of CRT by assessing scar patterns with late enhancement CMR imaging.<sup>137</sup> Currently, the selection of patients for implantation of cardioverters-defibrillators is largely based on LVEF. However, markers for increased susceptibility of myocardial tissue to arrhythmic events may prove to be of critical value in decision making. The presence of nonischemic, intramural scars, as defined by midwall layers of late enhancement, is predictive of inducible ventricular tachycardia<sup>138</sup> in dilated cardiomyopathy. This finding was associated with increased susceptibility to arrhythmia in hypertrophic cardiomyopathy.<sup>139,140</sup> There is also a strong association between heterogeneous signal intensity of peri-infarct regions and inducible arrhythmia, which probably reflects the pathological substrate for arrhythmic foci after myocardial infarction.<sup>141</sup>

### Nuclear Imaging

Radionuclide angiography has been used to quantify LV dyssynchrony by analysis of phase histograms and their standard deviation,<sup>142</sup> as well as to assess the effects of CRT. Gated SPECT and MPI with phase analysis could also be used to predict response to CRT.<sup>143</sup> PET has provided insight into the changes in myocardial perfusion, metabolism, and myocardial efficiency after CRT. Thus far, the effect of CRT on myocardial blood flow and metabolism has been investigated in several studies.<sup>144-147</sup> In ongoing studies, researchers are

evaluating the role of phase analysis and FDG PET in directing CRT. Development of novel strategies to identify substrates associated with a high risk of sudden cardiac death could improve selection of patients for device-based primary prevention of arrhythmia-related death.

## FUTURE DIRECTIONS IN CARDIAC IMAGING

### Echocardiography

#### 3-Dimensional Echocardiography

Many contemporary echocardiographic machines perform full 3-dimensional volume analysis of the heart with use of a hand-held ultrasonographic probe. LV systolic and diastolic volumes can be measured from the full volume data set, and they compare favorably with those obtained by MRI (Figure 36-16).<sup>148</sup> LV ejection fraction has also shown to be better estimated with 3-dimensional echocardiography than with 2-dimensional echocardiography and is more closely related to those obtained with MRI.<sup>149</sup> Furthermore, 3-dimensional echocardiographic LV and LA volumes have been predictive of prognosis in patients with heart failure.<sup>150</sup> Future advances in transthoracic and transesophageal echocardiography will probably be influenced or determined by 3-dimensional echocardiography.<sup>151</sup>

#### Speckle-Based Tracking Echocardiography

Speckle-based tracking is a method of non-Doppler 2-dimensional imaging ("speckle echocardiography") to track myocardial motion in various planes. Reflection scattering and interference of the ultrasound beam in the myocardial tissue produces on the images the formation of speckles, which can be tracked from frame to frame throughout the cardiac cycle; this provides information on displacement, velocity, deformation, and deformation rate (strain and strain rate, respectively) that is independent of angulation and cardiac translational motion.<sup>152</sup> Speckle-based tracking allows for the assessment of LV rotational movement, which is referred to as *torsion* or *twist* (Figure 36-17). Speckle-based echocardiography has provided detailed information

on myocardial mechanics in hypertensive heart disease, hypertrophic cardiomyopathy, and diastolic and systolic LV failure and in cases of pulmonary hypertension.<sup>152-155</sup> Currently, such speckle-based measurements are being studied to assess their role in predicting patient outcomes in heart failure. State-of-the-art and future applications are combining speckle-based imaging with 3-dimensional echocardiography to obtain a 3-dimensional velocity and strain map of the left ventricle.<sup>156</sup>

### Cardiac Magnetic Resonance Imaging

#### Role of Strain and Strain Rate Imaging in Patients with Heart Failure

As discussed previously, myocardial strain and strain rate can also be assessed with CMR imaging. Sequences with tagging pulses imprint a grid, or set of parallel stripes, onto the images of myocardial tissue (see Figures 36-4 and 36-5). The deformation of the visible patterns over the cardiac cycle allows for analyzing regional ventricular function,<sup>157</sup> as well as myocardial strain and strain rate. Among various parameters, systolic circumferential strain appears to be the most promising. Patients at risk for heart failure show distinct patterns of abnormal strain,<sup>104</sup> and standardized CMR protocols have been proposed and validated with a normal population.<sup>105</sup>

### Nuclear Imaging

#### Assessment of Cardiac Sympathetic Innervation

Neurotransmitter assessment and cardiac receptor imaging represent promising advances in molecular imaging that could facilitate the understanding of the pathophysiological processes involved in progression of heart failure.<sup>158,159</sup> The normal heart usually extracts norepinephrine from arterial blood, whereas in patients with moderate heart failure, the coronary sinus norepinephrine concentration exceeds the arterial concentration, which indicates that there is increased adrenergic stimulation of the heart. However, as heart failure progresses, there is a significant decrease in the myocardial concentration of norepinephrine. The mechanism responsible for cardiac norepinephrine depletion in severe heart failure is not clear; it may be related to an "exhaustion" phenomenon resulting from the prolonged adrenergic activation of the cardiac adrenergic nerves in heart failure. Iodine-123-labeled metaiodobenzylguanidine (<sup>123</sup>I-MIBG), a radiopharmaceutical that is normally taken up by adrenergic nerve endings, is not taken up normally in patients with cardiomyopathy, which suggests that norepinephrine reuptake is also impaired in heart failure. <sup>123</sup>I-MIBG imaging of cardiac sympathetic innervation has been predictive of outcomes in heart failure.<sup>160,161</sup> Researchers in the Prognostic Significance of <sup>123</sup>I-MIBG Myocardial Scintigraphy in Heart Failure (ADMIRE-HF) study examined the prognostic usefulness of the assessment of myocardial sympathetic innervation, as determined by the heart-to-mediastinum ratio on planar <sup>123</sup>I-MIBG imaging as either normal (>1.6) or abnormal (<1.6), for identifying patients with New York Heart Association (NYHA) class II or III heart failure with an ejection fraction of less than 35% who were at increased risk of experiencing an adverse cardiac event. Patients were monitored for a maximum of 2 years. Results showed that the composite endpoint—the first occurrence of NYHA heart failure class progression, potentially life-threatening arrhythmic event, or cardiac death—occurred significantly ( $P < .0001$ ) more frequently in patients who had low uptake of the tracer.<sup>162</sup> Interestingly, <sup>123</sup>I-MIBG imaging had independent prognostic capability complementary to B-type natriuretic peptide (BNP) and helped distinguish between patients who were likely to die from heart failure progression and those who would have an arrhythmic event. Patients with the lowest

**FIGURE 36-16** In a patient with ischemic cardiomyopathy, 3-dimensional echocardiography was used for assessment of increasing dyspnea on exertion. It revealed significantly dilated left and right ventricles and a calculated left ventricular ejection fraction of 28%. Left-sided heart catheterization study revealed severe three-vessel coronary artery disease. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; V, velocity.

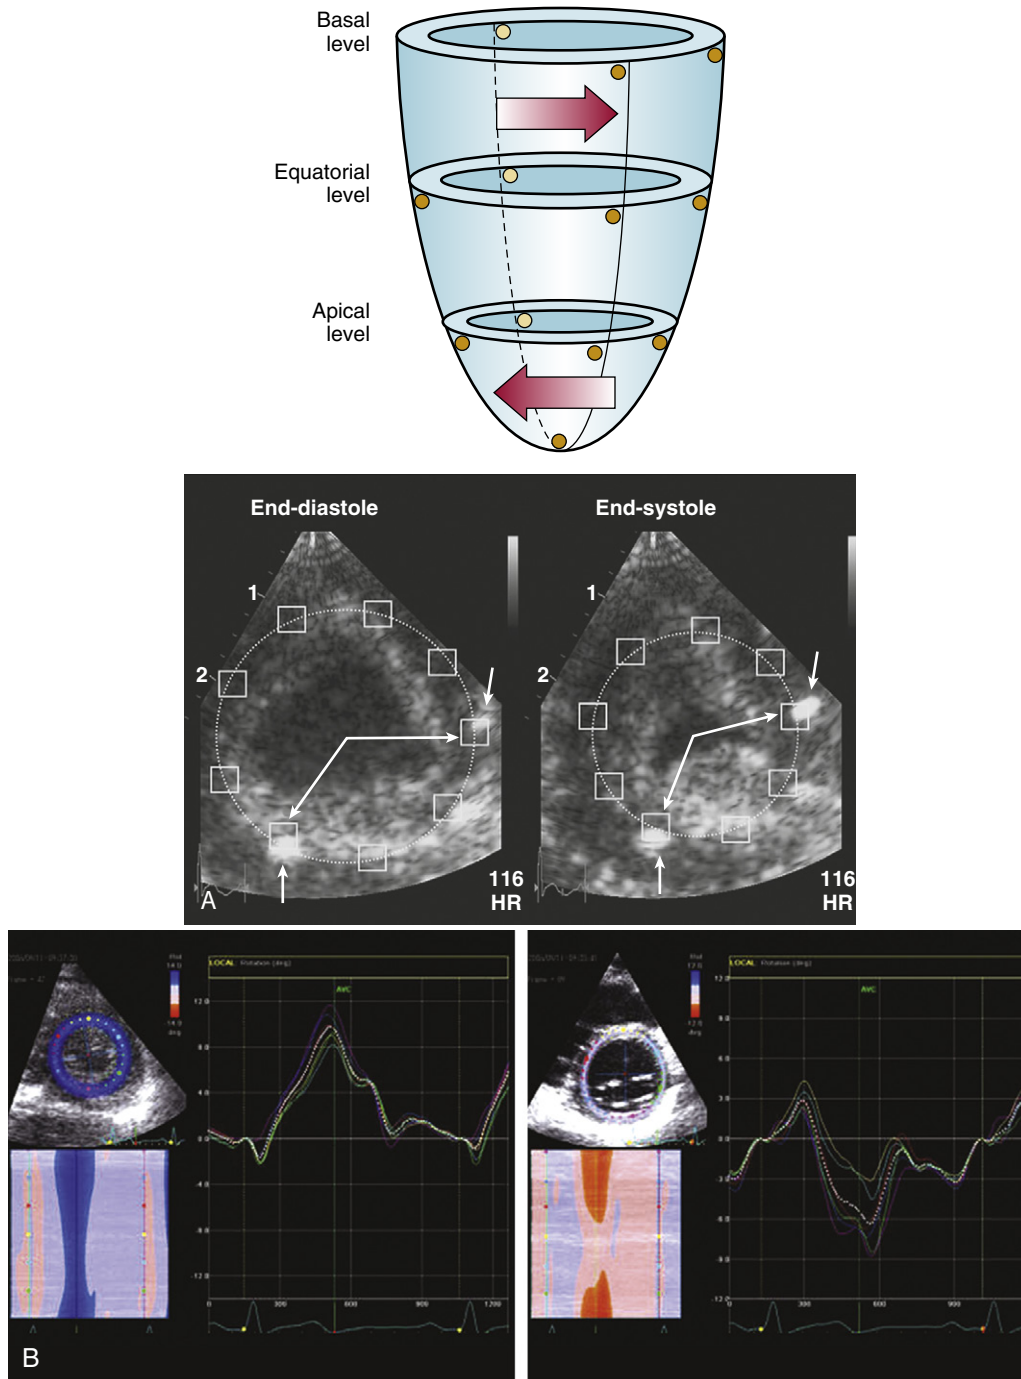

uptakes (heart-to-mediastinum ratio < 1.2) tended to die from heart failure progression, whereas arrhythmic events tended to occur in patients with heart-to-mediastinum ratios in the range of 1.2 to 1.6; this finding suggests that molecular imaging may be used to guide defibrillator therapy in the future.<sup>162</sup>

#### Molecular Imaging with PET

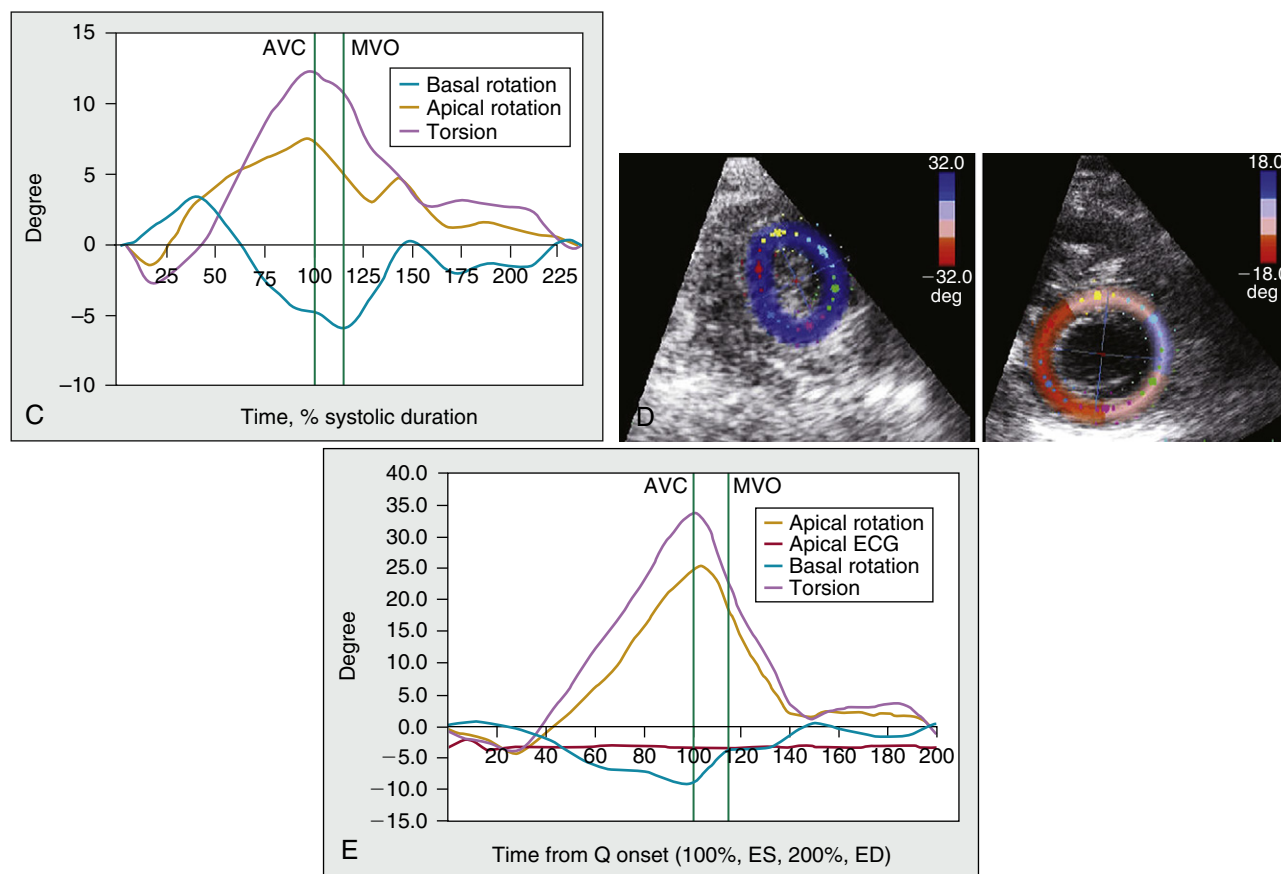

Carbon-11 (<sup>11</sup>C)-labeled meta-hydroxyephedrine (HED, *N*-methyl-metaraminol) is a catecholamine analogue, developed for PET, of sympathetic nerve terminals of the

heart and is used as an index of norepinephrine reuptake transporter density and synaptic norepinephrine levels. In conjunction with FDG viability imaging, <sup>11</sup>C-labeled HED imaging may prove useful in identifying patients with ischemic cardiomyopathy who are at risk for sudden cardiac death.<sup>163</sup> The branched-chain fatty acid  $\beta$ -methyl-*p*-[<sup>123</sup>I]-iodophenyl-pentadecanoic acid (<sup>123</sup>BMIPP) undergoes limited beta-oxidation after myocardial ischemia, despite restoration of myocardial blood flow.<sup>164</sup> These findings support the concept that <sup>123</sup>BMIPP imaging can be used to

**FIGURE 36-17** **A, Top**, Viewed from the apex, the apical rotation is counterclockwise (*top thick arrow*) and basal rotation is clockwise (*bottom thick arrow*). **A, Bottom**, Speckled tracking regions of interest are denoted by *white boxes* in the echocardiographic image of the animal model. Rotational changes are noted by the *dotted white arrows* during end-diastole and end-systole frames. **B**, Cardiac rotation in a normal person. The extent of rotation is colorized in these speckle-based tracking images. **B, Left**, Apical short-axis view with counterclockwise rotation (*blue*). Maximal rotation occurred at end-systole, shown as the graph above the baseline. The extent of rotation of multiple segments is shown in different colors. The rectangle below the speckle-based image shows colorized rotation of different segments during one cardiac cycle, which is a color M-mode of left ventricular rotation. **B, Right**, The basal segment of the left ventricle, with clockwise rotation by color and graph. Because rotation is clockwise, the graph is recorded below the baseline.

*Continued*

**FIGURE 36-17, Cont'd C**, The mean apical rotation (7-degree counterclockwise) and basal rotation (5-degree clockwise rotation) at the time of aortic valve closing (AVC) are shown. They resulted in a net torsion of 12 degrees. Untwisting of the torsion starts the myocardial relaxation process. **D, Left**, Apical short-axis view with speckle-based imaging, showing exaggerated counterclockwise rotation in a patient with abnormal myocardial relaxation. **D, Right**, Basal short-axis view, showing clockwise rotation. **E**, Quantification of the extent of the rotation and resulting torsion is shown in this graph from the same patient as in **D**. Apical counterclockwise rotation is 25 degrees (above the baseline), and the peak basal clockwise rotation (below the baseline) is 9 degrees. Both apical rotation and basal rotation are greater than those of a normal person. Therefore, torsion is higher than in a normal person at 34 degrees. *ED*, end-diastole; *ES*, end-systole; *MVO*, mitral valve opening. (From Connolly HM, Oh JK. Echocardiography. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier, pp 227-325.)

provide a metabolic imprint of a stress-induced ischemic episode, which has been referred to as *ischemic memory*. Another potentially useful tracer is  $^{11}\text{C}$  acetate, which has been used for studying myocardial oxidative metabolism and regional myocardial blood flow, and hence determining myocardial efficiency, in patients with dilated cardiomyopathy.<sup>165</sup>

PET is also able to quantify absolute myocardial blood flow.<sup>17</sup> This facilitates the detection of hemodynamically significant stenotic lesions in the coronary arteries and may facilitate detection of multivessel disease as well.<sup>166</sup> Absolute flow quantification by PET has been used extensively to determine the effects of drugs and devices on myocardial blood flow.<sup>167</sup> Whether this approach adds benefit in terms of diagnosis or prognosis in patients with heart failure remains to be determined.

#### Use of Dual Imaging Techniques in Patients with Heart Failure

Multimodal imaging PET and computed tomography (CT) systems have become established in clinical practice.<sup>168</sup> There is also a trend toward increasing use of hybrid SPECT and CT systems for conventional nuclear imaging. Moreover, the combination of PET with MRI may afford further advantages.<sup>169</sup> However, several technical issues need to be resolved before the true added value of these hybrid imaging systems can be assessed. These hybrid technologies are expected to expand the role of cardiac imaging in patients with heart failure.

# The Use of Biomarkers in the Evaluation of Heart Failure

Leo Slavin, Lori B. Daniels, and Alan S. Maisel

The approach to the diagnosis of acute heart failure is complex and challenging because it has heterogeneous manifestations and nonspecific signs and symptoms.<sup>1</sup> Classically, students are taught that a careful history in patients presenting with congestive heart failure (CHF) elicits symptoms of dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, whereas the physical examination reveals elevated jugular venous pressure, rales, an S3 gallop, and pitting peripheral edema (see also Chapter 35). However, it is well documented that in practice, the clinical manifestation of heart failure, even in combination with chest radiographs, electrocardiograms, and standard laboratory assessments, frequently does not clinch the diagnosis. Often clinicians must consider other causes of dyspnea, such as chronic obstructive pulmonary disease or pneumonia, which can delay necessary treatment. The growth and development of various classes of biomarkers are improving the understanding of the pathogenesis, diagnosis, and prognosis in heart failure.

## BIOMARKERS IN HEART FAILURE

Morrow and de Lemos<sup>2</sup> proposed three criteria required for a biomarker to be clinically useful. First, the assay should be precise, accurate, and rapidly available to the clinician at relatively low cost. Second, the biomarker should provide additional information that is not surmised from findings of the clinical evaluation. Third, the absolute measured value should help in clinical decision making.<sup>2</sup> Currently, few biomarkers can fulfill all these requirements. Biomarkers that do meet these criteria reflect the different mechanisms (such as biomechanical stretch, inflammation, and myocyte injury) that are involved in the pathophysiology and natural history of heart failure. These markers individually and jointly provide important information for assessing the progression of disease, diagnosing acute exacerbations, and establishing prognosis.

### Markers of Myocardial Stretch

#### *Natriuretic Peptides*

**Biology.** Three major natriuretic peptides—atrial natriuretic peptide (ANP), B-type natriuretic peptide (BNP), and C-type natriuretic peptide—counter the effects of volume overload or adrenergic activation of the cardiovascular system. ANP is synthesized primarily in the atria, stored in granules, and, under minor triggers such as exercise, released into the circulation.<sup>3</sup> BNP has minimal storage in granules and is synthesized and secreted in bursts primarily by the ventricles.<sup>3</sup> C-type natriuretic peptide is a product of endothelial cells and may be protective in post-myocardial infarction remodeling.<sup>4</sup> Upon release into the circulation, ANP and BNP bind to various tissues and induce vasodilation, natriuresis, and diuresis.<sup>5</sup>

Left ventricular pressure or volume overload results in myocardial wall stress that initiates the synthesis of precursor pro-B-type natriuretic peptide (pre-proBNP). Pre-proBNP is initially cleaved to proBNP and then to BNP, the biologically active form, and the inactive N-terminal fragment, NT-proBNP (**Figure 37-1**). The mechanism of action of natriuretic peptides is mediated through membrane-bound natriuretic peptide receptors (NPRs). NPR-A preferentially binds ANP and BNP, and NPR-B primarily binds C-type natriuretic peptide. The natriuretic peptide–receptor interaction activates the enzyme guanylyl cyclase, which leads to the production of cyclic guanosine monophosphate. Clearance of natriuretic peptides is mediated through NPR-C, degradation by

neutral endopeptidase, and by direct renal clearance (**Table 37-1**).

Patients with heart failure are in a state of BNP insufficiency that results from a deficiency of the active BNP form plus molecular resistance to its effects.<sup>6</sup> Studies have demonstrated that the BNP detected in acute heart failure is primarily the high-molecular-weight proBNP rather than the biologically active form.<sup>7</sup> Some authors have suggested that abnormal cellular processing of BNP is a factor in the relative BNP-deficiency state in heart failure.<sup>8</sup> In addition, upregulation of phosphodiesterases leads to rapid clearance of the secondary messenger, cyclic guanosine monophosphate, despite high activation of the NPRs by natriuretic peptides.<sup>9</sup>

What constitutes a normal natriuretic peptide level depends on the specific clinical setting. Two studies revealed that BNP levels in normal adults without cardiovascular disease increase with age and appear to be higher in women; NT-proBNP levels show greater age dependence than do BNP levels.<sup>10,11</sup> According to general guidelines, 90% of young, healthy adults have a BNP level of less than 25 pg/mL and an NT-proBNP level of 70 pg/mL or lower.<sup>12</sup> In patients presenting with acute dyspnea, a BNP cutoff level of less than 100 pg/mL and an NT-proBNP cutoff level of less than 300 pg/mL should be used to rule out heart failure.<sup>13,14</sup>

**Natriuretic Peptides in Acute Heart Failure.** BNP and NT-proBNP levels have become powerful diagnostic tools in the evaluation of patients presenting with dyspnea in a variety of clinical settings. In the Breathing Not Properly Multinational Study, BNP levels were measured in 1586 patients with shortness of breath upon arrival in the emergency department (ED). Use of this information resulted in a higher diagnostic accuracy, with an area under the receiver-operating characteristic curve (AUC) of 0.91.<sup>13</sup> A BNP cutoff level of 100 pg/mL was 90% sensitive and 76% specific for the diagnosis of heart failure as the cause of dyspnea (**Figure 37-2**). The data were similar for NT-proBNP levels in the ProBNP Investigation of Dyspnea in the Emergency Department (PRIDE) study, in which NT-proBNP level was measured in 600 emergency department

**FIGURE 37-1** Synthesis of B-type natriuretic peptide (BNP) and amino terminal B-type natriuretic peptide (NT-proBNP).

TABLE 37-1	Biochemical Properties of BNP versus NT-proBNP	
Property	BNP	NT-proBNP
Amino acids	32	76
Molecular weight (kDa)	3.5	8.5
Half-life (min)	22	60-120
<b>Clearance</b>		
• Primary	Neutral endopeptidase	Renal
• C-R	NPR-C	Renal
• Hemodialysis	No	No
Point-of-care	Yes	Pending
Correlation with GFR	Moderate	Strong
Biologically active	Yes	No
Clinical range (pg/mL)	0-5,000	0-35,000

patients with dyspnea; its sensitivity and specificity were demonstrated in the diagnosis of CHF (AUC = 0.94).<sup>14</sup> A NT-proBNP cutoff level of less than 300 pg/mL was proposed to rule out heart failure as the cause of dyspnea.

The use of natriuretic peptides has also proved to be significantly cost effective. In the BNP for Acute Shortness of breath EvaLuation (BASEL) study, 452 patients in the emergency department with dyspnea were randomly assigned to conditions involving a single measurement of BNP level versus no such measurement. The researchers reported a 10% reduction in the rate of admissions and a 3-day decrease in the median length of stay with the use of BNP level, which amounted to a total cost savings of \$1800 per patient without an increase in mortality or repeated hospitalization.<sup>15</sup> These results were also obtained with NT-proBNP level in the Improved Management of Patients with Congestive Heart Failure (IMPROVE-CHF) study.<sup>16</sup>

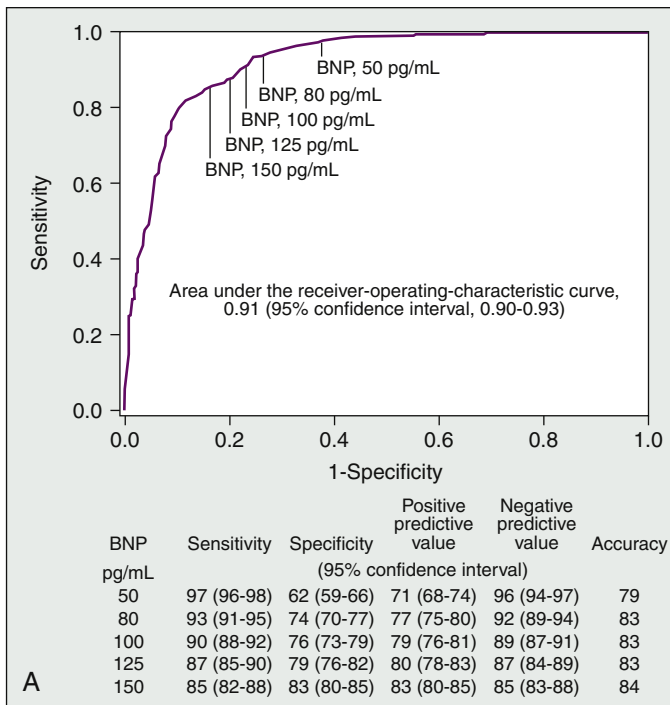

**Elevated Natriuretic Peptide Levels in Other Clinical Settings.** For optimal use of natriuretic peptides, it is important to be aware of clinical scenarios other than acute heart failure that can cause natriuretic peptide levels to rise. Patients with a history of heart failure but without an acute exacerbation

can have intermediate BNP levels, as shown in the Breathing Not Properly trial.<sup>13</sup> Acute coronary syndrome is also associated with elevated levels of natriuretic peptides: Acute ischemia causes transient diastolic dysfunction, which results in increased left ventricular end-diastolic pressure, a rise in wall stress, and increased synthesis of BNP.<sup>17</sup> The role of BNP is perhaps most useful in differentiating between cardiac and pulmonary causes of shortness of breath. Although natriuretic peptide values can be elevated to intermediate levels in patients with underlying lung disease, they tend to remain significantly lower than in patients presenting with CHF.<sup>18</sup> The Breathing Not Properly trial demonstrated that natriuretic peptide levels were useful in diagnosing heart failure, which was present in 87 of the 417 patients with a history of chronic obstructive pulmonary disease or asthma (BNP levels, 587 vs. 109 pg/mL,  $P < .0001$ ).<sup>13</sup> In addition, right-sided heart dysfunction from hemodynamically significant pulmonary embolism, severe lung disease, and pulmonary hypertension can lead to elevated levels of natriuretic peptides.<sup>19-22</sup> Therefore, when levels of natriuretic peptide levels are intermediate in an acutely dyspneic patient, it is important to consider other life-threatening causes of dyspnea.

Hyperdynamic states of sepsis, cirrhosis, and hyperthyroidism can also be associated with elevated levels of natriuretic peptides.<sup>23-25</sup> These levels are also increased in the setting of atrial fibrillation.<sup>26</sup> The Breathing Not Properly trial demonstrated that BNP still performed well in patients with atrial fibrillation; the AUC was 0.84, in comparison with 0.91 for the entire cohort. Increasing the cutoff to 200 pg/mL for these patients improved specificity and the positive predictive value for diagnosing heart failure.<sup>27</sup>

**Caveats.** In addition to wall stress, other factors have been associated with elevated natriuretic peptide levels. Aging appears to be associated with elevated levels of BNP, independent of the degree of diastolic dysfunction.<sup>10,11</sup> Possible mechanisms may include altered renal function, changes in the biosynthesis and processing of natriuretic peptides on a cellular level, or a reduction in the clearance receptor NPR-C.<sup>28</sup> Women appear to have higher natriuretic peptide levels than do men the same age.<sup>10,11</sup> Although the reasons for this sex difference are unclear, some authors have proposed that differences in estrogen or testosterone may be responsible.<sup>10,29</sup>

The association between natriuretic peptide levels and renal function is complex. In the setting of renal dysfunction, increased concentrations of natriuretic peptides may stem from elevation in atrial pressure, systemic pressure, or ventricular mass. Many patients with renal disease have hypertension that results in significant left ventricular hypertrophy, and comorbid cardiac conditions are also common.

**FIGURE 37-2** **A**, Receiver-operating-characteristic curve from the Breathing Not Properly Multinational Study for various cutoff levels of B-type natriuretic peptides in differentiating dyspnea caused by heart failure from dyspnea with other causes. **B**, Box plots showing the median levels of B-type natriuretic peptide among patients in different New York Heart Association classifications. (From Maisel AS, Krishnaswamy P, Nowak RM, et al. Rapid measurement of B-type natriuretic peptide in the emergency diagnosis of heart failure. *N Engl J Med* 2002;347:161-167.)

This interplay between the heart and kidneys in patients with reduced renal function accounts for one component of the increase in natriuretic peptide levels, reflecting elevated “true” physiological natriuretic peptide levels.<sup>30</sup> The Breathing Not Properly study revealed a weak but significant correlation between glomerular filtration rate (GFR) and BNP level, and the researchers suggested higher cutoff levels for patients with a GFR of less than 60 mL/min/1.7 m<sup>2</sup>.<sup>31</sup>

Interpretation of NT-proBNP levels in the setting of renal dysfunction is more challenging because clearance is not mediated by NPR-C or neutral endopeptidase and is more dependent on renal function. GFR seems to be more strongly correlated with NT-proBNP ( $r = -0.55$ ) than with BNP, although the discrepancy may be somewhat less prominent in patients with acute CHF ( $r = -0.33$  for NT-proBNP level, and  $r = -0.18$  for BNP level).<sup>32,33</sup> An analysis from the PRIDE study demonstrated that NT-proBNP levels in patients with GFR of less than 60 mL/min/1.7 m<sup>2</sup> were still the strongest predictors of outcome, and the researchers suggested a higher cutoff level, of more than 1200 pg/mL, for the diagnosis of heart failure.<sup>33</sup> In contrast, there is no significant relationship between NT-proBNP levels and GFR in relatively healthy patients with mild renal insufficiency.<sup>34</sup> Despite the relationship between natriuretic peptide levels and GFR, both BNP and NT-proBNP levels still provide important diagnostic and prognostic information in patients with renal dysfunction.

Several studies have demonstrated an inverse relationship between body mass index and BNP levels.<sup>11,35-37</sup> The reasons for this are not fully elucidated, although some authors have postulated a theory of increased clearance mediated through elevated levels of NPR-C in adipocytes<sup>38</sup>; data for this are conflicting.<sup>34,39</sup> A study of patients who had undergone bariatric surgery showed an increase in both BNP and NT-proBNP levels after the surgery, which suggests that downregulation of natriuretic peptide production in obesity, rather than increased clearance, may be responsible for the lower levels of natriuretic peptides in the obese population.<sup>40</sup> Despite lower circulating levels, natriuretic peptide values retain

their diagnostic capability in obese patients, albeit at lower cutoff levels.<sup>37</sup>

Flash pulmonary edema, CHF with causes upstream from the left ventricle (i.e., acute mitral regurgitation and mitral stenosis), and pericardial disease do not lead to substantial elevations in natriuretic peptides.<sup>30</sup> In flash pulmonary edema, because of the small amounts of natriuretic peptides that are preformed and residing in secretory granules, and because of the delay between wall stress and upregulation of gene expression, the levels of natriuretic peptides are disproportionately low in comparison to symptoms.<sup>30</sup> Patients with constrictive pericardial disease can present with symptoms of right-sided heart failure; however, because the stiff pericardium limits the myocardium's stretching, natriuretic peptide levels are typically normal or minimally elevated.<sup>30,41</sup>

**Prognosis.** There has been a tremendous increase in data demonstrating the prognostic power of natriuretic peptides in a variety of clinical settings. Several researchers reported that natriuretic peptide levels in patients presenting to the emergency department with heart failure are predictive of future cardiovascular events. Every 100-pg/mL increase is associated with a 35% increase in the risk of death in heart failure.<sup>42</sup> The prospective, multicenter Rapid ED Heart Failure Outpatient Trial (REDHOT), involving 464 patients presenting to the emergency department with heart failure, showed that BNP level was predictive of future heart failure-related events and of mortality and was superior to the emergency department physician's assessment of severity of illness. In patients with chronic heart failure, BNP level provides powerful prognostic information regarding survival and deterioration of functional status.<sup>43</sup> In more than 4300 outpatients with chronic heart failure in the Valsartan Heart Failure Trial (Val-HeFT), patients with the greatest rise in BNP level despite therapy had the highest rates of morbidity and mortality.<sup>44</sup>

In addition to heart failure, both BNP and NT-proBNP levels have strong prognostic value in patients with coronary

artery disease, acute coronary syndrome, and valvular heart disease and in the prediction of sudden cardiac death.<sup>45-50</sup>

### Monitoring Therapy

**Inpatient.** Several investigators evaluated the relationship between natriuretic peptide levels and pulmonary capillary wedge pressure (PCWP) derived from invasive hemodynamic catheters.<sup>51</sup> Because in various clinical scenarios, as described above, there can be discordance between natriuretic peptide levels and clinical manifestation, natriuretic peptide levels are not always correlated with PCWP.<sup>52</sup> However, in patients with decompensated heart failure caused by volume overload, a treatment-induced drop in PCWP usually leads to a rapid decrease in BNP levels (35 to 50 pg/mL/hour), especially in the first 24 hours of therapy, if adequate urine output is maintained.<sup>53</sup>

In the management of hospitalized patients with heart failure, it is probably not necessary to measure daily levels of natriuretic peptides. Instead, measurements obtained at admission and before discharge can be useful in tailoring the intensity of therapy and has been shown to have strong prognostic implications.<sup>54,55</sup> A third measurement of natriuretic peptide level in the first 24 to 48 hours after admission often enhances the success of a treatment plan. In a study with 114 patients admitted with CHF, the rate of mortality or readmission at 6 months was 15 times higher among patients with a predischARGE BNP level of more than 700 pg/mL than among patients with BNP levels of less than 350 pg/mL at discharge.<sup>56</sup>

**Outpatient.** Monitoring natriuretic peptide levels in the outpatient setting might help improve patient care. Changes in natriuretic peptide levels could potentially, help physicians titrate neurohormonal blockade agents and diuretics more aggressively and safely. Prospective studies in this area have yielded somewhat conflicting results. In the Systolic Heart Failure Treatment Supported by BNP (STARS-BNP) study, 220 patients with heart failure and left ventricular dysfunction were randomly assigned to receive therapy guided by natriuretic peptide levels versus standard of care; natriuretic peptide-guided treatment that targeted a BNP level of less than 100 pg/mL significantly reduced death and hospital stay for heart failure.<sup>57</sup> The smaller (130-patient) Strategies for Tailoring Advanced Heart Failure Regimens in the Outpatient Settings: Brain Natriuretic Peptides Versus the Clinical Congestion Score (STARBRITE) study failed to show significant improvement in the primary outcome of nonhospital days alive in patients whose treatment was guided by BNP levels. However, STARBRITE enrolled patients with more severe disease and used a higher BNP cutoff level.<sup>58</sup> In both studies, clinicians who adjusted medical therapy on the basis of natriuretic peptide levels prescribed higher doses of angiotensin converting enzyme (ACE) inhibitors and  $\beta$ -blockers.

In patients monitored in clinics, it is important to establish the “steady state” level of natriuretic peptide that corresponds to a patient’s optimized fluid status. Significant deviations from this baseline level allows for rapid diagnosis and institution of therapy, with more aggressive diuresis and follow-up when levels rise substantially.<sup>59</sup> Values that are considerably reduced from baseline can signal overdiuresis and impending prerenal azotemia. In view of significant intraindividual variability in natriuretic peptide levels, a change of at least 50% in the steady-state natriuretic peptide level might be a reasonable impetus for a more aggressive evaluation and modification of treatment.<sup>30</sup>

### Adrenomedullin

**Biology.** Adrenomedullin level, like natriuretic peptide levels, is elevated in the setting of myocardial stress. Adrenomedullin is a vasoactive peptide consisting of 52 amino acids that shares homology with calcitonin gene-related peptide.<sup>60</sup>

The downstream actions of adrenomedullin are mediated by an increase in cyclic adenosine monophosphate levels and nitric oxide, which lead to potent vasodilation, an increase in cardiac output, and diuresis and natriuresis.<sup>61-65</sup> This biologically active modulator is produced from the precursor proadrenomedullin, which is produced by the heart, adrenal medulla, lungs, kidneys, and vascular endothelium.<sup>66,67</sup> Adrenomedullin levels are increased in endothelial dysfunction, which is common in patients with heart failure and indicates a poor prognosis. In patients with heart failure, the magnitude of increase in adrenomedullin corresponds with the severity of heart failure and is inversely related to left ventricular function.<sup>66,68</sup> Adrenomedullin levels increase with worsening symptoms of heart failure and elevated PCWP and are reduced with appropriate therapy.<sup>66</sup> Because adrenomedullin combines with complement factor H and is rapidly cleared from the circulation, direct measurements are difficult; however, midregional proadrenomedullin (MR-proADM), another product of the precursor, appears to be more clinically stable and can be readily measured.<sup>69,70</sup>

**Adrenomedullin and Heart Failure.** In one of the first studies involving MR-proADM, Khan and colleagues<sup>71</sup> evaluated its prognostic capability in 983 patients after myocardial infarction. The data showed that MR-proADM level was increased in patients who died or developed heart failure (median, 1.19 nmol/L [interquartile range, 0.09 to 5.39 nmol/L]), in comparison with survivors (median, 0.71 nmol/L [interquartile range, 0.25 to 6.66 nmol/L],  $P < .0001$ ). The AUCs for MR-proADM, NT-proBNP, and the combination of both markers for prediction of death or heart failure were 0.77, 0.79, and 0.84, respectively,<sup>71</sup> which demonstrate that MR-proADM level is a powerful predictor of adverse outcome in patients after myocardial infarction and provides additive information with natriuretic peptides.

The prognostic implications of elevated MR-proADM levels in outpatients with both ischemic and nonischemic causes of CHF were evaluated by Adlbrecht and associates.<sup>72</sup> In 786 patients admitted with CHF, they demonstrated that MR-proADM level was a significant predictor of death (hazard ratio = 1.77,  $P < .001$ ) at 24 months.<sup>72</sup> Adrenomedullin also has predictive capability in asymptomatic patients with risk factors for coronary artery disease. In a study of 121 patients, Nishida and colleagues<sup>73</sup> reported that patients with elevated adrenomedullin levels had a higher risk of future cardiovascular events.

MR-proADM has also been evaluated in patients with acute decompensated heart failure. Gegenhuber and associates<sup>74</sup> evaluated the utility of natriuretic peptides, MR-proADM, and other biomarkers in predicting mortality in 137 patients with acute decompensated heart failure. The AUCs for the prediction of 1-year mortality were similar for BNP level (0.716; 95% confidence interval [CI], 0.633 to 0.790), midregional pro-A-type natriuretic peptide (MR-proANP) (0.725; 95% CI, 0.642 to 0.798), MR-proADM (0.708; 95% CI, 0.624 to 0.782), and copeptin (0.688; 95% CI, 0.603 to 0.764).<sup>74</sup> In the Biomarkers in the Assessment of Congestive Heart failure (BACH) study, MR-proADM level was compared with BNP and NT-proBNP levels in predicting mortality at 90 days in patients hospitalized for decompensated heart failure.<sup>75</sup> Of 1641 patients recruited, 568 (approximately one third) ultimately received a diagnosis of heart failure. The data showed that MR-proADM level was more accurate than BNP or NT-proBNP level at predicting outcome at 90 days.<sup>75</sup>

**Summary of MR-proADM.** Adrenomedullin is a relatively new biomarker that reflects biomechanical stretch and increases with pressure or volume overload. Although experience with adrenomedullin is limited, available data indicate that its levels are correlated with natriuretic peptide levels and may provide superior prognostic information in patients with acute and chronic heart failure.

### ST2 Receptor

**Biology.** ST2 is a member of the interleukin (IL)–1 receptor family and has two primary isoforms: a transmembrane receptor form (ST2L) and a soluble receptor form (soluble ST2), each regulated by different promoters.<sup>76–78</sup> Microarray analysis demonstrates marked upregulation of the transcript for both forms of ST2; the soluble form displays more robust expression in mechanically stimulated cardiomyocytes.<sup>78,79</sup> In response to mechanical strain, there is also an increase in the transcription and translation of the ligand, IL-33.<sup>80</sup> The IL-33/ST2 signaling cascade is thought to play a critical role in the regulation of myocardial response to pressure overload, which inhibits development of fibrosis.<sup>81–83</sup> Genetic knockouts of ST2 in mouse models demonstrated significant cardiac hypertrophy, interstitial fibrosis, and cavity dilation in response to transverse aortic constriction.<sup>78,84</sup> A similar phenotype is generated by infusion of soluble ST2, which is believed to serve as a decoy receptor, thereby decreasing the beneficial IL-33 interaction with ST2L. In this way, the ratio of soluble ST2 to IL-33 may regulate the IL-33/ST2L system.<sup>78</sup>

**ST2 and Acute Coronary Syndrome.** Clinically, ST2 levels increase early in the course of acute myocardial infarction and are inversely correlated with systolic function.<sup>79</sup> When ST2 levels were analyzed in more than 800 patients presenting to the hospital with an acute ST wave–elevation myocardial infarction (STEMI), the concentration of ST2 at the time of presentation was independently associated with in-hospital and 30-day mortality, after adjustments for age, hemodynamics, infarct territory, Killip class, and time from symptom onset to treatment.<sup>85</sup> Sabatine and colleagues<sup>86</sup> confirmed the utility of ST2 as a prognostic biomarker in 1239 patients presenting with STEMI in the Clopidogrel as Adjunctive Reperfusion Therapy—Thrombolysis in Myocardial Infarction (CLARITY-TIMI 28) trial. After adjusting for baseline characteristics and NT-proBNP level, the researchers showed that a concentration of ST2 above the median was a powerful predictor of cardiovascular death and heart failure, independent of baseline characteristics. The combination of ST2 and NT-proBNP levels significantly improved risk stratification in this patient population.<sup>86</sup>

**ST2 and Heart Failure.** In 161 patients with severe chronic New York Heart Association (NYHA) class III or IV heart failure, Weinberg and associates<sup>87</sup> demonstrated that change in ST2 levels over a 2-week period was an independent predictor of subsequent mortality or need for transplantation. ST2 has also proved to be an important biomarker in patients presenting with acute decompensated heart failure. In the PRIDE study,<sup>88</sup> ST2 concentrations were measured in 593 dyspneic patients in the emergency department and were found to be higher among patients with acute heart failure than in patients with other causes of dyspnea (0.50 vs. 0.15 ng/mL;  $P < .001$ ). An ST2 level of 0.20 ng/mL or higher was strongly predictive of death at 1 year in the entire cohort (hazard ratio = 5.6; 95% CI, 2.2 to 14.2;  $P < .001$ ). The 1-year mortality rate was less than 4.5% among patients in the lowest decile of ST2 levels but 45% among those in the highest decile (Figure 37-3).<sup>88</sup> In another study, researchers investigated change in ST2 concentrations during the course of a hospitalization in 150 patients with acute heart failure.<sup>89</sup> Multiple biomarkers were measured, including ST2, BNP, NT-proBNP, and blood urea nitrogen levels six times between admission and discharge. Among patients whose ST2 values decreased by 15.5% or more during the study period, the incidence of death was 7%, whereas those whose ST2 levels failed to decrease by 15.5% had a 33% chance of dying within 90 days.<sup>89</sup> Rehman and coworkers further examined the patient-specific characteristics of ST2 in 346 patients hospitalized with acute heart failure, demonstrating that, even after they controlled for established and clinical characteristics, ST2 remained

a predictor of mortality (hazard ratio = 2.04; 95% CI, 1.3 to 3.24;  $P = .003$ )<sup>90</sup> (see Figure 37-3). The highest mortality rate was observed in the subgroup that had elevated concentrations of both natriuretic peptides and ST2 (see Figure 37-3).<sup>90</sup>

**Summary of ST2.** ST2, induced by myocardial response to pressure or volume overload, has important clinical implications for patients with acute and chronic heart failure and acute coronary syndrome. ST2 level is a powerful prognosticator of future cardiovascular morbidity and mortality, providing incremental information to natriuretic peptides.<sup>91</sup>

### Markers of Inflammation

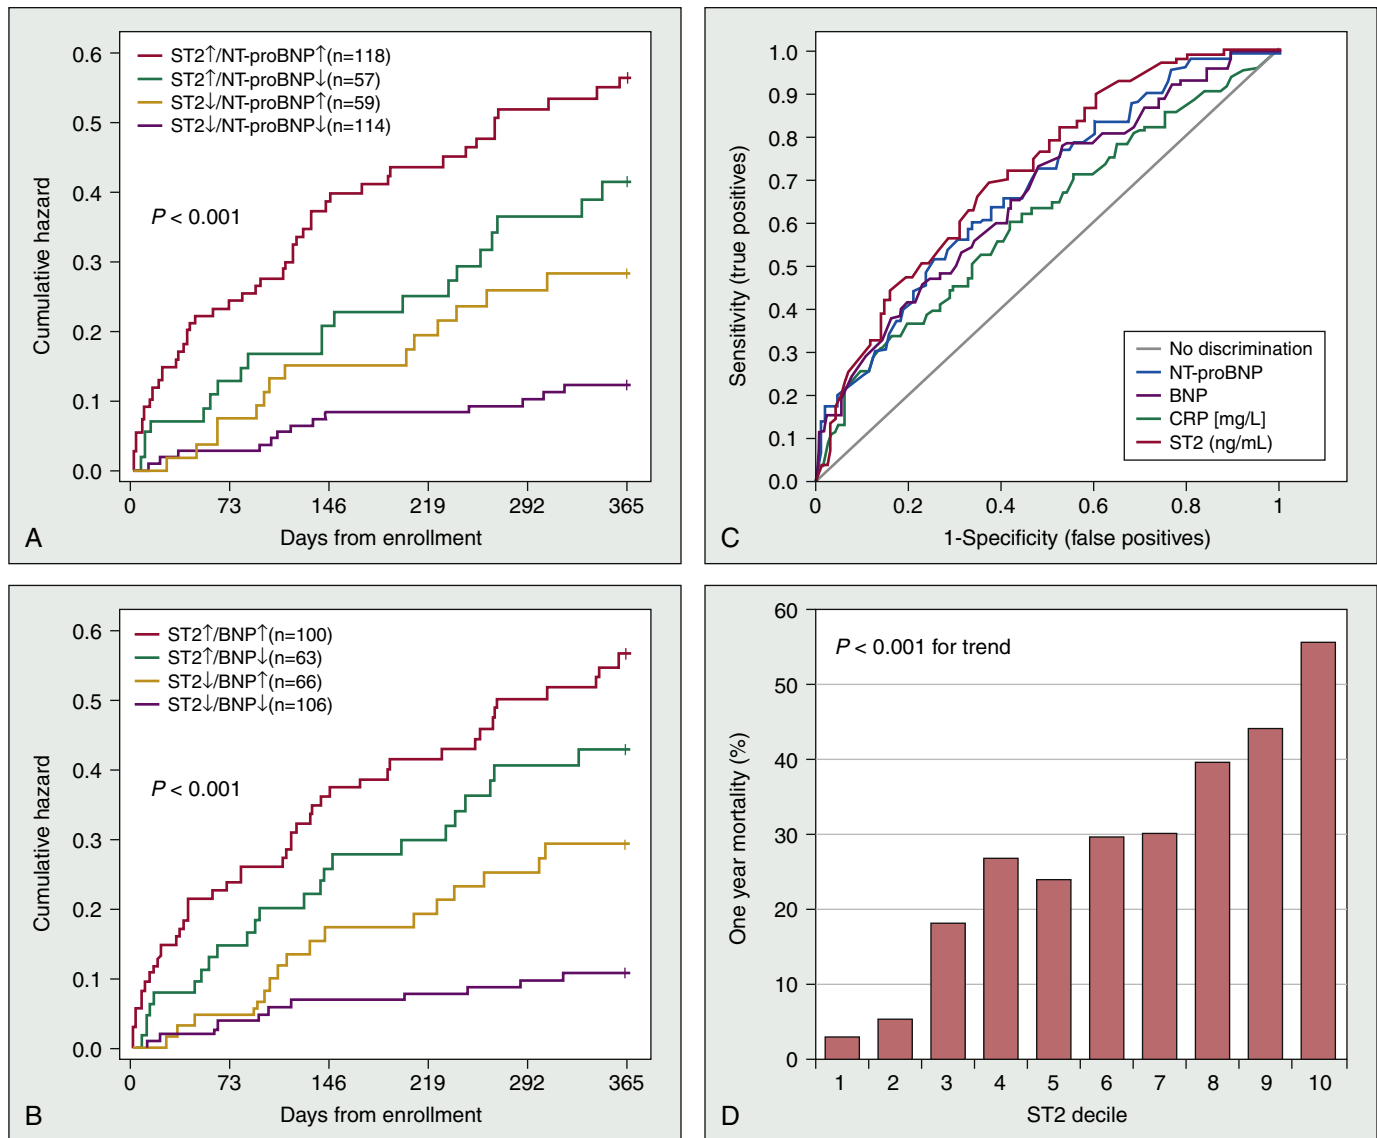

An abnormal inflammatory response in patients with heart failure is a mechanism for disease progression and deterioration (see also Chapter 11).<sup>92</sup> Ischemia and other biological insults to the heart trigger an innate immune response that leads to the upregulation of proinflammatory cytokines.<sup>91</sup> The activation of these mediators results in apoptosis, hypertrophy, and dilation, which in turn accelerate disease progression (Figure 37-4).<sup>91</sup> Many features of heart failure, including hemodynamic compromise and vascular abnormalities, can be explained through the effects of proinflammatory cytokines, including C-reactive protein (CRP), tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), IL-6, and IL-18.<sup>93–96</sup>

#### C-Reactive Protein

**Biology.** CRP is synthesized by hepatocytes in response mainly to IL-6.<sup>97</sup> CRP is an acute-phase reactant, its levels becoming significantly elevated shortly within the onset of an inflammatory process. It is, however, a nonspecific marker; its levels are commonly increased in the settings of infection, inflammatory diseases, acute coronary syndrome, smoking, and neoplastic processes.<sup>98</sup> CRP reduces the release of nitric oxide and increases expression of endothelin-1 and of endothelial adhesion molecules.<sup>99</sup> These features are suggestive of mechanisms by which CRP plays an important role in vascular diseases.

**hsCRP and Future Development of Heart Failure.** In four major population-based investigations (the Cardiovascular Health Study; the Framingham Heart Study; the Health, Aging and Body Composition [Health ABC] Study; and the Rotterdam Study), researchers have studied the development of heart failure in asymptomatic populations. In a total of 15,282 elderly patients with a follow-up period of 3.6 to 6.2 years, there was a significant association between elevated levels of high-sensitivity C-reactive protein (hsCRP) and development of heart failure (Table 37-2).<sup>98,100–103</sup> Subsets of patients with the highest levels of hsCRP had double the risk of developing heart failure. In the Health ABC study, high levels of other inflammatory cytokines such as TNF- $\alpha$  and IL-6 were also predictive of the development of heart failure.<sup>102</sup> The Rotterdam Study demonstrated that the association between hsCRP and heart failure was weaker in women and did not persist after the adjustment for traditional cardiovascular risk factors.<sup>103</sup>

**hsCRP and Patients at High Risk.** Large volumes of data have been collected to examine the relationship between hsCRP and the development of heart failure in high-risk patients, particularly those admitted with acute coronary syndrome (Table 37-3).<sup>98,104–112</sup> The initial study, in which Pietilä and colleagues<sup>104</sup> monitored 188 patients with acute myocardial infarction for 2 years, revealed that patients with higher peak CRP levels within the period immediately after myocardial infarction had increased risk of death and of development of heart failure. Subsequent analysis of more than 10,000 patients confirmed that elevated levels of CRP or hsCRP within 24 hours of acute myocardial infarction were predictive of short- and long-term development of heart failure. One of the largest studies of this association was a substudy from the Thrombolysis in Myocardial Infarction

**FIGURE 37-3** Mortality rates among patients hospitalized with acute heart failure as a function of ST2 and amino-terminal B-type natriuretic peptide (NT-proBNP) concentration (**A**) or B-type natriuretic peptide (BNP) concentration (**B**). **C**, Receiver-operator characteristic curve analysis, in which ST2 level was compared with BNP, NT-proBNP and C-reactive protein levels for predicting death at 1 year after hospitalization for acute heart failure. **D**, Frequency of mortality at 1 year as a function of ST2 decile. (From Rehman SU, Mueller T, Januzzi JL Jr. Characteristics of the novel interleukin family biomarker ST2 in patients with acute heart failure. *J Am Coll Cardiol* 2008;52:1458-1465.)

(TIMI) trials, in which increased concentrations of hsCRP within 48 hours of symptoms were strongly associated with development of heart failure.<sup>105</sup> More recently, analysis of data from more than 4000 patients with STEMI and non-STEMI revealed higher event rates for cardiovascular endpoints (cardiovascular death, recurrent myocardial infarction, stroke, and heart failure) with increasing quartile of hsCRP.<sup>106</sup> Patients with chronic stable angina have a similar association between hsCRP levels and the development of heart failure.<sup>113,114</sup>

**hsCRP and Prognosis in Heart Failure.** The prognostic implications of hsCRP on patients with chronic heart failure has been evaluated in multiple studies with a combined total of more than 6600 patients (Table 37-4).<sup>98,115-123</sup> There is a significant association between increasing level of hsCRP and worse cardiovascular outcome, including mortality, poorer left ventricular systolic function, higher prevalence of NYHA class III or IV symptoms, and poorer quality of life. This association appears to translate to both ischemic and nonischemic causes of heart failure.<sup>98,115-123</sup>

In contrast, there is a paucity of data regarding the prognostic significance of hsCRP in acute heart failure.

Alonso-Martínez and associates<sup>124</sup> prospectively studied the role of hsCRP in 76 patients admitted with acute heart failure. The data showed that elevated hsCRP levels were associated with increased rates of readmission at 18 months. Subsequently, Mueller and colleagues<sup>125</sup> evaluated 214 patients with acute heart failure to determine the impact of CRP on rates of all-cause mortality at 24 months. Patients in the highest tertile of CRP had significantly higher in-hospital and all-cause mortality rates at 24 months. In a study in Finland, researchers evaluated clinical and biochemical predictors of 1-year mortality in patients hospitalized for acute heart failure. The data showed that elevated CRP was independently predictive of mortality at 1 year.<sup>126</sup> Villacorta and coworkers<sup>127</sup> confirmed that finding in 119 patients hospitalized in Brazil for acute heart failure: CRP proved to be the most important prognosticator of mortality at 1 year. Although the role of CRP as a prognostic biomarker in patients hospitalized with heart failure is yet to be firmly established, limited data suggest that it may complement other biomarkers in predicting mortality in this clinical setting.

**FIGURE 37-4** Cytokine hypothesis of heart failure. Injury to the myocardium leads to increased production of proinflammatory cytokines (tumor necrosis factor  $\alpha$ , interleukin-6, and interleukin-18), leading to depressed cardiac function. Decreased cardiac output causes hypoperfusion of the skeletal muscle, which activates monocytes to produce proinflammatory cytokines, further impairing cardiac function. (From Braunwald E. Biomarkers in heart failure. *N Engl J Med* 2008;358:2148-2159.)

**Summary of CRP.** CRP is perhaps the most important marker of inflammation and is analyzed routinely in clinical practice. It has validated utility in predicting the development of heart failure in populations at low and high risk, as well as prognostic value in patients with chronic heart failure. In practice, interpretation of CRP levels is somewhat hampered by the fact that different cutoff levels were used in different studies, which makes it difficult to interpret individual CRP levels. Determining the real-world clinical utility of hsCRP necessitates further investigation with uniform studies that use similar assays and cutoff levels.

## Markers of Myocardial Cell Death

### Troponin

**Biology.** Myocardial cell death occurs in heart failure and may represent the common final pathway to refractory failure. Although cardiac troponin levels are well-validated markers of myocyte injury during myocardial infarction, the pathophysiological mechanisms underlying troponin elevations in heart failure are probably distinct from those underlying acute coronary syndrome.<sup>128</sup> Multiple mechanisms, including inflammation, interstitial fibrosis, increased wall stress, oxidative stress, and neurohormonal activation, are responsible for adverse cardiac remodeling that leads to progressive heart failure.<sup>129-132</sup> Troponin is a cardiac structural protein that is part of the troponin-tropomyosin complex, with a small amount present in the cytosol.<sup>128</sup> Mild elevations in troponin levels have been documented in a number of cardiovascular diseases, including heart failure. Hypotheses for why troponin levels may be elevated in the setting of heart failure, even in the absence of overt ischemia, include myocardial injury, loss of cell membrane integrity, excessive wall

tension that leads to subendocardial ischemia, apoptosis, or some combination.<sup>91,133,134</sup>

**Troponin and Acute Heart Failure.** Several small studies have reported elevated cardiac troponin levels in patients with decompensated heart failure, in the absence of acute coronary syndrome, and found associations between elevated levels of troponin and poor prognosis.<sup>135-138</sup> La Vecchia and associates evaluated the clinical associations and prognostic implications of detectable cardiac troponin I (cTnI) in 34 patients with severe heart failure.<sup>139</sup> Modest elevations of cTnI ( $0.7 \pm 0.3$  ng/mL) were associated with lower left ventricular ejection fraction, and there was a trend toward higher pulmonary artery pressures. In patients who evinced clinical improvement after admission, cTnI levels became undetectable after a few days.<sup>139</sup> However, in patients with refractory heart failure who ultimately died in the hospital, detectable levels of cTnI persisted throughout the observation period.<sup>139</sup> In a larger subsequent study, cTnI's role in predicting adverse outcomes was evaluated in 238 patients with advanced heart failure who were referred for cardiac transplantation.<sup>128</sup> Patients with detectable cTnI levels of 0.04 ng/mL or higher had higher levels of BNP, impaired hemodynamics (indicated by lower cardiac index and higher PCWP), progression of left ventricular dysfunction, and increased mortality (relative risk, 2.05; 95% CI, 1.22 to 3.43).<sup>128</sup>

Researchers for the Acute Decompensated Heart Failure National Registry (ADHERE) evaluated the association between cardiac troponin level and adverse events in 84,872 patients with acute decompensated heart failure.<sup>140</sup> Patients with positive troponin levels (6.2%) had lower systolic blood pressure on admission, a lower ejection fraction, and higher rates of in-hospital mortality (8.0% vs. 2.7%;  $P < .001$ ) than did those with undetectable troponin levels (odds ratio for

death, 2.55; 95% CI, 2.24 to 2.89;  $P < .001$ ). The study confirmed the powerful prognostic utility of elevated troponin levels in predicting mortality in patients hospitalized with decompensated heart failure (Figure 37-5).<sup>140</sup>

**Troponin and Chronic Heart Failure.** The role of myocyte injury in prognosis of stable outpatients with heart failure was evaluated by Hudson and colleagues.<sup>141</sup> The authors assessed the association of elevated cardiac troponin T (cTnT) levels with the severity, cause, and prognosis of heart failure in 136 stable, ambulatory patients. Patients with elevated cTnT levels had an increased risk of death from or hospitalization for heart failure (relative risk, 2.7; 95% CI, 1.7 to 4.3;  $P = .001$ ) and of death alone (relative risk, 4.2; 95% CI, 1.8 to 9.5,  $P = .001$ ) at 14 months.<sup>141</sup> In a larger outpatient data set from the Val-HeFT study, Latini and associates<sup>142</sup> measured levels of cTnT and high-sensitive troponin T (hsTnT) in 4053 patients with chronic stable heart failure. Levels of cTnT were detectable in 10.4% of the population with the cTnT assay (lower limit of detection, 0.01 ng/mL), in comparison with levels of hsTnT in 92.0% with the new hsTnT assay (lower limit of detection, 0.001 ng/mL). Patients in whom cTnT level was elevated or in whom hsTnT level was above the median (0.012 ng/mL) had more severe heart failure and worse prognoses.<sup>142</sup> Increased concentration of cTnT (cTnT level > 0.01 ng/mL) was associated with an increased risk of death (hazard ratio, 2.08; 95% CI, 1.72 to 2.52;  $P < .0001$ ) and increased risk of first hospitalization for heart failure (hazard ratio, 1.55; 95% CI, 1.25 to 1.93;  $P < .0001$ ) in multivariable models. For each 0.01-ng/mL increase in hsTnT level, risk of death increased 5% (95% CI, 4% to 7%).<sup>142</sup>

**Troponin Summary.** Cardiac troponin level, an indicator of myocardial necrosis, is an established biomarker in the evaluation and management of acute coronary syndrome. There is clear evidence that even low levels of detectable troponin in patients with heart failure have significant prognostic implications in terms of morbidity and mortality. Such data hold true for patients with both acute decompensated and chronic heart failure.

## Markers of Renal Function (see also Chapter 18)

### Neutrophil Gelatinase–Associated Lipocalin

In patients with heart failure who develop concurrent renal dysfunction, management is challenging, requiring a careful balance between diuretic and vasodilator therapy. The cardiorenal syndrome is a well-documented phenomenon and is common among patients with acute heart failure; approximately 60% of these patients manifest at least a 0.1-mg/dL rise in creatinine level during hospitalization.<sup>143</sup> However, nephrotoxic insult, as manifested by an increase in serum creatinine level, usually takes at least 24 hours to become evident. A biomarker that rapidly increases with acute kidney injury could prove to be very powerful in guiding therapy in these complex clinical scenarios.

**Biology.** Neutrophil gelatinase–associated lipocalin (NGAL) is a small (25-kDa) molecule that belongs to a superfamily of lipocalins and is normally secreted in low amounts in the lungs, kidneys, trachea, stomach, and colon.<sup>144,145</sup> Levels of NGAL are elevated in various pathological states, including acute or chronic kidney injury, neoplasia, chronic

inflammatory processes, and atherosclerosis.<sup>144</sup> Cellular action of NGAL is mediated by binding to two types of cellular receptors: 24p3R (a brain-type organic cation transporter) and the megalin multiscavenger complex (found on the brush-boarder surface of renal tubular cells).<sup>146,147</sup> NGAL interacts with these receptors and forms a complex with its ligand, iron siderophores; this leads to receptor-mediated endocytosis and to intercellular and intracellular iron trafficking.<sup>144</sup> By depleting iron and iron-binding molecules critical for bacterial survival, NGAL exerts bacteriostatic effects.<sup>145</sup> In addition to its antimicrobial properties, in vitro experiments have demonstrated that NGAL is a stress-induced renal biomarker. In renal tubules, NGAL messenger RNA is upregulated within a few hours of exposure to harmful stimuli.<sup>144</sup> NGAL production is rapidly induced and expressed in mice upon intraperitoneal injection of cisplatin, and the subsequent rise in levels of NGAL precedes the rise in serum creatinine or urine *N*-acetyl glucosaminidase levels.<sup>148</sup>

**NGAL and Acute Kidney Injury.** The promise of NGAL as an early marker of acute kidney injury has been demonstrated in small clinical studies.<sup>149-152</sup> In 71 children undergoing cardiopulmonary bypass, Mishra and associates<sup>149</sup> evaluated NGAL levels in both serum and urine at baseline and 2 hours after the procedure. Multivariate analysis confirmed that the level of urinary NGAL was the most powerful independent predictor of severe kidney injury; a cutoff level of 50  $\mu$ g/L was strongly predictive of acute kidney injury onset (AUC = 0.99; sensitivity, 100%; specificity, 98%).<sup>149</sup> Hirsch and colleagues<sup>150</sup> evaluated the utility of NGAL in predicting contrast material-induced nephropathy (CIN) in 91 children with congenital heart disease who

underwent cardiac catheterization. In patients who subsequently developed contrast material-induced nephropathy, there was a significant increase in urinary NGAL and serum NGAL 2 hours after the procedure, according to a cutoff level of 100 ng/mL (urine NGAL, 0.92; serum NGAL, 0.91; sensitivity, 73%; specificity, 100% for both).<sup>150</sup> Other studies have confirmed these observations, which suggests that NGAL measurement may be a very powerful predictor of acute kidney injury, regardless of the mode of injury.<sup>151,152</sup>

**NGAL and Heart Failure.** Data on the utility of NGAL in heart failure are limited. A small study of 90 patients showed that, in comparison with age- and sex-matched healthy control subjects, patients with left ventricular dysfunction, as expected, had a lower GFR and higher NT-proBNP levels and urinary albumin excretion.<sup>153</sup> The median urinary NGAL levels were significantly higher in the group with left ventricular dysfunction (175 vs. 37  $\mu$ g/gCr,  $P = .0001$ ). Both serum creatinine level and estimated GFR were significantly correlated with urinary NGAL levels.<sup>153</sup> In another study involving 46 elderly patients with CHF, higher levels of NGAL were found in patients with heart failure than in healthy age-matched control subjects (458 vs. 37.8 ng/mL,  $P = .0001$ ).<sup>154</sup> Moreover, NGAL level was found to increase in parallel with severity of heart failure and proved to be prognostic, inasmuch as among patients with a baseline NGAL level exceeding 783 ng/mL, the mortality rate was significantly higher (hazard ratio = 4.08,  $P = .001$ ).<sup>154</sup> In CHF, reduction in GFR arises in large part from reduced renal perfusion, which serves as a hypoxic trigger for acute tubular necrosis.<sup>155</sup>

**NGAL Summary.** NGAL level represents a first in its class: a renal stress biomarker that signifies acute kidney injury. Its

utility in predicting the development of renal insufficiency with good sensitivity and specificity has been shown in small studies involving cardiopulmonary bypass and angiography. Future studies may further define the role of NGAL level in assisting clinicians to achieve a proper balance between diuretics, vasodilators, and inotropes when treating patients with acute heart failure.

MULTIMARKER APPROACH AND FUTURE DIRECTION

The evolution of numerous biomarkers has created valuable assets for the classification and management of heart failure. There is growing interest in the use of multimarker strategies to stratify patients with heart failure, similar to acute coronary syndromes. The interaction in heart failure between biomechanical strain, inflammation, and cellular injury allows a variety of biomarkers to jointly lead to better understanding of the pathogenesis, clinical diagnosis, and prognosis of heart failure.<sup>91</sup> These markers are complementary to the clinical data and enhance prediction of morbidity and mortality.

In evaluating the association between cTnI and mortality in advanced heart failure, Horwich and coworkers<sup>128</sup> demonstrated that using both cTnI and BNP levels further improves prognostic value.<sup>128</sup> Patients with both detectable cTnI level and a BNP level exceeding 485 pg/mL had a twelve-fold higher risk of death than did those with both undetectable cTnI level and a BNP level of less than 485 pg/mL. The prognostic value of this combination was confirmed with the hsTnT assay.<sup>142</sup> Prediction was also enhanced with measurements of natriuretic peptides and MR-proADM, ST2, or CRP.<sup>71,88,156</sup> In 983 consecutive patients who had suffered myocardial infarction, Khan and associates showed that the combination of MR-proADM provided further risk stratification for patients with NT-proBNP levels above the median ( $P < .001$ ).<sup>71</sup> The PRIDE study verified the prognostic capability of the multimarker approach. Of the 184 patients with NT-proBNP level of 986 pg/mL or higher, 56 (30.4%) died. All but 1 of the decedents within this group had an ST2 level of 0.2 ng/mL or higher.<sup>88</sup> In contrast, of the 28 patients with NT-proBNP levels of

986 pg/mL or higher and ST2 levels of less than 0.2 pg/mL, only 1 (3.5%) died at 1 year.<sup>88</sup>

Dunlay and colleagues<sup>157</sup> used CRP, BNP, and cTnT levels in 593 patients with heart failure to evaluate the prognostic utility of a multimarker approach. Among patients with CRP (<11.8 mg/L), BNP (<350 pg/mL), and cTnT (≤0.01 ng/mL) levels all lower than the median, the 1-year mortality rate was low (3.3%), whereas among those with two or three biomarkers higher than the median, the mortality rate was markedly increased (30.8% and 35.5%, respectively). A strategy involving two biomarkers offered greater improvement in predicting 1-year mortality risk than did use of a single biomarker. In this study, however, the addition of a third biomarker conferred no added benefit over a two-biomarker approach.<sup>157</sup>

Short-term prognosis with a multimarker strategy was also evaluated in a study of 577 consecutive patients admitted with severe decompensated NYHA class III or IV low-output heart failure, to determine the combined prognostic value of admission BNP, cTnI, and hsCRP levels at 31 days.<sup>158</sup> The total mortality rate in the group was 17.7%. Multivariate Cox analysis revealed that elevated levels of BNP, cTnI, and hsCRP were independent predictors of mortality.<sup>158</sup> There was a significant, gradually increased risk of 31-day cardiac death with increased numbers of elevated biomarkers ( $P < .001$ ).<sup>158</sup>

The multimarker approach provides powerful prognostic information in both compensated and decompensated heart failure. Combinations of biomarkers allow clinicians to better stratify risk for patients and perhaps tailor more aggressive therapy for those with a higher predicted risk. As new biomarkers are developed and implemented, more powerful multimarker approaches are likely to follow.

## CONCLUSION

Biomarker use has skyrocketed since 2000. Natriuretic peptide levels, because of their low cost and rapid and accurate ability to provide additional information not surmised from clinical evaluation, are the standard biomarkers. But work with natriuretic peptide levels has also shown that they are not to be used as stand-alone tests; rather they are best used as adjuncts to other tests used by health care providers. There are many caveats to using natriuretic peptide levels, as there will be with all future biomarkers; thus, there is always much to learn about them. Finally, because complex pathological conditions are widespread, panels of multiple biomarkers will be needed in evaluation, risk stratification, and, ultimately, treatment initiation and follow-up.

## Measuring Quality Outcomes in Heart Failure

Edward P. Havranek

Systematic efforts to measure and improve the quality of medical care date back to the early 1900s<sup>1</sup> but have gained momentum only since about 2000. The pursuit of higher quality care is best viewed as an extension of clinical care in the movement toward increasing scientific rigor that has characterized the explosive growth in medical science since World War II. The forces behind the movement toward improved quality of care are both internal, coming from within medicine, and external, from society at large.<sup>2</sup> Thus, measures of the quality of care must be useful within health care organizations for the purpose of guiding internal quality improvement efforts

However, measuring outcomes is generally not sufficient for guiding quality improvement efforts within organizations, since outcomes cannot be acted on directly. Although the ultimate goal might be reduction in operative mortality at a hospital, the goal cannot be accomplished unless the preoperative, intraoperative, and postoperative processes that potentially contribute to mortality can be identified, measured, and changed. Outcome events may not be suitable for comparing quality of care across organizations because numbers of cases are so small that differences in event rates may not be statistically significant; rather, the events may occur by chance.<sup>9</sup> Organizations using continuous quality improvement techniques need to remeasure quality at relatively frequent intervals; when numbers of outcomes are small, it can be difficult to judge whether differences over time are random or are the result of the organization's quality improvement effort. Finally, fair comparison of outcomes requires that the risk of the outcome intrinsic to the patient be equalized across the organizations being compared; this process is known as "risk adjustment."<sup>10,11</sup> The development of statistical models for risk adjustment is a laborious process, and retrospective statistical adjustment for risk is always subject to error from unmeasured confounding.

In addition to statistical concerns regarding the use of outcomes to measure quality of care, there are philosophical concerns regarding the selection of which outcome or outcomes to measure. Care for heart failure is an excellent example, in which mortality seems to be the obvious outcome to measure, as it has been in clinical trials (see also Chapter 34). If, however, mortality is being used to assess the quality of a hospital's care, problems arise in specifying the time frame used to define mortality. Mortality over long terms, such as 1 year, is affected by care related to the index hospitalization, but it also may be affected by care during subsequent hospitalizations, perhaps at other institutions, and to outpatient care outside the control of the index hospital. Shorter observational time frames such as 30 days may better reflect care during the index hospitalization, but it may be too short to detect

and across health care organizations for the purpose of motivating organizations to improve care. Within organizations, quality measurement became important as quality improvement methods developed in manufacturing by W. Edwards Deming<sup>3,4</sup> began to be transferred to service organizations such as health care (Figure 38-1). Across organizations, measurement of quality of care has assumed increasing importance as quality measures have become publicly reported and comparisons have been made to determine reimbursement in "pay-for-performance" schemas.

Heart failure has occupied a prominent position in efforts to improve quality of care. Along with acute myocardial infarction, atrial fibrillation, and pneumonia, it was a condition targeted by Medicare for quality improvement efforts in 1998.<sup>5</sup> The reasons for this focus on heart failure are several: Mortality is high, heart failure is a common condition, and because of its chronicity and frequently severe morbidity, hospitalization is often needed. In combination, these factors result in exceptionally high cost to the health care system. Heart failure is thought to be the diagnosis entailing the highest cost among Medicare patients.<sup>6</sup> Finally, basic care for heart failure is strongly evidence-based, which has facilitated the development of consensus on quality measures.

### GENERAL PRINCIPLES OF QUALITY MEASUREMENT

#### Defining Quality

Quality is an elusive concept that, particularly when applied to health care, defies definition. As detailed in a report from the Institute of Medicine,<sup>2</sup> high-quality health care is agreed to be described along six dimensions (Table 38-1).

#### A Measurement Framework

Although quality should be described by measurement of the *outcomes* of care, this may not always be possible. Circumstances may dictate that, under the framework first proposed by Donabedian<sup>7,8</sup> (Table 38-2), quality be measured by *processes* or *structures* of care.

**Outcomes.** Measuring outcomes such as mortality, hospital admission, and functional capacity have the obvious advantage of being recognized as relevant and important. Most outcomes are measured precisely, and those measurements may be readily available from administrative records.

**FIGURE 38–1** The role of quality measurement in continuous quality improvement. Quality measurement occurs during the study phase of the “plan-do-study-act” (PDSA), or Shewhart, cycle (attributed to W. Edwards Deming).

**TABLE 38–1** Institute of Medicine Scheme for Describing Quality of Care<sup>2</sup>

Health care should be...	
Safe	Avoids injuries to patients from the care that is intended to help them
Effective	Provides services on the basis of scientific knowledge to all who could benefit and refrains from providing services to those not likely to benefit (avoiding underuse and overuse, respectively)
Patient-centered	Provides care that is respectful of and responsive to individual patient preferences, needs, and values and ensures that patient values guide all clinical decisions
Timely	Reduces waits and sometimes harmful delays for both those who receive and those who give care
Efficient	Avoids waste, including waste of equipment, supplies, ideas, and energy
Equitable	Provides care that does not vary in quality because of personal characteristics such as gender, ethnicity, geographical location, and socioeconomic status

differences related to high-quality care, such as initiation of  $\beta$ -blocker therapy (see also Chapter 46).

In addition to problems defining time frame, care that reduces mortality may not always satisfy the imperative that care be patient-centered. Again, heart failure provides an excellent example. It is well known to clinicians who specialize in heart failure that elderly patients and patients with advanced disease may value functional capacity and quality of life over duration of survival.<sup>12,13</sup> High-quality care for such individuals would generally not involve life-prolonging therapy such as defibrillator implantation as it might for other patients, and a lower mortality rate among such individuals would not necessarily reflect higher quality care.

**Processes.** Because of these difficulties in using outcomes to measure quality of care, investigators often rely on measurement of processes of care.<sup>14</sup> In order for a process to serve as a measure of quality, there must be consensus that there is a strong link between the process and a desirable outcome. It must also be actionable; that is, it must describe an aspect of care that is within the health care provider's control. Process measures are expressed as the percentage of eligible patients receiving a given aspect of care, and both numerator (the

**TABLE 38–2** A Classification of Quality Measures

Measure	Advantages	Disadvantages
Outcomes	Validity is usually obvious Measurement is usually more precise	Numbers of events may be too small to judge whether observed differences are random or significant Statistical risk adjustment is required Time frame for observation may be difficult to specify Not directly actionable
Processes	Greater numbers of events are available for analysis	Validity may be less obvious when links with outcomes are less well established Greater effort is necessary to specify May be more costly to measure
Structures	May be most actionable	Validity is frequently questioned because of weakest links with outcomes

parameters specifying that the treatment was delivered) and denominator (the population eligible for the treatment) must be carefully and explicitly defined. Specifications for process measures necessarily involve a trade-off between specificity and sensitivity. For example, there is undeniable evidence from multiple clinical trials that angiotensin-converting enzyme (ACE) inhibitors decrease mortality and improve functional capacity in patients with heart failure caused by systolic dysfunction (see also Chapter 45). The strength of this evidence base is reflected in recommendations for ACE inhibitor use in guidelines of care for heart failure promulgated by several cardiology professional societies, and this evidence has served as the basis for measures of quality of care. Specification of these measures must strike a balance between being sensitive (designed to apply to the largest number of patients possible) and specific (designed to apply only to the subset of patients who are unequivocally eligible). In a sensitive measure, the numerator might include only patients receiving a dose consistent with benefit in clinical trials, and the denominator might include all patients who have an ejection fraction of less than 40% and have no absolute contraindication to an ACE inhibitor, such as prior angioedema or known bilateral renal artery stenosis. In a specific measure, the numerator might include patients receiving any dose, and the denominator might include all patients who have an ejection fraction of less than 40% and have no absolute or relative contraindications (such as renal insufficiency). Although specific measures have the advantage of greater validity for clinicians, they may be less useful because they do not address care for larger segments of the population of patients with heart failure than do more sensitive measures. More specific measures also tend to yield higher rates, which are less useful for guiding quality improvement because they are subject to “ceiling effects”; it is more difficult to improve rates from 90% to 100% than it is to effect an improvement from 50% to 60%.

Once numerator and denominator have been specified, process measures are typically subjected to pilot testing to determine feasibility and reliability. *Feasibility* implies that the data needed to calculate the measure can be obtained at reasonable cost within a reasonable time frame. The cost of collecting data to determine process measures is a hidden disadvantage of such measures. Because computerized medical records are not used in many hospitals and practices, data collection may require chart review, which is expensive. Tests of *reliability* typically involve assessment of reproducibility across providers and across data collectors.

**Structures.** Finally, quality of care can be judged by assessing structures used to deliver care. Structures may include equipment and facilities, training and numbers of staff, administrative processes, and other materials. The links between structures and outcomes are generally not as strong as those demonstrable between processes and outcomes, and structures are less amenable to standardized evaluation across organizations. This approach has not been widely applied and has not been applied in heart failure. One example of a structural measure of quality is the use of procedural volumes to assess high-quality care.<sup>15-17</sup> Although in general there is a positive association between higher procedural volume and better outcomes, the associations are not strong, and variability in outcome at a given volume can be large. Computerized entry of physicians' orders and "closed" intensive care units, in which only critical care subspecialists serve as attending physicians, have also been used as measures of quality.<sup>18</sup>

## The Role of the Organization of the Health Care System

The quality of health care must be viewed in the context in which it is delivered. Although many examples of integrated delivery systems exist, the current U.S. health care system is best characterized as being made up of a rather large number of independent components. Outpatient care is delivered jointly by primary care and specialist physicians who do have common medical records or administrative relationships. Hospital care may be provided by the same physicians who provide outpatient care, but it is increasingly delivered by hospital-based physicians. Physicians and hospitals are loosely affiliated and do not have administrative relationships. Additional independent components of the health care system include pharmacies, home health agencies, and long-term care facilities. Under these circumstances, responsibility for care of a patient with a chronic condition who requires frequent hospitalization is diffuse. When responsibility cannot be assigned, actionable quality measures are very difficult to formulate, and quality improvement efforts are fragmentary at best.

In addition to barriers created by fragmentation in the delivery system, financial incentives are often misaligned with efforts to measure and improve quality.<sup>19</sup> One of the best examples is the fate of hospital-based programs that manage the transition from inpatient to outpatient care for patients with heart failure. Such programs have been shown to produce beneficial outcomes, including reduced rates of readmission. Because hospital revenue may decline with decreased readmission rates under most reimbursement patterns currently in place, however, many transition management programs have been discontinued. Health care organizations that make investments in measuring and improving care are unlikely to see returns on those investments.

## The Role of Health Information Technology

As discussed, measurement of process indicators is always necessary for purposes of internal quality improvement and sometimes necessary for comparing performance across organizations. Collection of data for calculating these measures is typically labor intensive. This can make data collection prohibitively expensive; furthermore, by the time data have been collected and measures calculated, conditions within organizations may have changed so that relevance of the data is questioned. Automated and ongoing query of properly structured electronic medical records can dramatically reduce the time and expense associated with data collection. Automated electronic record review often fails to identify contraindications to therapy. As a result, process measures derived from automated review often falsely identify failure to adhere to quality measures. They are thus more suitable for serial measurement

within organizations rather than comparisons across organizations. In one study of over 1000 patients with diabetes at 21 Veterans Affairs facilities,<sup>20</sup> rates of best-practice diagnostic testing and medication use were lower with automated than manual chart review. In a more recent study, Baker and colleagues<sup>21</sup> focused on heart failure and obtained similar results. They reviewed patients' charts when an automated algorithm identified quality problems in 517 outpatients with heart failure. They found that performance was better, ranging from a 1.9% absolute increase on a  $\beta$ -blocker measure to a 23.2% absolute increase on a measure of warfarin in atrial fibrillation when additional chart review was performed.

Ongoing debate concerns whether use of an electronic record by itself improves quality. The subject was reviewed by Chaudhry and associates,<sup>22</sup> who focused on 76 studies conducted in the United States on multifunctional information systems; a comprehensive database of all studies they reviewed is available.<sup>23</sup> Although only one small early study they reported focused on heart failure,<sup>24</sup> studies of care that adhered to guidelines for preventive services (such as influenza vaccination) and for chronic illnesses (such as hypertension) revealed improvement, whereby decision support was linked with electronic records. There seemed to be consistent reduction in medication errors associated with computerized entry of physicians' orders.

## THE CURRENT STATE OF QUALITY OF CARE FOR HEART FAILURE IN THE UNITED STATES

Of the six dimensions of quality measurement as defined by the Institute of Medicine<sup>2</sup> (see Table 38-1), three are relevant to the assessment of the quality of care for heart failure.

### Effectiveness

Using the dimension of effectiveness to measure the quality of care implies that structures or processes of care known to be efficacious and effective are applied to the population of patients known to benefit, and the net result of this application is the achievement of desired outcomes. The key elements of this scheme are that (1) measured structures or processes are known to be *efficacious* to the highest level of certainty possible, (2) the measures are applied to a *defined population* rather than to individuals, and (3) the *net effects* on outcomes are considered.

A process for developing measures of effectiveness has been defined explicitly by the American College of Cardiology and the American Heart Association (ACC/AHA).<sup>14</sup> Once a target for the quality effort has been defined, the relevant literature is reviewed and synthesized. In practice, this review and synthesis are usually provided by guidelines, ideally developed independently of influence from commercial entities that might benefit materially from implementation of the process measure. In general, ACC/AHA class I and class III indications for therapy identify potential performance measures; class I indications are the "procedures/treatments that *should* be performed," and class III indications are the "procedures/treatments that *should not* be performed since they are not helpful and may be harmful."<sup>14</sup> Potential process measures are developed by specifying a numerator and a denominator for the measure and a period of time to which the measure will be applied. Not all class I and class III recommendations survive this process; in many cases, a sufficiently explicit specification may not be feasible. For instance, addition of an aldosterone antagonist is a class I recommendation for patients with severe symptoms except "under circumstances where monitoring for hyperkalemia or renal dysfunction is not anticipated to be feasible" because "the risks may outweigh the benefits."<sup>14</sup>

Although the specification of the guideline recommendation accurately reflects the known efficacy of these agents from randomized trials and the limits on their effectiveness from outcomes research, something that is “not anticipated to be feasible”<sup>14</sup> cannot be reliably turned into something measurable. Finally, measures are subjected to assessment of how interpretable, actionable, and feasible they are (Table 38-3). Measures not passing these three tests may still be useful to individual organizations as quality metrics<sup>25</sup> rather than performance measures in order to achieve self-directed quality goals.

Independent practice guidelines have been available for heart failure since 1994,<sup>26</sup> have been updated regularly, and are contemporary through 2009.<sup>27,28</sup> Few class I recommendations have been turned into process measures (Table 38-4). Currently, only assessment of left ventricular ejection fraction, prescription of an ACE inhibitor or angiotensin receptor blocker (ARB) to patients with reduced systolic function, provision of discharge instructions, and delivery of advice to quit smoking are addressed for hospitalized patients with heart failure.

Imperfect adherence to these measures has been documented extensively, with a general trend toward improvement over time; trends toward improved performance on the measures, however, have leveled off (Figure 38-2A). Rates of ejection fraction determination were 66% to 70% and rates of ACE inhibitor prescription were 68% to 72% at the beginning of Centers for Medicare and Medicaid Services’ (CMS’s) scrutiny of care for heart failure in the period 1998 to 2001.<sup>5</sup> According to the available data from the Medicare program for the period October 2007 through September 2008, national average rates of adherence to the discharge instruction measure were 17%; to the ejection fraction determination measure, 89%; and to the ACE inhibitor/ARB prescription measure, 88%.<sup>28a</sup> Certain patients’ characteristics (including older age, presence of chronic kidney disease, and nonblack race) and providers’ characteristics (smaller hospital size, nonteaching status, absence of advanced cardiac facilities, for-profit or public structure) have been associated with lower rates of guideline adherence.<sup>29,30</sup>

Whether adherence to the widely reported measures of the quality of care for heart failure has a net effect on outcomes remains somewhat controversial; thus, some authors have questioned whether the currently reported measures are sufficient.<sup>31,32</sup> Werner and Bradlow<sup>33</sup> examined the relationship between performance on the process measures for heart failure and risk-adjusted mortality rate during the inpatient stay and at 30 days and 1 year for 3657 hospitals with data available in the Hospital Compare database.<sup>28a</sup> They compared mortality rates in hospitals with performance above the 75th percentile with those in hospitals whose performance was below the 25th percentile. Absolute mortality reductions were small and of borderline statistical significance: 0.1% for inpatient mortality ( $P = .03$ ), 0.2% for 30-day mortality

**TABLE 38-3** Criteria for Designating Possible Process Measures for Clinical Use

Interpretable	The degree to which a practitioner is likely to understand what the results mean and can take action if necessary
Actionable	The degree to which the performance measure is under the control of the entity being assessed
Feasible	The ease with which the required data can be collected and the measure can be assessed reproducibly; pilot testing is generally needed

**TABLE 38-4** Relationship between Guideline Recommendations and Performance Measures

Elements of Care for ACC/AHA 2009 Guideline Class I Recommendations for Patients with Heart Failure	ACC/AHA Performance Measure*	JCAHO/CMS Performance Measure*
Recommended elements of clinical assessment (history and physical examination: weight, blood pressure, activity level, volume status)	✓	
Initial and follow-up laboratory testing, chest radiography, and electrocardiography	✓	
Assessment of left ventricular systolic function	✓	✓
Assessment for coronary heart disease		
Diuretics for volume overload		
Use of ACE inhibitors and ARBs	✓	✓
Use of $\beta$ -blockers	✓	
Use of warfarin with concomitant atrial fibrillation	✓

\*Counseling for smoking cessation is an inpatient performance measure but is not an explicit guideline recommendation.

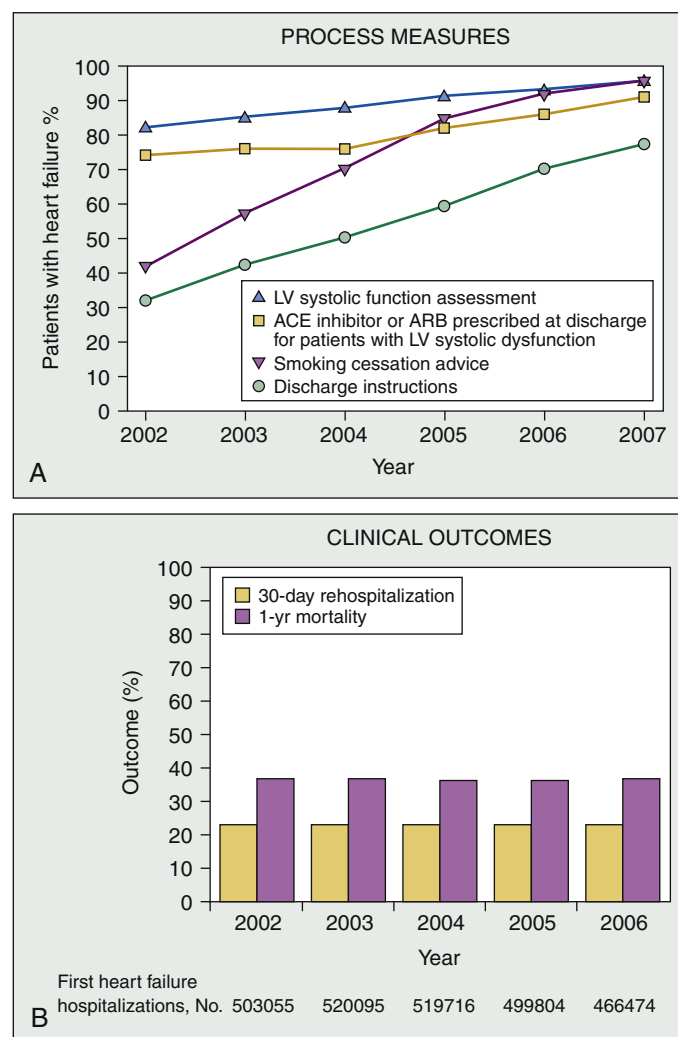

( $P = .01$ ), and 0.2% for 1-year mortality ( $P = .08$ ). Fonarow et al<sup>34</sup> reported associations between mortality at 60 to 90 days and performance on the CMS inpatient quality measures in a sub-sample consisting of 10% of patients enrolled in a multi-center heart failure registry. There was a significant reduction in likelihood of death or rehospitalization (odds ratio, 0.51;  $P = .002$ ) for patients who were prescribed ACE inhibitors or ARBs at discharge, but no differences were found for the other measures. Mehta and coworkers,<sup>35</sup> reviewing the literature on process-outcome links for myocardial infarction and heart failure, cited four regional studies that demonstrated a reduction in heart failure–related mortality associated with use of ACE inhibitors. For elderly heart failure patients hospitalized between 2002 and 2006, there was no overall change in mortality despite significant improvement in performance on quality indicators. (see Figure 38-2B).

## Patient-Centeredness

Patient-centeredness was further defined in the Institute of Medicine report<sup>2</sup> as

- Respect for patients, values, preferences, and expressed needs
- Coordination and integration of care

**FIGURE 38-2** Temporal trends in process measures and clinical outcomes for Medicare patients hospitalized with heart failure. ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; LV, left ventricular. (From Fonarow GC, Peterson ED. Heart failure performance measures and outcomes: real or illusory gains. *JAMA* 2009;302 (7):792-794.) copyright © American Medical Association. All rights reserved (2011).

- Information, communication, and education
- Physical comfort
- Emotional support
- Involvement of family and friends

Each of these aspects has relevance for heart failure. Measurement of patient-centeredness in heart failure quality measures, however, has been rudimentary at best. One of the quality indicators adopted jointly by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) and CMS was the proportion of patients who received instruction at discharge regarding their medications, follow-up, and other care, which thus addresses the issue of information, communication, and education.

Provision of care in which patients' preferences are respected could be evaluated by assessing whether processes that provide end-of-life care when appropriate are in place. The degree to which physical comfort and emotional support are addressed could be evaluated with use of appropriate survey instruments. Coordination and integration of care should be an important goal of care for heart failure, but because of the barriers created by the organization and financing of care in the United States, the use of this dimension to evaluate quality across organizations seems premature. Evaluation of this dimension within some organizations, such as closed-panel health maintenance organizations, or globally budgeted systems, such as the U.S. Department of Veterans Affairs, may be of value. Improvement of transitions from hospital to outpatient care is currently under investigation as part of the Department of Veterans Affairs' Chronic Heart Failure Quality Enhancement Research Initiative (CHF QUERI).<sup>37</sup> A number of well-validated questionnaires have been used to measure health status in heart failure, a concept that encompasses physical capacity, emotional health, and quality of life. These questionnaires have not been used to compare the quality of care for heart failure across organizations. Emotional support is a common need among patients with heart failure; estimates of the prevalence of depression in patients with chronic heart failure have ranged from 23% to 47%.<sup>38,39</sup> There is as yet no consensus regarding routine screening for and management of depression in patients with heart failure.

## Equity

Variation (by age, gender, race/ethnicity, and geography) in the quality of care for heart failure has been investigated. When issues of equity in medical care are studied, it must be kept in mind that differences in care do not necessarily constitute disparities in care.<sup>40</sup> For a difference to be considered a disparity, possible contraindications, patient preferences, clinical characteristics, and differences in eligibility must be accounted for. Differences in structures or processes of care should also be associated with differences in outcomes. Because it may not be clear whether a difference results from overtreatment in one group or undertreatment in the other.

## Age

In general, advanced age is independently associated with lower rates of guideline-concurrent care.

Yancy and associates<sup>41</sup> reported that with increase in age, by tertile, the less likely patients would be to receive ACE inhibitors,  $\beta$ -blockers, aldosterone antagonists, and devices. Fonarow and colleagues<sup>42</sup> reported that in a large national registry of hospitalized patients with heart failure, patients older than 75 were less likely to receive guideline-based care than were younger patients. Forman and colleagues,<sup>43</sup> reporting results from a national quality improvement registry, found that older age was associated with lower rates of medical therapy. For instance,  $\beta$ -blockers were prescribed to 90.9% of eligible patients younger than 65 years but to only 82.7% of patients older than 85 years. In an analysis restricted

to patients older than 65, another study did not reveal significant gradients with regard to age in the prescription of ACE inhibitors.<sup>44</sup>

Whether these age-related differences represent unacceptable variation in care remains somewhat open to interpretation. Eligibility may not be equivalent for older and younger patients. The studies that demonstrated the efficacy of drugs that reduce mortality in heart failure may not have enrolled sufficient numbers of elderly subjects.<sup>45</sup> Presence of contraindications may vary with age in ways that are difficult to measure. Enrollment criteria for studies of ACE inhibitors and aldosterone antagonists included serum creatinine level to exclude patients with significant kidney disease; however, this measure reflects renal function relatively poorly in older individuals. Preferences for life-prolonging therapy, a factor difficult to infer from chart review, may be lesser in the elderly. Nonetheless, there is adequate documentation in the literature that age bias affects medical decision making, and clinicians specializing in heart failure should make efforts to ensure that guideline-based therapy is not withheld from older patients without good reason.

### Gender

In general, investigators have failed to demonstrate consistent patterns of differences by gender in the quality of care for heart failure after accounting for a lower incidence of ischemic heart disease and older age in women.

Within the context of a nationwide quality assessment of hospitalized patients with heart failure, Fonarow and colleagues<sup>42</sup> found no differences between men and women in the likelihood of receiving guideline-based medical therapy. Similar data sources<sup>41,46</sup> have revealed similar results; most, but not all, measures have shown no gender differences. A review of studies comparing treatment for heart failure and acute myocardial infarction by gender in Medicare patients<sup>47</sup> concluded that “within multivariate models, gender differences in treatment were small and in many cases insignificant. These national datasets fail to reveal a strong sex bias in treatment among patients aged  $\geq 65$  years.” Readmission rates and mortality did not differ appreciably by gender after other demographic and clinical characteristics were controlled.

In contrast to findings of no significant gender differences in medication use in heart failure, there may be significant differences in device use. Use of implantable defibrillators and biventricular resynchronization pacing is not a formal quality indicator, and indications have changed considerably as a result of studies and changes in Medicare payment rules. Nonetheless, data from registries<sup>48,49</sup> and from a national sample of Medicare data<sup>50</sup> indicate that women are less likely to receive implantable defibrillators than are men with comparable indications.

This pattern is consistent with prior findings that women are less likely to undergo other cardiac procedures such as catheterization.<sup>51</sup> Whether gender bias is playing a role in differential procedure use remains somewhat uncertain, but quality measurement in heart failure, when expanded to

device use, should include efforts to ensure equity, both in process and in outcome,<sup>52,53</sup> across gender.

### Race and Ethnicity

Investigation into possible inequities in care by race and ethnicity is inevitably complicated by the confounding effects of socioeconomic status; minority individuals in the United States are more likely to be poor and to lack health insurance. Race and ethnicity are so tightly linked to socioeconomic status that, for the purposes of identifying disparities, separating them is not useful. Also complicating the investigation is the fact that robust adjustment is needed because the epidemiological profile of heart failure differs between white people and African Americans. African Americans are more likely to have a hypertensive cause, and less likely to have an ischemic cause, of heart failure<sup>54-56</sup> (Table 38-5). They also have similar or better survival rates, despite higher readmission rates.<sup>57,58</sup> In general, African American and white patients have similar rates of guideline-based care for heart failure. Care for Latino, Asian descent, and Native American patients has not been well characterized.

In a national quality-of-care registry,<sup>54</sup> African Americans were slightly more likely to be treated with ACE inhibitors. Similar findings have been noted in nationwide surveys by Medicare<sup>57</sup> and the Department of Veterans Affairs.<sup>58-60</sup> In a study of the same Medicare cohort,<sup>61</sup> lower socioeconomic status (determined from the average for the patients' area of residence) was not associated with likelihood of receiving guideline-based therapy, but it was associated with higher 1-year mortality rates. These studies, conducted in settings in which access to care based on insurance status is not an issue (Medicare and the Veterans Affairs system), suggest that when access to care is similar across racial lines, medical treatment for heart failure is equitable.

The situation with regard to use of implanted defibrillators is somewhat different: The available data have consistently demonstrated that African American patients are less likely than white patients to receive implanted defibrillators.<sup>48,49,62,63</sup> These studies are hampered by the fact that registries of patients receiving defibrillators and registries of patients hospitalized with heart failure may not accurately reflect the population of patients eligible for defibrillator implantation. Access may be different according to geography.<sup>64,65</sup> It is tempting to ascribe remaining disparities to bias and prejudice, but direct measurements of bias and prejudice have not been made.

### Geography

Relatively little attention has been paid to potential differences in the quality of care for heart failure by location. Researchers have looked for small area variation<sup>66</sup> and for rural-urban differences.

Using chart review data from a sample of over 30,000 Medicare heart failure discharges, Havranek and coworkers<sup>29</sup> assessed variation across 306 hospital referral regions in the United States. A smoothing technique was used to account

**TABLE 38-5 Differences in Causes of Heart Failure, by Race\***

Cause	OPTIMIZE-HF <sup>54</sup>		U.S. Carvedilol Heart Failure Study <sup>55</sup>		SOLVD <sup>56</sup>	
	African American	White	Black	Nonblack	African American	White

Ischemia	30%	49%	32%	52%	54%	78%

OPTIMIZE-HF, Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure; SOLVD, Studies of Left Ventricular Dysfunction.

\*A higher likelihood of hypertensive cardiomyopathy in African Americans may explain the higher likelihood that evidence-based medical treatment will be initiated for African American patients.

for random variation. Rates of left ventricular ejection fraction documentation ranged from 30.1% to 67.2%, and rates of ACE inhibitor prescription varied from 55.8% to 87.1% (Figure 38-3). Small, rural, nonteaching hospitals without advanced cardiac facilities tended to have lower rates on quality indicators. Nawal Lutfiyya and associates<sup>67</sup> examined differences in care for several conditions, including heart failure, provided in rural critical access hospitals in comparison with urban acute care hospitals. Critical access hospitals are designated for differential reimbursement by the CMS on the basis of rural location at least 35 miles from another hospital, provision of 24-hour emergency services, short average length of stay, and a size of no more than 25 beds. Rural hospitals were less likely than urban hospitals to document left ventricular function in patients with a diagnosis of heart failure (85.8% vs. 63.3%), but for patients with documented systolic dysfunction, they were equally likely to prescribe ACE inhibitors. Despite these process differences, Ross and colleagues<sup>68</sup> reported no differences in risk-adjusted 30-day mortality rates for heart failure across the continuum from rural to urban hospitals in a nationwide sample of Medicare records.

These studies suggest that regional differences in quality of care for heart failure may be related to limited availability of cardiac services in rural areas and that overall variation is lower than has been documented for other medical care. Data, however, are limited to the Medicare population and to a narrow range of quality indicators.

## Uses of Quality Measures

### Continuous Quality Improvement

Measurement of quality, typically in the form of process measures, is a necessary component of continuous quality improvement within organizations (see Figure 38-1). Although internal efforts are typically directed at the measures used to compare effectiveness across organizations, high-performing organizations may be replacing these measures with quality metrics<sup>69</sup> not used for cross-organizational comparison. An example might be a quality improvement initiative to ensure that all patients with heart failure who are eligible for an implantable cardioverter-defibrillator, according to the most recent guidelines, have received a referral.

### Public Reporting

Data on provider performance have been made public by government organizations since at least 1986, when the predecessor of CMS, the Health Care Financing Organization (HCFA), published a list of 269 hospitals whose risk-adjusted in-hospital mortality rates were high enough to be considered outliers.<sup>70</sup> A review published in 2000 found that rigorous evaluations of the impact of public reporting of performance data had been published for seven organizations that had released data<sup>71</sup>. These data covered a wide range of services and conditions, including obstetrics, cardiac surgery, myocardial infarction, and hip fracture. Since then, the type and volume of provider performance data reported by government agencies to the public has continued to grow. Despite the technical difficulties in producing valid measurements, outcomes of care are increasingly being reported. In this regard, an ACC/AHA task force<sup>72</sup> proposed standards for outcome measures intended for public reporting, in view of the high potential for the publication of misleading information (Box 38-1). Such measures must be explicitly defined, be constructed according to reliable data, and account for pre-existing differences in patients' risk of the outcome in question. Reporting of the measures must account for the inherent uncertainty of statistical models.

CMS began reporting process measures for heart failure in 2004, 30-day mortality rates in 2007,<sup>73</sup> and 30-day readmission rates in 2009 on its Hospital Compare website.<sup>28a</sup> The outcome measures employ risk adjustment models<sup>10,11</sup> that generally conform to the ACC/AHA recommendations cited previously.

#### BOX 38-1 Preferred Attributes of Models Used for Publicly Reported Outcomes

- Clear and explicit definition of an appropriate patient sample
- Clinical coherence of model variables
- Sufficiently high-quality and timely data
- Designation of an appropriate reference time before which covariates are derived and after which outcomes are measured
- Use of an appropriate outcome and a standardized period of outcome assessment
- Application of an analytical approach that takes into account the multilevel organization of data
- Disclosure of the methods used to compare outcomes, including disclosure of performance of risk-adjustment methodology in derivation and validation samples

From Krumholz HM, Brindis RG, Brush JE, Cohen DJ, et al. Standards for statistical models used for public reporting of health outcomes: an American Heart Association Scientific Statement from the Quality of Care and Outcomes Research Interdisciplinary Writing Group. *Circulation*. 2006; (24)113:456-462. © American Heart Association. Used with permission.

Similar data are reported by JCAHO.<sup>73a</sup> The process measures cover the four inpatient measures discussed previously: left ventricular function assessment, use of ACE inhibitors or ARBs, smoking cessation advice, and discharge instructions. The mortality and readmission measures are reported as relative to the national averages with appropriate error estimates and are further characterized as being above, below, or no different from the average. In practice, the number of hospitals characterized as have rates below the average has been quite small.

The effect of public reporting is difficult to gauge. Its purpose is presumably to enable health care to more closely resemble an efficient market, with consumers and purchasers gravitating toward providers with the best performance and away from underperforming providers. There is some evidence that this is taking place with regard to consumer's choice of health plan,<sup>74,75</sup> although most of the information available to them is about quality of service rather than quality of care. There is essentially no evidence that choice of hospitals is affected by the availability of quality-of-care information, even when that information is about potentially actionable choices such as coronary artery surgery.<sup>71,74</sup> Public reporting does, however, appear to motivate hospitals to initiate quality improvement efforts.<sup>74</sup> It has been suggested that public reporting may have unintended adverse consequences<sup>76</sup>: It may increase the likelihood that providers will avoid caring for patients at high risk or the likelihood that socioeconomically disadvantaged patients, with less access to information, will have no choice except underperforming providers. No reported data have demonstrated that this is the case. In the end, therefore, it is difficult to argue that measures of quality should *not* be made available to the public. The most important effect of public reporting, although not quantifiable, may be changing providers' fundamental attitudes about their responsibilities for transparency and accountability.

## Pay for Performance

There have been efforts in the United States and in the United Kingdom to improve quality by providing financial incentives to providers that score well on performance measures. In the United States, data are available from the Premier Hospital Quality Incentive Demonstration Project and the Physician Group Practice Demonstration Project, conducted by CMS. Although pay for performance is being used by commercial insurers<sup>77</sup> and Medicaid,<sup>78</sup> results from these programs have not been reported. In the United Kingdom, the National Health Service has reported results from the Quality and Outcomes Framework. Care for heart failure was featured in all these projects.

The Premier Hospital Quality Incentive Demonstration Project was initiated by CMS in October 2003. Participants were part of the Premier nationwide network of not-for-profit hospitals; as of July 2009, 227 hospitals were participating. Hospitals scoring in the top decile on composite quality measures for acute myocardial infarction, heart failure, coronary artery bypass grafting, pneumonia, and total hip or knee replacement were given a bonus of an additional 2% of their diagnostic group-related payment; those in the second decile received a 1% bonus. In the third year, comparable decreases in payment were instituted for the bottom two deciles. A report of the initial result of the project<sup>79</sup> demonstrated overall improvement in composite measures of quality in participating hospitals, in comparison with a similar group of nonparticipating hospitals. For heart failure, care on a composite appropriate care measure encompassing left ventricular function assessment, use of ACE inhibitors, provision of discharge instructions, and smoking cessation assessment improved from 76.1% to 84.0% in the control hospitals and from 76.1% to 88.3%

in the hospitals receiving financial incentives. The initial 3-year project was extended for 3 more years, through the end of September 2009. During the extension phase, risk-adjusted mortality and readmission rates were added to the roster of quality measures. Results for the extension period are not yet available, although trends from the first 3 years have been reported to have continued through the end of the fourth year.<sup>80</sup> Evaluations of the program independent of CMS, however, have yielded contrasting results. Ryan<sup>81</sup> used econometric modeling of 30-day risk-adjusted rates of mortality from heart failure, as well as from pneumonia, acute myocardial infarction, and coronary artery surgery, and could find no benefit associated with the program. Another study of acute myocardial infarction alone also demonstrated no effect on mortality.<sup>82</sup>

The Physician Group Practice Demonstration Project had a slightly different structure and was based not only on quality measures but also on cost savings.<sup>83</sup> Ten large geographically diverse group practices were chosen for the project. If a group demonstrated savings for Medicare in the targeted patient populations, it became eligible for an annual performance bonus funded by those cost savings. The amount of the bonus was based on performance on quality measures for heart failure, diabetes, coronary heart disease, hypertension, and cancer screening. Because this was an outpatient-based project, the heart failure measures were significantly more comprehensive than those previously used for cross-organizational comparison, addressing use of ACE inhibitors,  $\beta$ -blockers, warfarin in the presence of atrial fibrillation, ejection fraction assessment, patient education, and monitoring of weight at the time of writing and blood pressure. The 3-year program began in 2005, and final results are not yet available. It has been reported that of the 10 groups, 5 earned bonuses for the first year of the program.<sup>83,84</sup>

The Quality and Outcomes Framework program in the United Kingdom was not a demonstration project but rather a full-faith wholesale change in the reimbursement structure for physicians in England to one that includes incentives for performance in clinical care, practice organization, and patients' experience.<sup>85</sup> Care for heart failure was not assessed under this framework; the current discussion is limited to its use in the general assessment of pay-for-performance schema. A study of the performance of 42 primary care practices before and after introduction of the program revealed modest improvements in quality.<sup>86</sup> The authors concluded that "once targets were reached, the improvement in the quality of care...slowed, and the quality of care declined for two conditions that had not been linked to incentives."

The bulk of the evidence suggests that providing financial incentives to organizations produces modest gains in quality that are limited to the care being scrutinized. Incentive structures different from those employed thus far may produce better results.<sup>87,88</sup> There are also remaining questions about whether such programs will exacerbate inequities in care by giving incentives to providers that do not care for the underserved.<sup>89-91</sup>

## FUTURE DIRECTIONS

Aligning financial incentives with quality, adopting information technology wisely, and widening the range of care processes measured are all necessary if the quality of care for heart failure is to improve in the future. Such changes, however, should be viewed as enabling and will not be sufficient to achieve the optimal level of care.

This chapter began by noting that much of the approach to quality measurement and improvement currently practiced in health care comes from thinking developed in manufacturing by Deming. One of the consistent themes in Deming's

## BOX 38-2 Deming's 14 Points for Transformation<sup>3</sup>

1. Create constancy of purpose toward improvement of product and service.
2. Adopt the new philosophy.
3. Cease dependence on inspection to achieve quality.
4. End the practice of awarding business on the basis of price tag.
5. Improve constantly and forever the system of production and service.
6. Institute training on the job.
7. Institute leadership. The aim of supervision should be to help people to do a better job.
8. Drive out fear.
9. Break down barriers between departments.
10. Eliminate slogans, exhortations, and targets for the workforce.
11. Eliminate work standards, objectives, numbers, and numeric goals. Substitute leadership.
12. Remove barriers that rob people of their right to pride of workmanship.
13. Institute a program of education and self-improvement.
14. Transformation is everybody's job.

work is that improving the quality of the products of a system must result from fundamental change in the attitudes and behaviors of the participants in the system. In his 14 points<sup>3</sup> (Box 38-2), he urged managers to cease dependence on inspection and to eliminate exhortations and targets. In a sense, current national efforts to improve quality through the reporting of and payment for quality measures are inspection, exhortation, and targets. Progress toward improving the quality of health care requires fundamental change in the attitudes and behaviors of participants in the system rather than more intensive scrutiny.<sup>92</sup> Lessons from such fields as education, organizational psychology, and behavioral economics are probably helpful in effecting the needed cultural change.<sup>93</sup> The motivation for making these changes must begin to come from within organizations rather than be imposed from the outside.

Providing care of the highest possible quality is the most important basic value of health care professionals. Professionals deserve to work in a system that grows directly from this value, and patients deserve to be treated in such a system.

ure (AHF), surgical and device-based interventions, and trials of monitoring devices in heart failure.

## FUNDAMENTAL COMPONENTS OF RANDOMIZED CONTROLLED TRIALS

The field of cardiovascular medicine has led the way in the development of high-quality clinical evidence, primarily on the basis of robustly designed multicenter RCTs. This rigor in clinical research in the cardiovascular field has been facilitated by the high prevalence of disease, which allows for enrollment of large numbers of patients, and the high event rates in these populations, which increases the feasibility of conducting adequately powered trials. The large multicenter trials are

based on a foundation of basic science investigations, observational studies, and clinical experience. Those other types of investigation are different from RCTs in that RCTs entail randomization (the random assignment of study subjects to a given treatment or exposure), the use of a parallel control group (subjects who are treated and evaluated identically except not given the intervention to be studied), the uniform ascertainment of pre-specified endpoints, and the robust statistical estimation of both the magnitude and validity of the observed treatment effect. Each of these fundamental “building blocks” of the modern RCT is described as follows, with a focus on the large, multicenter, phase III studies that provide definite evidence of efficacy and drive the approval of new therapies. Challenges related to trial design for earlier phase studies are discussed in a later section.

## Hypothesis and Study Design

As with any experiment, the generation of the hypothesis to be tested is the first step in the design of a clinical trial, and a properly developed hypothesis provides significant guidance in the other aspects of the trial design. Although large, multicenter RCTs may contain multiple planned subgroups, secondary endpoints, and ancillary studies, the primary hypothesis of an RCT should be stated clearly and succinctly. The hypotheses for RCTs are in two broad categories: *superiority designs* and *noninferiority designs*. In superiority trials, the primary hypothesis is the assertion that the outcome of interest in patients randomly assigned to the study intervention will be superior to the outcome in the control group. In technical statistical terms, “proving” the study hypothesis actually involves rejecting the contrary assertion (i.e., the null hypothesis) that there is no difference in the outcome of interest between the intervention recipients and the control group, within a prespecified statistical certainty (typically 95%, or  $P < .05$ ). Of importance is that failure to demonstrate a statistically significant difference between the intervention and control groups is not the same as demonstrating that there is no difference between the two treatments: “lack of evidence of a difference” is not the same as “evidence of a lack of difference.”<sup>6</sup>

New therapies may be easier to administer, may be better tolerated, may have a

better safety profile, or may be less expensive, but not all these aspects may be accounted for in the primary efficacy endpoint of a traditional superiority design. Whether a new treatment yields outcomes equivalent to those of standard therapy is therefore often an important clinical question and has important implications for both the hypothesis and the overall study. In the design of noninferiority, or equivalence, trials, the hypothesis and statistical techniques must be framed in specific ways that are often underappreciated.<sup>7,8</sup> Because there would be little rationale for establishing equivalence with placebo, the purpose of noninferiority trials is to compare a new intervention with established therapy; thus, they are sometimes termed *active-control trials*. An essential prerequisite of an active-control trial is that the control therapy has already been sufficiently demonstrated to yield better results than does placebo. This issue is particularly relevant to regulatory agencies that evaluate trials for potential drug approval, and specific guidelines have been developed for the selection of the active comparator.<sup>9</sup> Noninferiority trial designs are fundamentally based on the hypothesis that the new intervention does not yield results different from those of the control treatment to a clinically important degree, often termed the *noninferiority margin* and frequently expressed as  $\Delta$ . In other words, the null hypothesis to be rejected in equivalence studies is that the control is superior to the investigational therapy by a clinically important margin ( $\Delta$ ). If that null hypothesis is rejected, then the two therapies can be claimed to be at least equivalent. The use of confidence intervals in assessing treatment effect can be a significant aid in the interpretation of equivalence studies, as shown in Figure 39-1.<sup>10</sup> Both the noninferiority design and  $\Delta$  must be prespecified and justified on clinical and statistical grounds. Although the necessity of prespecified statistical approaches for noninferiority designs has been increasingly recognized, accurate reporting and interpretation of noninferiority designs continue to be problematic.<sup>11,12</sup> Formal guidelines that may serve to improve standardization of reporting for noninferiority designs have been published.<sup>10</sup>

In conjunction with the general design of the trial (superiority vs. noninferiority), the therapeutic intervention being tested must be carefully defined. In the simplest form of RCT, a single intervention is compared with a placebo control condition in a traditional parallel group design. However, as trials have become larger and more expensive and as therapeutic regimens have become increasingly complex, designs in which multiple hypotheses can be tested have become more common. In factorial designs, subjects are randomly assigned to multiple, balanced combinatorial groups. One attractive aspect of factorial designs is the ability to address two clinical questions simultaneously in the same patient population without sacrificing statistical power for either question. In reality, the preservation of statistical power in factorial study designs depends on whether there is an interaction between the two treatments, which may be independent (i.e., no interaction), additive, or subadditive. Although factorial designs may substantially increase efficiency in clinical trials, they must be interpreted carefully, particularly with regard to interactions between the two treatments.<sup>13</sup> Because of the increasing size, complexity, and expense of international multicenter RCTs, factorial designs have become increasingly common in cardiovascular studies.<sup>14</sup>

Another study design that is often considered is a crossover design, in which each patient serves as his or her own control. In its simplest form, a crossover design involves assigning patients randomly to the intervention or control group and then changing treatments (intervention changes to control and vice versa) after a designated period. Crossover designs may allow for smaller sample sizes because of limiting variability (because each patient is his or her own control, by definition the intervention group and control group are identical except for the intervention). In order for crossover designs to be valid, there must be no carryover effect: that is, the effect of the intervention must be the same whether patients receive it first or second. For these reasons, crossover designs are typically more appropriate for early-phase trials focused on surrogate endpoints<sup>15</sup> than for curable conditions

**FIGURE 39-1** Possible scenarios of observed treatment differences for adverse outcomes (harms) in noninferiority trials. Error bars indicate two-sided 95% confidence intervals (CIs). The tinted area is the zone of inferiority. If the CI lies wholly to the left of zero (A), the new treatment is superior. If the CI lies to the left of  $\Delta$  and includes zero (B and C), the new treatment is noninferior but not shown to be superior. If the CI lies wholly to the left of  $\Delta$  and wholly to the right of zero (D), the new treatment is noninferior in the sense already defined, but it is also inferior in the sense that a null treatment difference is excluded. This puzzling case is rare; detecting it requires a very large sample size. This finding can also result from too wide a noninferiority margin. If the CI includes  $\Delta$  and zero (E and F), the difference is nonsignificant, but the result regarding noninferiority is inconclusive. If the CI includes  $\Delta$  and is wholly to the right of zero (G), the difference is statistically significant, but the result is inconclusive with regard to possible inferiority of magnitude  $\Delta$  or worse. If the CI is wholly to the right of  $\Delta$  (H), the new treatment is inferior. (Adapted from Piaggio G, Elbourne DR, Altman DG, et al, for the CONSORT Group. Reporting of noninferiority and equivalence randomized trials: an extension of the CONSORT statement. *JAMA* 2006;295:1152-1160.) Copyright © (2011) American Medical Association. ## Patient Population

CH 39 The patients selected for an RCT must be thought to have a reasonable possibility of benefiting from therapy according to preclinical data, observational studies, earlier phase studies, or a combination of these. In order to ethically justify the random assignment of human subjects between two therapies, there should be genuine clinical uncertainty about which treatment is preferable in a given patient population. In selecting the patient population in whom to test the study hypothesis, the researchers balance a variety of potentially conflicting considerations, including anticipated therapeutic effect, event rates, safety profiles, enrollment rates, and generalizability. The patient population for a given study is defined by the inclusion and exclusion criteria, which define what types of patients can and cannot be enrolled in a given study. Inclusion criteria are frequently designed to select patients with specific pathophysiological markers that suggest the potential to benefit from the putative mechanism of action of the therapy to be tested. In heart failure trials, such markers of potential response may be based on ventricular structure and function (e.g., ejection fraction, ventricular dimensions), symptom severity (e.g., New York Heart Association [NYHA] class), specific symptoms (e.g., edema), or other disease markers (e.g., elevated levels of B-type natriuretic peptide [BNP]). If an intervention is not expected to be efficacious or could lead to unacceptable risks in certain subjects, exclusion criteria would ensure that it is not studied in these patients.

In addition to subjects' possibility of responding to the given therapy, the patient population should be at some meaningful risk for the primary endpoint, particularly when the primary endpoint is an event such as death or hospitalization for heart failure. Selecting patients with high event rates allows for relatively smaller sample sizes (and more economical studies for the same treatment effect). In heart failure trials, such inclusion criteria are usually designed to select populations with high event rates and typically include ejection fraction, functional capacity, NYHA class, prior hospitalizations, or elevated neurohormone levels. However, not only is it desirable to select a population with a high event rate, but also these patients should have a high *disease-specific* event rate. For example, patients with advanced cancers have a high mortality rate, but it is unlikely that a heart failure therapy in such patients would have a significant effect on the rates of death. Consequently, exclusion criteria are usually chosen to exclude patients with comorbid conditions or characteristics that would place them at significant risk of an event caused by reasons other than heart failure or that would confound the interpretation of the endpoint.

A major issue in the selection of inclusion and exclusion criteria for RCTs is the balance between limiting variability (by studying a more homogeneous population) and maximizing generalizability (by studying as heterogeneous a population as possible). Studying more homogeneous populations limits background variance, which allows for a trial to be more sensitive to smaller effect sizes (i.e., an increased "signal-to-noise" ratio). Exclusion criteria are often designed to limit this variance. For example, patients with relatively rare causes of heart failure, such as myocarditis, are routinely excluded from most heart failure studies because the different natural history of such disorders increases variance in possible treatment response. Conversely, defining the population too narrowly may have important implications for study enrollment, generalizability, and labeling of approved therapies.

## Implications of Patient Selection: Enrollment, Generalizability, and Labeling Considerations

Expedition completion of RCTs is of significant concern for patients, investigators, and sponsors. Rapid enrollment of patients in the study will result in answering the study question as quickly as possible, which will either support approval of the therapy, for the greater benefit of other patients, or lead to the discontinuation of a potentially harmful or useless intervention. In addition, rapid enrollment reduces costs to the investigators and the sponsor and frees up resources for other lines of investigation. Stringent inclusion and exclusion criteria can be a significant impediment to patient recruitment, resulting in a tension between enrolling the "perfect" patients for a trial and rapid recruitment rates.

A basic principle of evidence-based medicine is that results from clinical trials should be applied to patients who are generally similar to those enrolled in the trial. In general, even when study populations are broadly defined, there is a tendency for patients enrolled in RCTs not to be representative of the broader population. In particular, women, minorities, elderly patients, and patients with significant comorbid conditions are often underrepresented in clinical trials.<sup>16</sup> As a result, the patients at highest risk tend to be excluded from clinical trials, and event rates for a given disease in clinical trials are typically lower than in population-based samples. This issue may be exacerbated by defining the study population too narrowly. Because it is important to be able to apply the results of a clinical trial to clinical practice, there has been considerable discussion of ways in which to make trials more generalizable by recruiting the most representative group of patients. Many approaches have been used to address this issue, including consecutive screening and enrollment, greater emphasis on enrollment in community hospitals or the primary care setting, and developing a registry of all the patients who were candidates for enrollment in the study. Comparisons between the candidates and the patients actually enrolled in the trial could provide insight into differences between the groups. The problems engendered by patient selection are important; however, the primary purpose of the clinical trial is to test a hypothesis in a scientifically valid manner, and any approaches to broaden the study population must not undermine the rigor of the trial. Although general rules are difficult to define, earlier phases in proof-of-concept studies may benefit from a more narrowly defined study population, whereas later phases should enroll as broad a population as is feasible and scientifically valid.

## Controls, Randomization, and Blinding

A robust clinical trial is intended to provide an accurate estimate of the effect of a given intervention in a given population, and the researchers must therefore attempt to eliminate or minimize the chance of systematic bias that may lead to inaccuracy in the estimation of treatment effect. The use of an appropriate control group, randomization, and blinding are all important aspects of modern RCTs.

Control groups are fundamental in a clinical trial, and their use distinguishes a clinical trial from other types of clinical research (such as a longitudinal cohort study). Control groups ensure that the observed treatment effect is related to the intervention being tested and not to other characteristics of the patient population. Although various potential types of control groups exist (e.g., historical controls or non-randomly assigned controls), a parallel control group with the intervention assigned at random is by far the most rigorous method for evaluating new therapies. Randomization serves to ensure that the baseline characteristics of patients in both the treatment and control groups are similar and that any differences in the baseline characteristics between the

treatment recipients and the control group arise by random chance rather than through systematic bias. Although methods for adjusting for known confounding factors are powerful tools (e.g., multivariable analyses), these approaches cannot account for all the potential differences between groups and are not a substitute for randomization. The ability to control for both known and unknown confounding factors provided by randomization imparts tremendous power to properly designed trials; thus, these types of trials have become the standard for investigations of new therapeutic interventions.

In this simplest case, study subjects are randomly assigned to one treatment condition or another as they are enrolled, in a 1:1 ratio (simple randomization). Other variations on the traditional random assignment of patients may be helpful in the conduct of RCTs. In block randomization, patients are assigned on the basis of prespecified “blocks,” so that the numbers of patients assigned to the control group and the intervention group remain relatively balanced throughout the study. The sizes of the blocks may be varied at random throughout the trial to prevent investigators from preferentially trying to assign patients to a specific study condition. If particular patient characteristics are a priori thought to be likely to affect the response to therapy, stratified randomization may be used to ensure that these characteristics are balanced between the intervention and control groups. For example, if the effect of a therapy on patients with an ischemic cause of heart failure is of particular interest, stratified randomization can be used to ensure a balance of treatment assignment among those patients.

The process of keeping patients, investigators, and other study personnel unaware of the assigned treatment group is often termed *blinding* or *masking*. Masking the conditions for patients limits the placebo effect, inasmuch as patients are unaware whether they are receiving the investigational therapy. Masking the conditions for investigators limits bias that could be introduced by the knowledge of treatment assignment. For example, investigators may monitor patients more closely or use concomitant therapies differently according to whether patients are assigned to intervention or control groups. Although double-blind trials are the standard, blinding may be challenging or impossible with some types of trials, such as those with surgical or device-based interventions (described later in this chapter). In other sorts of trials, blinding may be compromised by investigators’ inferences based on accessory clinical information (e.g., reduced heart rate may suggest random assignment to a condition with a  $\beta$ -blocker vs. placebo).<sup>17</sup> Although no procedures can completely eliminate unanticipated unmasking of conditions to investigators, careful attention to this issue in the design and conduct of RCTs is critical. In studies in which blinding is not possible, the use of objectively measured endpoints and endpoint committees who are unaware of conditions to adjudicate events can significantly limit potential bias. Although breaking of a blinding code is occasionally required for issues of patient safety, it should be done rarely and only with careful consideration.

## Follow-up and Adherence

Adherence to the study protocol both by investigators and by study subjects is crucial for the validity of a clinical trial but often gets relatively little attention. Lack of adherence to the study protocol can complicate analysis and interpretation of trial data substantially and can undermine the validity of the results. Investigators must select sites carefully and use appropriate regulatory monitoring. To maximize patient adherence, inclusion and exclusion criteria must explicitly or implicitly result in selection of patients who are more likely to adhere to follow-up and study procedures. As with many other aspects of trial design, there is a need to balance

between optimizing the study conduct (by enrolling a population likely to complete follow-up procedures and adhere to treatment) and ensuring generalizability of the results (by enrolling a broadly representative population). Patients who adhere to treatment are likely to be very different in a variety of ways from those who do not, and data have confirmed that greater adherence (even to placebo procedures) is associated with improved outcomes; this suggests that adherence is a marker of other favorable health behaviors.<sup>18</sup>

One somewhat controversial method for maximizing adherence to the protocol is the use of run-in periods, in which potential study subjects demonstrate adherence to study protocol for some period before randomization. These run-in periods may be either placebo conditions (in which compliance is assessed) or “active” conditions (in which patients’ tolerance of the study intervention is assessed). Although such active run-in periods can enhance the statistical power of trials by tending to exclude subjects who would not tolerate the study drug, they can also substantially complicate analysis. For example, the U.S. Carvedilol Heart Failure Study Group used a 3-week active run-in period to ensure tolerability of carvedilol before randomization to carvedilol or placebo condition.<sup>19</sup> During the run-in period, 17 patients experienced worsening heart failure and 7 died; none of them were described in the report on morbidity and mortality. This early clinical worsening led to significant controversy over the interpretation of the carvedilol trials, and researchers remain divided on how to handle events that occur during a run-in period. In general, run-in periods may be more acceptable in earlier phases of proof-of-concept studies in which tolerability of the drug is a major unanswered concern (as in the U.S. Carvedilol Heart Failure Studies<sup>19</sup>) but may not provide sufficiently generalizable results for definitive-phase outcome studies (such as Metoprolol CR/XL Randomised Intervention Trial in congestive Heart Failure [MERIT-HF]<sup>20</sup> and Carvedilol Prospective Randomized Cumulative Survival [COPERNICUS]<sup>21</sup>).

Adherence to the study protocol is substantially influenced by duration of the study and type of intervention: Subjects are much more likely to be adherent in short-term studies of acute interventions, than in interventions that are complicated, time-consuming, painful, or inconvenient. In studies in which interventions are long term and challenging, specific attention to promoting adherence is critical. In the National Institutes of Health (NIH)–sponsored Heart Failure and A Controlled Trial Investigating Outcomes of Exercise Training (HF-ACTION) study, the intervention group’s adherence to exercise training was specifically maximized and carefully quantified.<sup>22</sup> To the extent possible, follow-up procedures should be frequent enough, long enough, and temporally convenient to affirm the worth of the patient’s participation and demonstrate respect for their time and schedule. Adherence may also be enhanced by reminders of follow-up visits or tests and by adequate and flexible time windows. Reimbursement for travel or for time-consuming procedures affirms respect for the patient’s autonomy, although the amount cannot be viewed as coercive.

## Endpoints

The selection of the endpoints is crucial in the design of the clinical trial, with broad implications for the analysis and interpretation of the study. The *primary endpoint* reflects the central hypothesis of the trial. It should pertain to the desired benefit of the treatment strategy, and its reliable assessment should be feasible. Endpoint selection must also take into account the context of the overall stage of development of the therapy. In early-phase trials, *surrogate endpoints* (discussed in detail later) are often selected in order to identify a signal for moving forward with larger trials or

selecting a dosing regimen. In more definitive studies, *clinical endpoints* are typically designed to determine whether a patient feels better or lives longer, as demonstrated by improvement in survival, decrease in morbidity, or improvement in symptoms and quality of life. Endpoints that are considered important to evaluate rigorously are termed *secondary endpoints*; these must be viewed in the context of the primary results, particularly when there are many secondary endpoints. The advantages and disadvantages of various types of endpoints in heart failure studies are discussed as follows.

### Mortality Endpoints

The best outcome of a therapy is improvement in the survival rate, and in common diseases with high mortality rates (such as heart failure), even modest reductions can have an important effect on public health. The clinical relevance of mortality as an endpoint is undisputed, but the question of whether to study all-cause mortality or disease-specific mortality is salient. All-cause mortality as an endpoint has many advantages: such mortality is self-evidently relevant, easy to assess, and not subject to bias in interpretation. However, many authorities have argued that evaluating all-cause mortality can dilute the significance of beneficial effects of therapies that target one specific cause of death (e.g., an implantable defibrillator device's effect on sudden cardiac death) and that in these cases, disease-specific mortality is a more useful endpoint.<sup>23</sup> The advantages of this approach include a higher sensitivity to the treatment effect, a resistance to the influence of random variations in other outcomes unlikely to be affected by treatment, and a relative absence of confounding. The major disadvantage of disease-specific mortality as an endpoint relates to the challenges in accurately assigning a cause of death in an unbiased manner. The specific mode of death is often difficult to classify, and interobserver agreement is often poor.<sup>24,25</sup> Clinical events committees (reviewed later), which review events in a blinded manner by using prespecified rules, may improve event adjudication. Regardless of the endpoint selected, total mortality rates must always be evaluated, so as to ensure that unforeseen adverse effects of the therapy are appropriately detected.

Despite the obvious advantages of mortality endpoints, they may not be feasible in many clinical situations. Some therapies may not target mechanisms that are anticipated to play a major role in mortality, or their projected effect size may be minimal, necessitating prohibitively large trials. In addition, as life-saving therapies are serially incorporated into the “standard of care,” it becomes increasingly difficult to demonstrate improvements in mortality rate.<sup>26</sup> These trends have led to the increasing use of primary endpoints that focus on other aspects of the patient experience beyond mortality alone.

### Morbidity Endpoints

Morbidity endpoints typically focus on nonfatal events. In heart failure trials, the most commonly used such event by far is hospitalization. As with mortality endpoints, the issue of all-cause versus disease-specific endpoints must be considered, and hospitalizations for all causes, for cardiovascular events, or for heart failure have been used in various trials. Heart failure accounts for about half of all hospitalizations in most heart failure trials—in all trials, fewer events are related to heart failure in comparison to total number of hospitalizations (a lower event rate would necessitate a larger sample size)—but, as expected, there is a compensatory greater reduction in the heart failure–specific hospitalizations in most trials, in comparison to total admissions (an increased effect size would necessitate a smaller sample size).<sup>27</sup> On balance, these considerations have generally favored the use of

the more specific endpoint, and “hospitalization for heart failure” is the most common morbidity endpoint in contemporary studies of chronic heart failure.

Of importance is that there are limitations associated with the use of morbidity endpoints such as hospitalization. Morbidity endpoints should generally not be used in isolation from mortality, because a treatment that improves survival may lead to more hospitalizations (patients are living long enough to experience nonfatal events: the “survivor effect”). For this reason, hospitalizations are generally combined with mortality in composite endpoints (death or hospitalization). In addition, hospitalizations may be influenced by economic and cultural considerations, as well as regional differences, which may cloud interpretation of hospitalization data. Finally, rigorous definitions and adjudication are required for hospitalizations, which adds a level of complexity and expense to the trial. For example, how hospitalizations for cardiac procedures (such as an elective surgery for implantable cardioverter-defibrillators [ICDs] or heart transplantation) are handled must be defined in a prespecified manner in the study protocol. Furthermore, definitions of what counts as a hospitalization must be prespecified. For example, in the Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events (OVERTURE), differences in the definitions of hospitalizations for heart failure had a significant effect on the results of the trial.<sup>28</sup> The protocol-specified primary endpoint—the combined risk of death or hospitalization for heart failure requiring intravenous treatment—resulted in a nonsignificant decrease in events ( $P = .187$ ), a result that fulfilled prespecified criteria for noninferiority but not for superiority. However, post hoc analysis of the primary endpoint with the definition used in the Studies of Left Ventricular Dysfunction (SOLVD) treatment trial, the combined risk of death or all hospitalizations for heart failure, revealed an 11% lower risk in patients treated with omapatrilat (nominal  $P = .012$ ).

### Symptom-Based Endpoints

Endpoints for evaluating the symptomatic status of patients are a logical approach to the “feel better or live longer” goal of major clinical trials. A therapy that markedly improves symptom status, quality of life, or other measures of a patient's sense of well-being is beneficial, as long as it does not have an adverse effect on morbidity and mortality. The objective, quantitative assessment of inherently subjective phenomena, however, presents a substantial challenge. Assessments of symptom severity by physicians (most commonly according to NYHA class) have been widely used in clinical trials, but such assessments are highly subjective, lack granularity, and are very vulnerable to investigator bias. A large body of literature concerning quality of life (QOL) has developed, and two QOL instruments specifically for use in chronic heart failure have been validated: the Minnesota Living with Heart Failure Questionnaire<sup>29</sup> and the Kansas City Cardiomyopathy Questionnaire.<sup>30</sup> Although somewhat time consuming to fill out, both these instruments have proved useful in a variety of research settings, including clinical trials. Other measures of specific symptoms, especially dyspnea, have been studied, through the use of visual analog scales or Likert scales, in several trials for acute decompensated heart failure, but such methods have not been extensively validated.<sup>31</sup> Investigators have begun to compare various methods for assessing symptoms in heart failure, but more research in this area is clearly needed.<sup>32</sup>

### Composite Measures as Heart Failure Endpoints
