#### Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Professor of Medicine, Division of Cardiology, Department of Medicine, Medical University of South Carolina, The Gazes Cardiac Research Institute, Charleston, South Carolina

In what seems on the surface to be a paradox, the prevalence, incidence, and mortality of heart failure are steadily climbing despite phenomenal progress in the diagnosis and treatment of all forms of cardiac disease. As we successfully manage—yet not cure—patients with heart disease, the damage to their cardiac muscles persists and sometimes progresses as adaptive compensatory mechanisms become maladaptive. With steadily increasing life spans and the growing “epidemics” of diabetes, obesity, and atrial fibrillation in the elderly, the stage is now set for a large increase in the number of heart failure cases. Thus we are facing great challenges in our quest to control cardiac disease.

How are we going to win this battle? Surely not with a single magic bullet, whether it is a gene, device, or drug. We believe Douglas Mann’s excellent book, *Heart Failure*, details the right plan. As with any battle, we must understand the terrain on which it will be fought. The first three sections of *Heart Failure* do just that. Section I delves into the basic underlying mechanisms on genetic, molecular, tissue, organ, and organismal levels, whereas Section II describes the pathophysiology of disease progression. These discussions involve not only the heart but also the vascular bed, neurohormonal systems, kidneys, and lungs. The most common etiologies of heart failure are described in Section III.

Section IV provides a detailed description of the clinical manifestations and laboratory features of heart failure. Finally, the current armamentaria in the treatment of heart failure—drugs, devices, and surgery—and how each of these (and their combinations) can be optimally deployed are described in Section V.

A leader in the fight against one of humankind’s most stubborn enemies, Dr. Mann should be congratulated on selecting the right topics and the best authors to write about them. His skillful editing pulled everything together, making this book much greater than simply the sum of the excellent individual chapters.

This second edition builds on the first, which was warmly received. Fully one third of the chapters are new. Many chapters that appeared in the last edition have new authors and all have been updated to include the most current data and research.

Special thanks are due the authors, all distinguished investigators or clinicians, for their fine contributions. This splendid second edition of *Heart Failure* will be enormously useful to cardiovascular specialists who care for the growing number of patients with heart failure; it will be equally useful to those who are training to deliver this care, as well as to their teachers. However, the ultimate beneficiaries of this book will be the millions of patients with heart failure worldwide.

We are proud that this second edition of *Heart Failure* is a valued and indispensable companion to *Heart Disease: A Textbook of Cardiovascular Disease*.

Eugene Braunwald  
Boston, Massachusetts

Robert Bonow  
Chicago, Illinois

Peter Libby  
Boston, Massachusetts

Douglas P. Zipes  
Indianapolis, Indiana

The observation that several of the topics discussed as emerging therapies in the first edition of *Heart Failure: A Companion to Braunwald's Heart Disease* have now become either the standard of care (e.g., cardiac resynchronization) or are being tested in multicenter, multinational clinical trials (e.g., stem cell therapy) could be viewed as the major justification for publishing a second edition of the *Heart Failure Companion*. Beyond updating the chapters covered in the first edition, the vision for the second edition was to provide an extremely broad educational platform that would serve to foster a more complete understanding and appreciation of the clinical syndrome of heart failure.

To that end, the second edition contains 20 entirely new chapters that were not included in the first edition. Particular emphasis has been given to the sections on clinical assessment and treatment of heart failure (see below), which have been expanded by 75% compared to the first edition. As with the first edition, the goal in organizing this text was to provide trainees, scientists, and practicing clinicians with a resource that would present a complete bench-to-bedside overview of the field of heart failure that could be read from start to finish, or section by section. The second edition retains the same organization as the first edition and is divided into five sections that progress logically from basic molecular and cellular mechanisms that underlie heart failure (Section 1), to the mechanisms that lead to disease progression in heart failure (Section 2), to the etiologic basis for heart failure (Section 3), and finally to the clinical assessment (Section 4) and treatment of heart failure (Section 5).

As with the first edition, many of the chapters were designed to parallel one another, which should allow readers to focus on the aspects of heart failure that they find most interesting. For example, the second edition features chapters

that cover the basic and clinical aspects of heart failure with a preserved ejection fraction as well as basic and clinical aspects of stem cell therapy and myocardial regeneration. The second edition also includes new chapters that reflect the overall growth in the field (e.g., biomarkers, cardiac devices, cardiac imaging, pharmacogenomics, palliative care in heart failure), as well as increased depth of understanding in the field (e.g., myocardial recovery, diabetic cardiomyopathy, heart failure as a consequence of chemotherapy, heart failure in special populations). In addition, this edition features several unique chapters that have not heretofore been covered in traditional textbooks on heart failure, including the important topic of heart failure in developing countries, the emerging issue of meaningfully measuring quality of outcomes in heart failure, and the neglected area of cognition in heart failure.

The extent to which the second edition of *Heart Failure: A Companion to Braunwald's Heart Disease* provides readers with a comprehensive bench-to-bedside overview of the field of heart failure reflects the extraordinary expertise and scholarship of the authors who contributed their professional time and efforts to this undertaking. It has been a great pleasure to work with them and it has been my great fortune to learn from them. Although every attempt was made to make the content of individual chapters as up-to-date as possible and include all the changes that were occurring in the field while this text was in development, we recognize the challenge of capturing all the essential elements of a field that is evolving rapidly. Accordingly, this second edition will be accessible online as well as in print, on the same Expert Consult platform that houses the parent text, *Braunwald's Heart Disease*, which features regular content updates.

Douglas L. Mann, MD, FACC

## In Memoriam – Helmut Drexler

I first met Helmut Drexler in December 1996 at a symposium at the European Heart House in Sophia Antipolis, France. Helmut was in the audience listening to a presentation that I was giving. After the presentation was finished, Helmut stood up and began asking a series of challenging and incredibly insightful questions. Although I did my best to answer his questions, he must not have been satisfied because he waited until I stepped down from the podium and continued to ask me even more challenging questions. He was absolutely relentless. Thus began my friendship with Helmut Drexler that lasted up until his untimely death on September 13, 2009.

Helmut was a critical thinker who took nothing for granted. He was a classic epistemologist, who questioned everything because he wanted to understand the nature of things at their most fundamental level. His passion for understanding the basic mechanisms of heart failure was unending and his energy for translating this knowledge to the bedside was boundless. Over the span of his career he made seminal contributions to our understanding of the role of endothelial dysfunction, the renin angiotensin system, and inflammation in heart failure. He was the first to direct a randomized clinical trial of transcatheter aortic valve replacement for patients with aortic stenosis, as well as the first to highlight the shortcomings of this trial. His most significant work, which came shortly before his death, focused on the molecular mechanisms of postpartum cardiomyopathy and has paved the way for developing a potential new treatment for patients with this orphan disease. Despite all of his success Helmut's foremost priorities were always his family and friends, as well as his faculty, many of whom have gone on to have successful independent academic careers, such as Denise Hilfiker-Kleiner, Kai Wollert, Bernhard Schieffer, and Ulf Landmesser, among others. He is survived by his beautiful wife Krista and daughter Beatrice, who has recently completed medical school.

The last time I saw Helmut we had dinner together. After updating each other on our scientific pursuits and sharing our mutual passion for family, friends, and red wine, I told him that I was thinking of moving to a different city to assume a new academic position. Helmut raised his eyes from the table and was genuinely excited for me, but then mentioned that moving was difficult because it was hard to establish strong friendships as one became older. As I learned during the years that I knew Helmut, he was generally right about most things. With his death, I have lost a good friend who cannot be replaced at any age.

Douglas L. Mann, MD, FACC

Any clinical reference work of the size and complexity of *Heart Failure: A Companion to Braunwald's Heart Disease* does not occur in a vacuum. I would like to begin, first and foremost, by thanking Dr. Eugene Braunwald for giving me the opportunity to edit the companion volume focusing on heart failure. I would also like to thank Drs. Bonow, Libby, and Zipes, who taught me the art of editing during my apprenticeship on the eighth edition of *Braunwald's Heart Disease*. The extent to which the second edition of the heart failure companion is improved over the first is attributable to what I learned from my senior co-editors. I also want to thank the incredibly supportive staff at Elsevier, who enabled me to make a myriad of improvements to the content and visual design of the text as it was being developed. In particular, I would like to thank the

following members of the Elsevier staff for their forbearance and indefatigable assistance: developmental editor Marla Sussman, project manager Janaki Srinivasan, executive publisher Natasha Andjelkovic, and her editorial assistant Brad McIlwain. I would also like to thank my administrative assistant, Ms. Mary Wingate, who remained unflappable no matter how many times I asked her to re-edit, re-format, or redo the same chapter. Lastly, I would be completely remiss if I did not thank my incredibly supportive wife, Laura, who tolerated both my presence and absence throughout the process of editing and writing for the second edition of *Heart Failure: A Companion to Braunwald's Heart Disease*.

## Evolving Concepts in the Pathophysiology of Heart Failure

Arnold M. Katz

We have achieved our current understanding of heart failure through a remarkable evolution of ideas that, for Western medicine, extends back more than 2500 years.<sup>1-2</sup> Since the fifth century BCE, physicians and scientists have viewed this clinical syndrome in at least nine different ways (Table 1-1).<sup>3</sup> Improved understanding of this syndrome has been made possible by an interplay between basic and clinical sciences that is narrowing the gap between bench

and bedside, between basic science and clinical medicine.<sup>4</sup> This iterative process has used new knowledge of pathophysiology to improve patient care while at the same time clinical validation of new therapeutic approaches has added to our knowledge of basic physiology.

### HEART FAILURE AS A CLINICAL SYNDROME

The clinical texts attributed to Hippocrates, most of which were written between the fifth and third centuries BCE, describe patients with shortness of breath, edema, and anasarca.<sup>5</sup> However, as these are not specific, many of these patients probably suffered from conditions other than heart failure. The major reason why diagnosis is difficult, and often impossible, is that these texts lack a foundation in pathophysiology. Palpitation and shortness of breath, for example, were commonly attributed to the passage of phlegm, a cold humor generated by the brain, into the chest.

During the third century BCE, the center of medical science shifted to Alexandria, Egypt, where Herophilus and Erasistratus carried out human dissection and physiological experiments. Although the Alexandrian physiologists recognized that the heart contracts and understood the function of the semilunar valves, their efforts had no impact on understanding heart failure because they did not realize that the heart is a pump that circulates the blood. Their views did, however, have a major influence on Galen, a Greek physician who lived in the Roman Empire during the second century and whose writings were to dominate western thinking for more than 1500 years. Galen also knew that ventricular volume decreases during systole and understood the function of the heart's valves, but viewed the heart as a source of heat rather than a pump (Figure 1-1). Galen palpated the arterial pulse and described what almost certainly represents atrial fibrillation when he noted "complete irregularity or unevenness [of the pulse], both in the single beat and in the succession of beats";<sup>6</sup> however, he believed that the pulse is transmitted along the walls of the arteries, rather than by pulsatile blood flow through their lumens.<sup>7</sup>

Failure to understand the pathophysiology of heart failure made it impossible to appreciate the causes of the signs and symptoms of this syndrome and precluded any rational therapy. This provided a background for treatments of dyspnea and dropsy that include "take scabwort and grind and squeeze its juice through a cloth, collect in an eggshell and temper with honeycomb; give the patient daily a full shell of

the juice, do this for eleven days when the moon is waning because also man wanes in his abdomen."<sup>8</sup>

### HEART FAILURE AS A CIRCULATORY DISORDER

Correlations between clinical manifestations and cardiac abnormalities became possible at the beginning of the sixteenth century, when physicians began to perform autopsies to identify causes of illness.<sup>9</sup> However, there was no way to define mechanistic relationships between the clinical and autopsy findings in patients with heart failure until 1628, when William Harvey (Figure 1-2) described the circulation:

"I am obliged to conclude that in animals the blood is driven round a circuit with an unceasing, circular sort of movement that this is an activity or function of the heart which it carries out by virtue of its pulsation, and that in sum it constitutes the sole reason for that heart's pulsatile movement."<sup>10</sup>

During the following century, physicians began to use Harvey's discovery to understand the pathophysiology of heart failure (Figure 1-3). The first description of the hemodynamic basis of this syndrome cannot be credited to a single individual in part because medical advances in the seventeenth and eighteenth centuries were

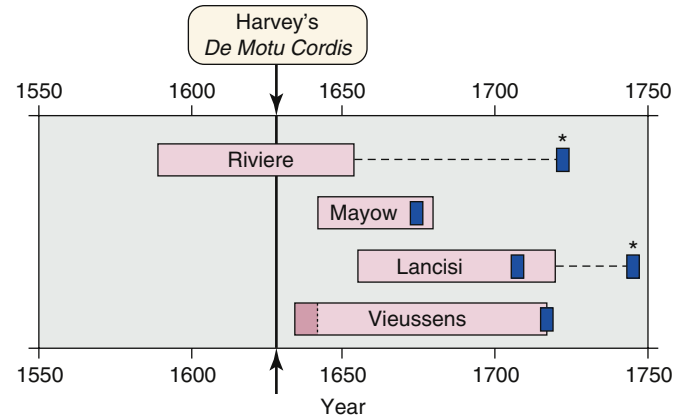

**FIGURE 1-1** Two views of the circulation. **A**, Galen's view. Pneuma derived from air reaches the heart from the lungs via the venous artery (pulmonary artery) and arterial vein (pulmonary veins). Natural spirits that enter the heart from the liver, along with vital spirits (heat) generated in the left ventricle, are distributed throughout the body by an ebb and flow in the arteries. Animal spirits transported from the brain through nerves as phlegm contribute to the formation of pleural effusions. **B**, The view after Harvey. Deoxygenated blood is darkly shaded, oxygenated blood is lightly shaded. Modified from Katz AM, Konstam MA. *Heart failure: pathophysiology, molecular biology, clinical management*, ed 2, Philadelphia, Lippincott/Williams (2009).<sup>73</sup>

**FIGURE 1-2** William Harvey. State portrait at the Royal College of Physicians, painted when Harvey was in his late 60s.

widely discussed among authorities and there were few publications, many of which appeared after the author's death. Among the first to relate the clinical features of heart failure to abnormal hemodynamics were Rivière,<sup>11</sup> Mayow,<sup>12</sup> Lancisi,<sup>13</sup> and Vieussens.<sup>14</sup> The latter (Figure 1-4), in his *Traité nouveau de la structure et des causes du mouvement naturel du coeur*, published in 1715 (the year he died), integrated a

**FIGURE 1-3** Time lines showing events following the publication of Harvey's *De Motu Cordis* in 1628 (vertical dotted line), and the birth and death of Rivière, Mayow, Lancisi, and Vieussens (rectangles; the shaded area for Vieussens reflects uncertainty regarding the date of his birth). Dates of key publications are shown by the thick vertical rectangles; posthumous publications are indicated by asterisks. Modified from Katz AM. Raymond Vieussens and the "first" pathophysiological description of heart failure. *Dialog Cardiovasc Med* 2004;9:179-182.<sup>74</sup>

superb case history, a detailed autopsy, and a surprisingly modern discussion of pathophysiology to describe the hemodynamic basis for the dyspnea and pleural effusions in a patient with rheumatic mitral stenosis.

## ALTERED ARCHITECTURE OF FAILING HEARTS

Efforts to understand heart failure shifted to the architecture of diseased hearts at the beginning of the eighteenth century. Lancisi, in 1707, distinguished between "dilation," where cavity size is increased, and "hypertrophy," where wall thickness is increased,<sup>13</sup> and in 1759 Morgagni described the causal

**FIGURE 1-4** Vieussens as a young man. Reproduced from Fishman AP, Richards DW. *Circulation of the blood: men and ideas*, New York, 1964, Oxford University Press.<sup>75</sup>

link between hemodynamic overload and cardiac hypertrophy.<sup>15</sup> These observations were followed by more than a century of discovery that focused on architectural changes in the failing heart. Corvisart's observation that dilation (eccentric hypertrophy) of the left ventricle has a worse prognosis than concentric hypertrophy<sup>16</sup> led Flint to suggest that hypertrophy is an adaptive response that protects the patient from the adverse effects of dilation.<sup>17</sup> By the end of the nineteenth century, however, it had become apparent to Osler<sup>18</sup> and others that hypertrophy itself is deleterious.

### Abnormal Hemodynamics

Many nineteenth century physiologists had been aware that a physiological increase in diastolic volume leads to an increase in cardiac output,<sup>19</sup> whereas physicians had viewed the effects of increased cavity size in terms of evidence that pathological dilation is associated with a poor prognosis (see previous discussion). Starling's description of the Law of the Heart that bears his name, which demonstrated that physiological increases in end-diastolic volume increase cardiac output,<sup>20</sup> was confusing to clinicians because it seemed to contradict the nineteenth century view that dilation weakens the heart. Furthermore, for the next 60 years it was commonly taught that failing hearts operate on the descending limb of the Starling curve, where increasing chamber volume decreases the heart's ability to eject.<sup>21</sup> This erroneous view became untenable when, in 1965, I pointed out that it is impossible for a heart operating on the descending limb of the Starling curve to function at a steady state.<sup>22</sup>

Hemodynamics remained central for understanding heart failure throughout the first half of the twentieth century, when most patients with heart disease had structural abnormalities caused by rheumatic fever, syphilis, and congenital anomalies. However, the work of Starling, Wiggers, and others who

studied cardiac hemodynamics had little impact on patient care until the early 1940s, when Cournand and Richards brought cardiac catheterization to the bedside.<sup>23</sup> Subsequent developments in cardiac surgery<sup>24</sup> made it possible to palliate many forms of structural heart disease, both rheumatic and congenital, but did not solve the challenges posed by heart failure because ischemic heart disease, dilated cardiomyopathies, and diastolic heart failure were emerging as the major causes of this syndrome.

### Disordered Fluid Balance

Dyspnea and anasarca, which had dominated the clinical picture in heart failure since the time of Hippocrates, gave rise to horrible suffering that is virtually unknown today. Although fluid retention had been proposed as a cause of dropsy as early as the sixteenth century, there had been no safe way to get rid of the excess salt and water until 1920, when Saxl and Heilig accidentally observed the diuretic properties of an organic mercurial that had been given to treat syphilitic heart disease.<sup>25</sup> Subsequent efforts to develop powerful diuretics that could be administered orally shifted the focus in heart failure research to renal physiology. This effort ended successfully in the 1950s and 1960s with the introduction of the thiazides, and subsequently of loop diuretics. Although these and other drugs can usually cause a diuresis so effective as to eliminate congestion, albeit sometimes at the expense of causing a low output state, they do little to alter the underlying causes of this syndrome. For this reason, the focus in heart failure research returned to the heart.

### Biochemical Abnormalities

Three areas of biochemistry began to have a major impact on cardiology during the 1950s. The first was energetics, which had influenced thinking in muscle physiology since the beginning of the nineteenth century (see Chapter 7). The second, elucidation of the mechanisms responsible for muscle contraction, relaxation, and excitation-contraction coupling, became part of cardiology when the role of changing myocardial contractility was recognized as a key to an understanding how hearts failed (see Chapter 3 and 13). The third area, the biochemistry of ligand-receptor interactions and the intracellular signal transduction pathways responsible for the neuro-humoral response to reduced cardiac output, led in the 1980s to the first major advances in treating this syndrome since the introduction of mercurial diuretics (see Chapter 2).

#### Energy Starvation

Muscle thermodynamics had been studied since 1848 when Helmholtz, who described the First Law of Thermodynamics, published records of energy release by muscle as work and heat. Between the 1920s and 1950s, several groups studied the mechanical efficiency of failing hearts, but most experimental studies at that time had little pathophysiological resemblance to clinical heart failure because they used either mammalian heart-lung preparations that had deteriorated when particulates in the perfusates occluded the coronary microcirculation, or a model of heart failure caused by pulmonary stenosis and tricuspid insufficiency. More recently, NMR spectroscopy and other analytic methods demonstrated that myocardial ATP and phosphocreatine levels are significantly reduced in failing hearts,<sup>26-27</sup> and so made it clear that energy starvation plays an important role in heart failure (see Chapter 7 and 20).

#### Depressed Contractility

In 1955, Sarnoff's demonstration that the heart can shift from one Starling curve to another clarified the role of *myocardial contractility* in regulating cardiac performance.<sup>28</sup> Although

characterization of this regulatory mechanism in patients was hampered by difficulties in measuring myocardial contractility, in the late 1960s Braunwald's group was able to show that contractility is reduced in patients with chronic heart failure.<sup>29</sup> This emphasis on myocardial contractility occurred at a time when muscle biochemists had found that calcium delivery to the cytosol and its binding to troponin, a regulatory protein in the myofilaments, are major determinants of contractility.<sup>30</sup> The widely held view that powerful inotropic agents would benefit patients with failing hearts, along with discoveries regarding mechanisms that depress contractility, stimulated efforts to develop new inotropic drugs. However, clinical trials showed that long-term inotropic therapy with  $\beta$ -agonists and phosphodiesterase inhibitors does more harm than good.<sup>31–32</sup>

The importance of impaired filling in the pathogenesis of heart failure was not widely recognized until the 1980s, when echocardiography and nuclear cardiology made it possible to document lusitropic abnormalities in clinical heart failure. Unfortunately, efforts to improve ventricular filling and prognosis in patients with heart failure and preserved left ventricular ejection fraction have had little success (see Chapter 48).

### Neurohumoral Stimulation

The importance of a third type of biochemical abnormality in failing hearts was described in 1983, when Harris<sup>33</sup> pointed out the adverse effects of the neurohumoral responses to reduced cardiac output. Although these responses, the most important of which are vasoconstriction, salt and water retention, and adrenergic stimulation, had evolved to maintain cardiac output during exercise and support the circulation when cardiac output falls after hemorrhage, they become harmful when they are sustained in chronic heart failure.<sup>34</sup>

The ability of vasoconstriction to increase cardiac energy expenditure<sup>35</sup> and reduce cardiac output<sup>36</sup> led Cohn and others to examine the effects of vasodilators on long-term prognosis in patients with heart failure.<sup>37–38</sup> V-HeFT and subsequent trials made it clear that although afterload reduction causes a short-term hemodynamic improvement, not all vasodilators prolong survival and some worsen long-term prognosis.<sup>39</sup> The dramatic benefit of angiotensin II–converting enzyme (ACE) inhibitors, which was first documented in the CONSENSUS I trial,<sup>40</sup> suggested that beneficial effects of ACE inhibitors are due to factors other than their ability to reduce afterload (see later discussion).

## MALADAPTIVE HYPERTROPHY

By the late 1980s, therapy for heart failure had become so effective that it was often assumed that the judicious use of diuretics, vasodilators, and inotropes could solve most of the problems in these patients. At that time, before clinical trials had documented the poor prognosis in heart failure, many experts denied that this was a progressive syndrome. However, the view that heart failure is simply a hemodynamic disorder complicated by fluid retention was challenged when long-term trials showed that direct-acting vasodilators can worsen prognosis, and a central role for depressed contractility became untenable when inotropes were found to shorten survival in these patients (see previous discussion). Explanations for these apparently counterintuitive clinical findings began to emerge in the 1990s, when new data from the expanding fields of molecular biology rekindled interest in the deleterious effects of cardiac hypertrophy.

The emphasis on cardiac hypertrophy a century earlier (see previous discussion) had not been entirely forgotten; Meerson, who in the 1950s used modern methods to study the hypertrophic response to hemodynamic overload in animals, observed, as had Osler more than 50 years earlier,<sup>18</sup> that

overload-induced hypertrophy is both beneficial and deleterious.<sup>41</sup> The beneficial effects of this growth response were shown clearly in the 1960s and 1970s when left ventricular hypertrophy was found to normalize wall stress in compensated aortic stenosis.<sup>42–44</sup> These findings, which also demonstrated that deterioration of failing hearts is not simply a consequence of sustained overload, suggested that the hypertrophic response itself might play a central role in causing maladaptive hypertrophy.<sup>45</sup>

Evidence that changes in the molecular composition of failing hearts play a role in this syndrome was published in the 1950s, when the molecular weight of myosins isolated from failing hearts was reported to increase.<sup>46</sup> However, the inability of several other groups to reproduce these findings<sup>47</sup> provoked a fierce controversy that was resolved when the original physicochemical data were shown to have been technically flawed.<sup>48</sup> A more durable line of evidence stemmed from early findings that changes in myosin ATPase activity represent a “tonic” mechanism that regulates myocardial contractility, which differs fundamentally from the “phasic” mechanisms mediated by changes in calcium binding to the contractile proteins (see previous discussion).<sup>49</sup>

The modern era in understanding the pathophysiology of heart failure began in 1962, when Alpert and Gordon reported that ATPase activity is reduced in myofibrils isolated from failing human hearts.<sup>50</sup> The molecular basis for this abnormality was identified in 1976 by Hoh et al.<sup>51</sup> who found that differences in the rate of energy release by myosin are the result of expression of different myosin isoforms. Scheuer and Penpargkul, in collaboration with my group, found that overload not only decreases energy turnover by the contractile proteins, but also slows calcium transport by the sarcoplasmic reticulum.<sup>52</sup> Izumo, Nadal-Ginard, and others<sup>53–54</sup> subsequently demonstrated that increased expression of the low ATPase  $\beta$ -myosin heavy chain isoform in failing hearts is part of a reversion to the fetal phenotype. The importance of these molecular changes was highlighted by the finding that *opposite* changes occur in training-induced physiological hypertrophy (the “athlete’s heart”), where increased expression of the high ATPase  $\alpha$ -myosin heavy chain isoform increases ATPase activity and contractility.<sup>55</sup>

The practical importance of maladaptive hypertrophy became apparent in 1985 when Janis Pfeffer, Mark Pfeffer, and Braunwald reported that ACE inhibitors slow the progressive cavity enlargement, which they called *remodeling*, that follows experimental myocardial infarction (see Chapter 15).<sup>56</sup> At the same time, evidence began to appear suggesting that these drugs are not only vasodilators, but also modify proliferative signaling.<sup>57</sup> These observations, along with evidence that overload causes the heart to deteriorate (see previous discussion), indicates that the hypertrophic response can, depending on the specific signaling mechanisms that are activated, be either adaptive or maladaptive.<sup>58–62</sup>

## GENOMICS

Shortly after molecular biology moved to center stage in cardiology in the late 1980s,<sup>63</sup> the Seidman laboratory described the first molecular cause of a familial cardiomyopathy, a missense mutation in the cardiac  $\beta$ -myosin heavy chain gene.<sup>64</sup> This molecular abnormality was subsequently shown to represent only one of a growing number of mutations involving additional proteins that cause both hypertrophic and dilated cardiomyopathies (see Chapter 27).<sup>65</sup> The possibility of modifying the signal pathways controlled by these mutations to activate adaptive cardiac myocyte growth and inhibit maladaptive hypertrophy represents one of today’s most promising lines of investigation.<sup>58–61</sup>

**FIGURE 1-5** Changing management of heart failure over the past 40 years as documented by the number of pages devoted to various treatments in several editions of Hurst's *The Heart* and Braunwald's *Heart Disease*. (Electronic and mechanical devices and surgical therapies are not included.) From Katz AM, Konstam MA. *Heart failure: pathophysiology, molecular biology, clinical management*, ed 2, Philadelphia, Lippincott/Williams (in press).<sup>73</sup>

## EPIGENETICS

A newly discovered type of regulation, referred to as *epigenetics*,<sup>66</sup> has recently been found to operate in heart failure. Epigenetic regulation differs from the more familiar genomic mechanisms, whose primary targets include transcription factors that interact with DNA and alternative splicing that allows synthesis of different protein isoforms by rearranging the information encoded in the exons of genomic DNA. Epigenetic mechanisms modify proliferative signaling by methylation of cytosine in genomic DNA, acetylation of histone, and inhibition of RNA translation by small RNA sequences called microRNAs. Cytosine methylation has been implicated in some familial cardiomyopathies,<sup>67–68</sup> while histone acetylation can modify overload-induced cardiac hypertrophy.<sup>69–70</sup> Evidence that microRNAs regulate cardiac hypertrophy<sup>71–72</sup> is of potential therapeutic importance because short RNA segments, called small interfering (si)RNAs, can silence specific genes. The ability of (si)RNAs, which are readily synthesized commercially to block specific proliferative pathways, promise additional approaches slowing deterioration of failing hearts by inhibiting maladaptive hypertrophy.

## CONCLUSIONS AND FUTURE DIRECTIONS

The growing impact of the discoveries summarized in this chapter on patient care are apparent when discussions of therapy for heart failure in recent cardiology textbooks are compared (Figure 1-5). The first edition of Hurst and Logue's *Heart Disease*, published in 1966, devotes almost two thirds of the discussion to cardiac glycosides and their toxicity; the remainder describes diuretics and rest. The relative lengths of the discussions of rest, diuretics, and digitalis in this text differ little from those in White's 1931 textbook *Heart Disease*. Looking back even farther, to 1908, the description of therapy for heart failure in Mackenzie's *Diseases of the Heart* devotes more than 11 pages to the actions and toxicity of the cardiac glycosides; a half page each to nitroglycerin and amyl nitrite, which are described as “vaso-dilators”; two pages to the appropriate level of activity; three to diet; care of the bowels and the “mental factor” receive a half page each; and there is virtually nothing about diuretics.

Textbook discussions of heart failure therapy have been changing dramatically since the 1970s. The space allocated to diuretics has remained about the same, but recommendations for rest have virtually disappeared and discussions of digitalis have decreased remarkably. The latter is due in part to a decrease in the frequency of digitalis toxicity because cardiac

glycosides, once viewed as among the few effective forms of therapy, were commonly given at very high doses in severely ill patients. Discussion of nonglycoside inotropes appeared in the 1970s, as did the short-term benefits of vasodilators. Neurohumoral blockade and  $\beta$ -blockers received separate discussions in the 2001 edition of Braunwald's *Heart Disease: A Textbook of Cardiovascular Medicine*. Even more striking are recent advances in device therapy, which are not included in Figure 1-5.

The evolution of our understanding of the pathophysiology and treatment of heart failure described in this chapter represents one of the major successes in biomedical research. This remarkable progress, which has been made possible by increasingly effective interactions between basic science and clinical investigation, continues a tradition that began when Harvey described the circulation. The growing impact of molecular biology, coupled with better understanding of the benefits and side effects of therapy offers considerable promise for future gains in our ability to manage patients with heart failure.

ties). Thus heart failure is the common clinical syndrome caused by any of a diverse group of injurious stimuli sufficient to produce myocardial insufficiency. The specific characteristics and clinical course of heart failure may be determined more by the myocardial response to injury and its accompanying hemodynamic overload than by the specific nature of the primary insult. With cardiac injury or hemodynamic stress, a multitude of signaling pathways are activated that may be predominantly compensatory or maladaptive. Accordingly, molecular surveys performed over the past 3 decades have defined biochemical and transcriptional signatures of failing myocardium, and reductionist experimentation has delineated responsible mechanisms of functional adaptation and decompensation.

Accumulated data reveal that molecular signaling of heart failure is complex and involves activation of multiple pathways exhibiting cross-talk inhibition and potentiation, functional redundancy, and feedback or feedforward regulation. Clinically important pathophysiological linkages have been established between molecular determinants of cardiomyocyte contractility, cardiomyocyte growth, and cardiomyocyte death. Thus the themes of heart failure pathophysiology have transitioned from a primary focus on mechanical to molecular factors. As a consequence, the field has moved away from early therapeutics that stimulated neurohormone pathways in attempts to enhance pump function by increasing cardiac myocyte inotropy (catecholamines, phosphodiesterase inhibitors) or by decreasing hemodynamic loading (arterial and venous vasodilators, diuretics).<sup>1,2</sup> The current approach for treating end-stage heart failure combines pharmacological inhibition of maladaptive molecular signaling pathways ( $\beta$ -adrenergic blockers, angiotensin-converting enzyme inhibitors) with “bionic” measures aimed at resting, restoring, and recovering failing myocardium (ventricular assist devices), or correcting electromechanical cardiac dysfunction (resynchronization therapy).<sup>3-5</sup> Ongoing and future clinical trials of gene- and cell-based therapies are building upon fresh molecular insights to develop novel targets and approaches for heart failure (see Chapter 50).<sup>6</sup>

## INVESTIGATIVE TECHNIQUES AND MOLECULAR MODELING

The explosion of molecular information on the pathophysiology of heart failure is the result of reductionist experimentation using advanced molecular and physiological modeling in genetically manipulated systems, and a more integrated approach that takes advantage of recently developed high-throughput platforms for genetic analysis of small clinical specimens in human heart failure. The overall paradigm is that of an extrinsic biomechanical stimulus that activates molecular signaling pathways. The cardiomyocyte responds with altered gene expression that changes the protein makeup of the cell, and

ultimately the structure and function of the heart. Experimental models for dissecting out and identifying important molecular events have therefore tended to genetically and physiologically perturb a hypertrophy stimulus (e.g., transgenic overexpression of G $\alpha_q$  and induction of pressure overload by microsurgical creation of a transverse aortic constriction<sup>8</sup>). Experimental manipulation of signaling pathways has largely transitioned away from pharmacological activators and inhibitors and toward creating gain-of-function and loss-of-function mutant organisms with complementary perturbations of the candidate factor specifically in the specific cell type of interest (cardiomyocyte). To enhance appreciation of the following detailed discussion of molecular pathways for hypertrophy and heart failure, here we briefly review some general techniques and approaches used in these types of studies.

Molecular investigation of cardiac hypertrophy began with development by Paul Simpson of an in vitro model system using neonatal rat cardiac myocytes.<sup>9</sup> In contrast to adult cardiac myocytes, neonatal rat myocytes are relatively easy to prepare and can be maintained in tissue culture for weeks. Under serum-free conditions, cardiomyocytes stimulated with Gq-coupled neurohormones such as phenylephrine, angiotensin, and endothelin undergo cellular hypertrophy with many characteristics of in vivo cardiomyocyte hypertrophy: Cells enlarge, protein synthesis is accelerated, and hypertrophy-associated genes are increased in expression, including atrial natriuretic factor (ANF)<sup>10</sup> and  $\alpha$ -skeletal actin.<sup>11</sup> Even when the stimulus is simple mechanical stretching, neonatal rat cardiac myocytes exhibit a characteristic hypertrophic gene program mimicking pathological hypertrophy.<sup>12</sup> Neonatal cardiac myocytes are less useful for studies of excitation-contraction coupling due to incompletely developed sarcomeres and sarcoplasmic reticulum network. Thus techniques were developed to isolate calcium-tolerant adult cardiac myocytes from multiple vertebrate species including mice, the predominant species used for genetic manipulation.<sup>13,14</sup> Isolated individual field-paced adult cardiac myocytes are now routinely used to

8 measure the effects of experimental manipulations on contraction, relaxation, and calcium transients.

A major limitation of cultured and isolated cardiac myocyte studies is that the impact of the experiment on integrated cardiac and cardiovascular function cannot be determined. This requires perturbation and analysis in an intact organism with sufficient similarity to man for conclusions to have relevance to the human condition. An additional requirement is the ability to perform specific genetic manipulations in the organism, which permits specificity of molecular perturbation and tissue targeting that is typically not possible using pharmacological agents. Although important basic information has derived from studies of fruit flies and zebra fish, the genetically modified (transgenic or knockout) and physiologically modeled mouse has become the dominant experimental system for in vivo examination of the molecular event mediating cardiac hypertrophy and heart failure.

Transgenic *gain-of-function* approaches are typically employed to evaluate whether a particular gene and its protein product are, by virtue of the protein's functional involvement in a particular pathway, *sufficient* to provoke a particular outcome. Cardiomyocyte-specific expression is conventionally achieved by driving cDNA expression using cardiac-specific promoters such as Mlc2v and  $\alpha$ MHC.<sup>15,16</sup> These promoters drive high-level gene expression in the early embryonic heart (Mlc2v) or shortly after birth ( $\alpha$ MHC) and thereafter. For genes with deleterious effects on fetal or postnatal cardiac development that confound the experimental interpretation or can be lethal,<sup>17</sup> conditional expression systems permit transgene expression under temporally defined conditions by administering tetracycline or mifepristone.<sup>18-20</sup>

*Loss-of-function* approaches are helpful to determine whether a certain gene (or its protein product) is *necessary* for a given outcome. There are several ways to decrease gene function, such as transgenic expression of dominant inhibitory mutants and transgenic or adenoviral/AAV-mediated expression of specific short interfering RNAs (siRNAs). Because of specificity and stability issues with siRNAs, the potential for unanticipated effects of mutant inhibitory proteins, and the possibility that forced expression itself can induce pathology,<sup>21</sup> targeted gene ablation is considered the gold standard for loss of function.<sup>22</sup> Limitations of germ line gene ablation relating to noncardiac effects have been addressed by tissue-specific ablation using Cre-Lox technology and cardiomyocyte-expressed Cre.<sup>23,24</sup>

Although genetic manipulations can produce cardiac phenotypes permitting mechanistic insight, frequently the consequences of an overexpressed or ablated gene are further interrogated through surgical or pharmacological intervention. Mouse cardiac surgery was not performed when genetic manipulation of the mouse first came of age. The development of microsurgical modeling for pressure overload, volume overload, heterotopic transplantation, infarction, and ischemia-reperfusion, together with advances in microanalytical techniques for invasive hemodynamic or electrophysiological studies and sophisticated noninvasive echocardiographic and magnetic resonance imaging, has completed the investigational "tool kit" for in vivo studies of genetically and physiologically modeled mice.<sup>7,25-27</sup>

## Molecular Ontogeny is Recapitulated by Cardiac Hypertrophy

Cardiac hypertrophy and heart failure in the adult are characterized by reexpression of fetal cardiac genes.<sup>28-30</sup> Here, we explore the reasons for this prototypical feature. Since cardiac failure results from loss of functioning myocardium, the optimal compensatory response to cardiac insufficiency is myocardial repair or regeneration. Indeed, the universal response

to myocardial insufficiency is cardiac hypertrophy. Hypertrophy is measured at the organ level using electrocardiographic, echocardiographic, or magnetic resonance imaging indices of myocardial mass and cardiac size, and is reflected by cardiomyocyte enlargement in the short axis (pressure overload) or long axis (volume overload).<sup>31</sup> Although there are many similarities in gene and protein content between developing embryonic hearts and hypertrophying adult hearts, a critical difference is the inability of adult cardiac myocytes to increase in number through mitosis and cytokinesis after the early postnatal period.<sup>32,33</sup> Accumulating evidence supports the presence of pluripotent resident and immigrant cardiac progenitor cells in the adult myocardium,<sup>34,35</sup> but the regenerative potential of these cells is not yet known; and these cells are not currently believed to contribute in a major way to cardiomyocyte renewal and repopulation under typical circumstances.

A hallmark of pathological hypertrophy in the adult heart is reexpression of embryonic cardiac genes (and the proteins they encode), often referred to as the "fetal gene program." This is the clearest example of how the cardiac response to stress or injury recapitulates aspects of cardiac development. As might be expected for a coordinated program of expressed genes, the earliest detectable change (within hours after pressure overloading hearts or stimulating cultured cardiomyocytes to hypertrophy) is induction of regulatory transcription factors, *c-fos*, *c-jun*, *jun-B*, *c-myc*, and *egr-1/nur77*, and heat shock protein (HSP) 70.<sup>8</sup> These changes are typical of cell cycle entry.<sup>36</sup> Induction of these and other transcription factors, called "early response genes," drives the expression of downstream genes in the fetal program (Figure 2-1). Atrial natriuretic factor (ANF) is the prototypical fetal cardiac gene, expressed early during heart development through the coordinated interactions of the Nkx2.5, GATA-4, and PTX transcription factors.<sup>37</sup>

GATA4, a zinc finger DNA binding protein, is essential for embryogenesis and formation of the linear heart tube<sup>38</sup> and is also expressed in the adult heart. GATA4 binding sites are found on the promoters of various cardiac expressed genes as ANF, BNP, ET-1,  $\alpha$ -skeletal actin,  $\alpha$ MHC,  $\beta$ MHC, cardiac troponin c, and AT1R and regulates transcription of multiple genes in response to pressure overload and neurohormonal signaling. Forced expression of GATA4 at low levels causes mild hypertrophy with increased fibrosis, whereas cardiomyocyte-specific deletion of GATA4 diminished exercise-induced and pressure-overload hypertrophy, with no effect on normal cardiac growth.<sup>39</sup> Antihypertrophic signaling mediated by GSK3 $\beta$ , a kinase downstream of the IGF-1-PI3K-Akt axis that regulates normal cardiac growth (see later discussion), is transduced in part by GSK3 $\beta$ -induced phosphorylation and suppression of GATA4 transcriptional activity. GATA4 also complexes with other transcription factors such as Nkx2.5, MEF2, coactivator p300, SRF, and NFAT to affect cardiac gene expression (see Figure 2-1).<sup>40</sup>

SRF (serum response factor), a cardiac-enriched transcription factor,<sup>41</sup> was identified as a transcriptional regulator that associated with the serum response element (SRE) with characteristic recognition sequences (CArG boxes) in the *c-fos* gene promoter. SRF is essential for sarcomerogenesis based on its coordinated interaction with other transcription factors, such as SMAD1/3, Nkx2-5, and GATA4. Conditional cardiac-specific gene ablation of SRF resulted in embryonic lethality due to cardiac insufficiency during chamber maturation, associated with cardiomyocyte apoptosis.<sup>42</sup> Confirmatory evidence for a critical role of SRF in normal cardiac and cardiomyocyte homeostasis came from conditional cardiomyocyte gene ablation in the adult mouse, which demonstrated progressive development of cardiomyopathy with disorganization of the sarcomeres leading to heart failure.<sup>43</sup> Myocardin is a cardiac and smooth muscle-specific co-activator of SRF.

**FIGURE 2-1** Regulation of gene expression in normal growth and pathological hypertrophy. A common set of transcription factors determine normal cardiac growth and pathological hypertrophy, such as GATA4, Nkx2.5, SRF, MEF2, and NFATs. Hypertrophy signaling pathways result in phosphorylation of histone deacetylases (HDACs) with export out of the nucleus, permitting histone acetylation by histone acetyl transferases (HATs), with activation of gene transcription to generate messenger RNA (mRNA). mRNA is spliced to yield a mature form, which recruits the protein synthesis machinery leading to protein translation. MicroRNAs (miRNAs) inhibit mRNA translation and/or enhance mRNA degradation to negatively regulate translation. The FoxO3 family and Wnt transcription factors (not shown) negatively regulate hypertrophic growth.

Its expression is induced by phenylephrine (PE) in vitro and it binds to SRF and induces ANF transcription. Accordingly, forced cardiac expression of myocardin causes pathologic in vivo hypertrophy with fetal gene expression.<sup>44</sup>

The consequences of altered cardiac gene expression on myocardial function are varied: (1) Ventricular ANF (and related brain natriuretic peptide [BNP]) expression is robust in pathological hypertrophy and heart failure, and the increase in BNP secretion from the heart forms the basis for a widely used clinical biomarker assay of heart failure.<sup>45</sup> (2) Because of differences in ATPase activity, and therefore efficiency, it has been suggested that increased  $\beta$ -MHC could impair myocardial contractility,<sup>46,47</sup> but there is little direct supportive evidence.<sup>48</sup> (3) Downregulation of the gene encoding the sarcoplasmic reticulum  $\text{Ca}^{2+}$  ATPase (SERCA), the  $\text{Ca}^{2+}$  pump responsible for rapid reuptake of calcium into the sarcoplasmic reticulum,<sup>49</sup> appears to be responsible for the characteristic calcium signaling abnormalities observed in experimental and human heart failure.<sup>50,51</sup> Experimental gene therapies for heart failure are therefore targeting SERCA and its endogenous inhibitor phospholamban.<sup>52</sup>

In addition to the classic five reported fetal genes ( $\beta$ MHC,  $\alpha$ -skeletal actin, ANF, BNP, and SERCA), transcriptome analysis using high-throughput microarrays in failing human and mouse hearts have identified hundreds of upregulated and downregulated genes in cardiac hypertrophy and failure<sup>53-55</sup> (a comprehensive database of these gene expression changes is now available at [cardiogenomics.org](http://cardiogenomics.org)). In addition to providing mechanistic insight into heart failure, myocardial mRNA signatures may be prognostic biomarkers or therapeutic guides.<sup>56-59</sup>

An exciting new prospect is the potential for microRNAs to provide incremental information on the molecular status of the myocardium.<sup>60</sup> MicroRNAs (miRNAs) are small (~22 nucleotide) naturally occurring RNAs that negatively regulate gene expression by promoting degradation of mRNAs and/or inhibiting mRNA translation,<sup>61</sup> thereby suppressing protein synthesis (Figure 2-1). Myocardial miRNA expression is altered in hypertrophic and failing myocardium,<sup>60,62,63</sup> suggesting that stress-induced regulation of miRNA contributes to reprogramming of myocardial genes in pathological hypertrophy and heart failure.

## Molecular Signaling of Normal Heart Growth and Physiological Cardiac Hypertrophy

Cardiac hypertrophy is frequently classified as either “physiological” (i.e., normal postnatal growth and the cardiac enlargement that results from physical conditioning) or “pathological” (i.e., reactive hypertrophy in response to hemodynamic overload and myocardial injury).<sup>31,64,65</sup> Descriptive terms such as “physiological” or “pathological” hypertrophy indicate the probable outcome of the hypertrophy and the nature of the inciting stimulus and signaling pathway. Physiological stimuli such as exercise and pregnancy produce physiological hypertrophy, whereas cardiac pathologies such as hemodynamic overload, myocardial infarction, or toxic and infectious myocardial damage produce pathological hypertrophy. The stimulus-response relationship was clearly defined in a recent study that used advanced microsurgical techniques to produce intermittent pressure overload, which induced quantitatively less severe hypertrophy with minimal fibrosis and fetal gene reexpression, but with the key pathological characteristics of traditional reactive pressure overload hypertrophy.<sup>66</sup>

Physiological hypertrophy of the adult heart shares important traits with normal cardiac growth that distinguish physiological from pathological hypertrophy: The extent of physiological hypertrophy in athletes and during pregnancy is typically not sufficient to impede normal cardiac mechanical function, myocardial collagen deposition is not observed, capillary density increases in proportion to the increase in myocardial mass, bioenergetic alterations enhancing fatty acid metabolism and mitochondrial biogenesis are favorable, and physiological hypertrophy regresses without permanent sequelae upon interruption of the inciting stimulus.<sup>65</sup> A likely determinant of these favorable characteristics is the absence of the hallmark fetal gene program seen in pathological hypertrophy.<sup>67</sup> Because of the generally beneficial effects of physiological hypertrophy, exercise<sup>68</sup> and molecular manipulation of cardiac growth signaling pathways<sup>69</sup> have been investigated to prevent or ameliorate the effects of pathological hypertrophy and heart failure.

Both normal cardiac growth and physiological hypertrophy are mediated via the peptide growth factor, IGF-1.<sup>70</sup>

**10** Growth hormone released from the pituitary gland stimulates IGF-1 synthesis in various tissues, primarily the liver. Likewise, development of physiological cardiac hypertrophy in response to exercise is also triggered by IGF-1, levels of which are increased in trained athletes and in cardiomyocytes in response to hemodynamic stress.<sup>71</sup> The direct effects of IGF-1 stimulation are beneficial, including decreased cardiomyocyte apoptosis in response to noxious stimuli in vitro and in vivo, and prevention of adverse remodeling with preservation of systolic function in vivo.<sup>72</sup> IGF-1 does not seem to be necessary for pathological hypertrophy, however, because knockout mice lacking IGF-1 exhibit a normal hypertrophic response to pressure overload. Thus the cardiomyocyte autonomous effects of IGF-1 appear to be stimulation of normal and physiological growth.

IGF-1, insulin, and other peptide growth factors activate membrane receptors with intrinsic tyrosine kinase activity (Figure 2-2). IGF-1 or transgenic expression of IGF-1 receptor causes physiological hypertrophy,<sup>73,74</sup> whereas ablation of insulin receptors and/or IGFR1 depresses normal myocardial growth.<sup>75,76</sup> PI3K $\alpha$  is recruited to activated IGF-1 receptors (see Figure 2-2). Genomic ablation of PI3K p110 $\alpha$  is embryonic lethal at day 9.5 of gestation,<sup>77</sup> but dominant negative expression of p110 $\alpha$  in the postnatal heart reduces adult heart size and prevents development of swimming-induced hypertrophy<sup>78</sup>; and forced cardiac expression of p110 $\alpha$  stimulates physiological growth.<sup>79</sup> PI3K p110 $\alpha$  maintains ventricular function via membrane recruitment of protein kinase B/Akt (see Figure 2-2): IGFR-mediated translocation of the p110 $\alpha$  subunit to the cell

membrane facilitates phosphorylation of membrane phosphatidylinositols at the 3' location, resulting in binding of Akt and its activator PDK1 via pleckstrin homology (PH) domains. Ablation of Akt1 and/or Akt2, and PDK1, reduces cardiac mass.<sup>80,81</sup>

Although IGF-1 and its downstream effectors clearly produce physiological hypertrophy, IGF-1 mediated hypertrophy evolves over time into pathological hypertrophy, with fibrosis and systolic dysfunction.<sup>82</sup> This transitional phenotype is similar to that observed with forced expression of Akt, in which inadequate angiogenesis contributes to the transition from hypertrophy to cardiac failure.<sup>83</sup> The hypothesis is that cardiomyocyte growth beyond a certain physical limit, whether initially physiological or pathological, exceeds the capacity for oxygen and nutrient delivery due to lack of concordant angiogenesis needed to meet the demands of the hypertrophied myocyte.<sup>84</sup> Thus there may be pathological consequences to excessive physiological hypertrophy that could explain the relatively rare occurrences of irreversible ventricular hypertrophy and dilation in endurance sports athletes.<sup>85</sup>

## **PATHOLOGICAL HYPERTROPHY: THE CARDIOMYOCYTE GROWTH/DEATH CONNECTION**

Pathological cardiac hypertrophy is an independent risk factor for cardiac death (see Chapter 22)<sup>86</sup> and classically exhibits progression from a compensated or nonfailing state to failing dilated cardiomyopathy.<sup>87,88</sup> At the cellular level, massive

**FIGURE 2-2** IGF-1 signaling in physiological hypertrophy. Normal growth and exercise induce cardiac hypertrophy signaling via IGF-1 release. IGF-1 binds to the membrane-bound IGF receptor (IGFR), leading to autophosphorylation and recruitment of PI3K isoform, p110 $\alpha$  to the cell membrane. PI3K $\alpha$  phosphorylates phosphatidylinositols in the membrane at the 3' position in the inositol ring, generating phosphatidylinositol triphosphate (PIP3). Protein kinase B (Akt) and its activator, PDK1, associate with PIP3, resulting in Akt activation, which also requires phosphorylation by PDK2 for full activity (not shown). Activated Akt phosphorylates and activates mTOR, resulting in ribosome biogenesis and stimulation of protein synthesis. Akt also phosphorylates GSK3 (both  $\alpha$  and  $\beta$  isoforms), resulting in repression of its antihypertrophic signaling. The phosphatase PTEN dephosphorylates PIP3 to generate PIP2 and shut off the signaling pathway.

cardiomyocyte hypertrophy is almost always observed in dilated cardiomyopathies. Thus hypertrophy both contributes to, and is a consequence of, heart failure. The essential feature of cardiac hypertrophy is increased cardiomyocyte size/volume. Other myocardial alterations, such as fibroblast hyperplasia, deposition of extracellular matrix, and a relative decrease in vascular smooth muscle and capillary density<sup>89,90</sup> also contribute to the progression from hypertrophy to heart failure (reviewed in Chapter 6).

Conventional wisdom has long held that the primary change in ventricular geometry in reactive pressure overload hypertrophy (i.e., wall thickening)<sup>91</sup> is helpful in postponing the inevitable functional decompensation and adverse remodeling (wall thinning and chamber dilation<sup>92</sup>) because ventricular systolic wall stress is normalized.<sup>87</sup> This relationship is described by the Laplace equation,  $s = Pr/2h$ , where  $s$  is wall stress (force per unit of cross-sectional area), which is synonymous with afterload and is directly proportional to  $P$  (intraventricular pressure) and  $r$  (ventricular radius), and is inversely proportional to  $h$  (ventricular wall thickness). Accordingly, an increase in ventricular  $h$  to  $r$  ratio in pressure overload (concentric) hypertrophy decreases wall stress for a given intracavitary pressure. The physics of ventricular remodeling are not disputed, but there is accumulating evidence that the quantity of myocardium may be a less important determinant of left ventricular ejection performance than the quality of myocardium.<sup>88</sup> Indeed, because of pathological upregulation of fetal cardiac genes<sup>29,30</sup> and increased programmed cardiomyocyte death,<sup>93,94</sup> it has been suggested that reactive hypertrophy may be entirely dispensable to functional compensation after hemodynamic overloading.<sup>95,96</sup>

Cardiomyocyte death or degeneration is a seminal feature of failing hearts, and is also detectable in pathological hypertrophy before the development of cardiomyopathy. Cardiomyocyte death may be programmed (cell suicide by necrosis, apoptosis, or autophagy) or nonselective (conventional necrosis),<sup>97</sup> and there is evidence for all three forms of death in end-stage human cardiomyopathy.<sup>98</sup>

## Apoptosis

Apoptosis (see Chapter 6), derived from the Greek expression for “the deciduous autumnal falling of leaves” (*apo* means away from, and *ptosis* means falling),<sup>99</sup> is an orderly and highly regulated energy requiring process that, in many tissues, provides for targeted removal of individual cells without provoking an immune response that could produce more extensive, collateral tissue damage.<sup>100</sup>

Geographically localized apoptosis is essential to normal development of the heart and ventricular outflow tract.<sup>101</sup> Apoptotic indices (number of TUNEL-positive nuclei/total nuclei) are highest in the outflow tract (~50%),<sup>102</sup> intermediate in the endocardial cushions that are sites of valve formation and left ventricular myocardium (10% to 20%),<sup>103</sup> and lowest in the right ventricular myocardium (~0.1% at birth).<sup>104</sup> Cardiomyocyte apoptosis parallels cardiomyocyte mitosis and therefore decreases toward the end of embryonic development, and apoptotic cardiomyocytes are extremely rare in normal adult myocardium (1 apoptotic cell per 10,000 to 100,000 cardiomyocytes).<sup>33</sup> Abnormal persistence of apoptosis in right ventricular myocardium may contribute to the pathogenesis of arrhythmogenic right ventricular dysplasia,<sup>105</sup> a disorder caused by mutations of the plakoglobin and desmoplakin genes and disorder of Wnt signaling, and that is characterized by right ventricular-specific apoptosis and fibrofatty replacement associated with arrhythmias and sudden death.<sup>106</sup> The prevalence of cardiomyocyte apoptosis is markedly increased in chronic cardiomyopathies.<sup>107,108</sup> Likewise, myocardial ischemia and reperfusion injury induce acute cardiomyocyte apoptosis in human disease<sup>109</sup> and

experimental animal models,<sup>110</sup> and in the subacute period following the infarction, wherein it contributes to ventricular remodeling.<sup>111</sup> Apoptotic cardiomyocyte death likely also plays a role in the transition of pressure overload hypertrophy to dilated cardiomyopathy.<sup>93,112</sup>

A powerful stimulus for cardiomyocyte apoptosis in heart failure is high levels of circulating cytokines.<sup>113</sup> Sustained experimental pressure overload is sufficient to induce expression of the prototypical death-promoting cytokine, TNF- $\alpha$ ,<sup>114</sup> and TNF signaling via the TNFR1 receptor is both negatively inotropic and stimulates cardiomyocyte hypertrophy and apoptosis.<sup>115,116</sup> A causal role for this cytokine in heart failure is suggested by elevated TNF- $\alpha$  plasma levels that are correlated with the degree of cardiac cachexia,<sup>117</sup> and by studies where TNF- $\alpha$  infusion or forced cardiac expression of the cytokine created myocardial hypertrophy with increased cardiomyocyte apoptosis, adverse ventricular remodeling, and systolic dysfunction in rodent models.<sup>118,119</sup>

TNF binds to the TNFR1 receptor homotrimer to trigger death receptor signaling (Figure 2-3). This results in formation of death inducing signaling complex (DISC) with recruitment of the adaptor protein FADD and activation of caspase 8, an upstream member of a family of executioner cysteine proteases (see Figure 2-3).<sup>120</sup> Activated caspase 8 cleaves caspase 3, the effector caspase, which activates a nuclear DNase (CAD—caspase activated DNase), resulting in internucleosomal cleavage of DNA and chromatin condensation. Caspase 8 also cleaves Bid, a proapoptotic Bcl-2 family protein. Generation of truncated (*t*Bid) links the extrinsic and intrinsic pathways (see Figure 2-3), leading to their simultaneous activation in TNF-induced cardiomyocyte apoptosis.<sup>119</sup>

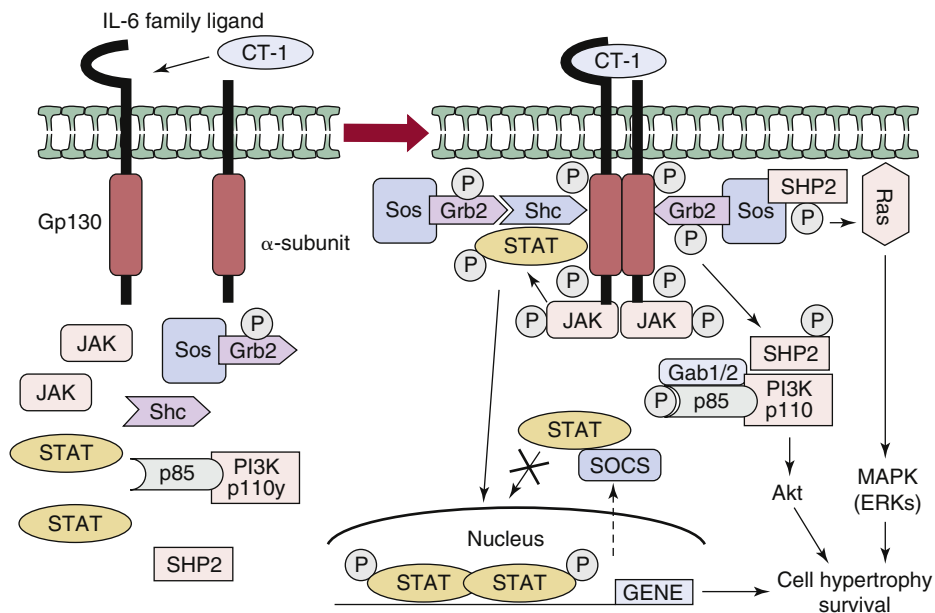

Whereas TNF- $\alpha$  receptors activate cardiomyocyte death pathways<sup>113</sup> cell survival signaling is stimulated by the IL-6 family of cytokines, including IL-6, cardiotrophin, and LIF. A shared membrane receptor for IL-6 family cytokines is glycoprotein (gp) 130 that, as with all cytokine and peptide growth factor receptors, has intrinsic tyrosine kinase activity. Binding of IL-6 or cardiotrophin induces gp130 homodimerization or oligomerization with  $\alpha$ -subunits of other cytokine receptors, stimulating autophosphorylation on receptor cytoplasmic tails and activating intrinsic tyrosine kinase activity (Figure 2-4). Receptor tyrosine phosphorylation permits binding of adaptor proteins Grb2 and Shc to SH2 binding domains, upon which multiple signaling effectors assemble for activation of the following signaling pathways (see Figure 2-4): (1) Janus kinases (JAKs) that phosphorylate STAT transcription factors, which then migrate to the nucleus as active dimers to regulate gene expression<sup>121</sup>; (2) SH2 domain-containing cytoplasmic protein tyrosine phosphatase (SHP2), which activates the MEK/ERK pathway; and (3) the Ras/mitogen-activated protein kinase that activates MAPK and extracellular signal-regulated kinase (ERK) signaling. These signaling pathways are inhibited by SOCS family proteins,<sup>122</sup> and transcriptional upregulation of SOCS proteins via STAT signaling providing for feedback inhibition of JAK/STAT pathways (see Figure 2-4).

Consistent with important roles in cardiac development and homeostasis during periods of stress, cardiotrophin 1 and related IL-6 family member cytokines are expressed in embryonic and adult myocardium and stimulate increases in cardiomyocyte size and protein synthesis.<sup>123</sup> Gp130 signaling is essential for embryonic cardiac development since germline deletion in mice is lethal at embryonic day 12.5 and the mice exhibit myocardial abnormalities<sup>124</sup> (although this does not appear to be a cell-autonomous requirement<sup>125</sup>). Gp130 signaling is sufficient to provoke hypertrophy in the adult heart,<sup>126</sup> whereas expression of dominant negative gp130 attenuates pressure overload hypertrophy.<sup>127</sup>

The gp130 signaling axis plays a critical role in cardiomyocyte survival after stress. Mice with cardiomyocyte-specific deletion of gp130 develop massive cardiomyocyte

**FIGURE 2-3** TNF-induced death signaling in heart failure: TNF- $\alpha$  binds to TNF receptor 1 (TNFR1) homotrimer, resulting in recruitment of proteins via death domains, namely TRADD and FADD; and procaspase 8 and assembly of DISC (death-inducing signaling complex). This causes cleavage activation of caspase 8, which cleaves and activates the effector caspase: caspase 3. Activated caspase 3 proteolyzes cellular substrates, causing cell death. This pathway is amplified by caspase 8-induced cleavage of Bid, a BH3 domain only Bcl-2 family protein, the truncated form of which, tBid, interacts with multidomain proapoptotic Bcl-2 proteins Bax and Bak (not shown). This results in mitochondrial outer membrane permeabilization and release of cytochrome c (cyt c), which associates with adapter protein Apaf-1, ATP, and procaspase 9, forming the apoptosome, with activation of caspase 9. Activated caspase 9 activates caspase 3. This process is opposed by Bcl-2 and Bcl-xl (not shown), and inhibitor protein XIAP. Smac/DIABLO and Omi/HtrA2 are released during mitochondrial permeabilization (not shown) and bind to XIAP, relieving its inhibitory effect. Also released are DNases: AIF (apoptosis-inducing factor) and endoG, which cause DNA cleavage.

**FIGURE 2-4** Gp130-mediated survival signaling in heart failure: Ligand-induced homodimerization of Gp130, a transmembrane receptor protein, or heterodimerization with  $\alpha$ -receptor subunits for IL-6 cytokine family members such as CT-1, LIF, or oncostatin M, causes tyrosine autophosphorylation and recruitment and activation of JAK1/2. Subsequently, two major intracellular signaling cascades are triggered: (1) Signal transducer and activator of transcription (STAT)-1/3 pathway, with STAT dimerization and translocation to the nucleus with activation of gene transcription. This pathway is opposed by induction of SOCS proteins, which bind to and prevent STAT translocation. (2) SH2-domain containing cytoplasmic protein phosphatase (SHP2)/MEK/Extracellular signal-regulated kinase (ERK) pathway. Additionally, Grb2 binding with Gab1/2 causes PI3K mediated Akt activation. These pathways signal to promote cardiomyocyte hypertrophy and survival.

apoptosis and rapid cardiomyopathic decompensation after induction of surgical pressure overload.<sup>125</sup> Gp130 activation is only transiently observed after pressure overload and the pathway is deactivated during the transition to failure.<sup>128</sup> A mechanism for the transition to failure in pressure overload stress-induced hypertrophy may be interruption of gp130-JAK-STAT signaling by stress-induced SOCS3 and resulting suppression of STAT3 signaling.<sup>129</sup> Accordingly, adenoviral-mediated transduction of SOCS3 prevents prohypertrophic and antiapoptotic signaling of cardiomyocyte gp130 receptors by inhibiting JAK2-STAT3/MEK1-ERK1/Akt activation. Signaling through gp130 also protects against viral myocarditis by accelerating viral clearance, whereas cardiomyocyte-specific gp130 gene ablation, or expression of the gp130 inhibitor, SOCS3, accelerates the myocarditis.<sup>130</sup>

#### Autophagy (see Chapter 6)

Autophagy (in Greek *auto* means “self” and *phagein* means “to eat”) is a normal cellular response to starvation and has been implicated in cell survival and cell death, depending upon the developmental stage, level of induction, and chronicity of the inciting stimulus.<sup>131</sup> Autophagic degradation of cellular proteins plays an important role in supplying the energy needs of newborns at birth, when a state of starvation occurs between separation from placental nutrients and not feeding. Accordingly, mice deficient in the important component of autophagy, ATG5, cannot upregulate the autophagic response and are prone to death during this period.<sup>132</sup>

Foci of degenerated cardiomyocytes with autophagic vacuoles are observed in human dilated cardiomyopathy and aortic stenosis.<sup>133</sup> Likewise, acute pressure overloading in mice causes rapid appearance of autophagic markers that persist during functional decompensation and the transition to dilated cardiomyopathy.<sup>134</sup> In this experimental model, induction of autophagy is clearly maladaptive because suppression of autophagy prevents ventricular remodeling and cardiomyopathic decompensation. However, the role of autophagy in hypertrophy development and decompensation is unclear at this time. Decreased autophagy is observed in pressure overloaded and catecholamine challenged myocardium,<sup>135</sup> but inhibition of autophagy that is induced in ischemic myocardium (a normal “starvation” response) increases cardiomyocyte death.<sup>136</sup> Autophagy increases with reperfusion, but autophagy inhibition protects against reperfusion injury.<sup>136</sup> Finally, inhibition of cardiomyocyte autophagy by conditional *ATG5* ablation early in mouse cardiac development does not affect normal developmental cardiac growth or pressure overload hypertrophy, but is associated with accelerated heart failure.<sup>137</sup> Available data suggest a multifaceted role for autophagy, which can be pathological, but may be necessary to prevent cardiomyopathic decompensation after cardiac injury or stress by eliminating misfolded or degraded proteins.

#### Necrosis (see Chapter 6)

The theme of capillary/myocardial mismatch as a causative factor in progression from hypertrophy to dilated cardiomyopathy has been advanced over the past few years as a general mechanism for decompensation of pathological hypertrophy. An adequate blood supply for growing myocardium is necessary for normal cardiac function. Accordingly, capillary density is closely coupled to myocardial growth during development.<sup>138</sup> Cardiac hypertrophy, on the other hand, is associated with decreased capillary density and coronary flow reserve, and increased diffusion distance to myocytes.<sup>139</sup> Capillary density is increased during the compensated phase of pathological hypertrophy, but decreases and is associated with cardiomyocyte “dropout” during decompensation.<sup>140</sup> GATA4-mediated regulation of angiogenic VEGF and angiotensin play an important role in hypertrophy-associated capillary/myocardial mismatch.<sup>39,83,141,142</sup>

### Catecholamine Cardiomyopathy: The Cardiomyocyte Contractility/Death Connection

Activation of the sympathetic nervous system in heart failure happens early after stress to maintain cardiac function (see Chapter 10). Persistent sympathetic activation, however, becomes progressively maladaptive over time. Catecholamines are toxic to cardiomyocytes in vitro and persistent activation of catecholamine signaling pathways causes cardiomyopathies associated with cardiomyocyte loss.<sup>143,144</sup> These are largely  $\beta_1$ -receptor-mediated effects, and can be blocked by pharmacological inhibition of the L-type calcium channel.

There are nine subtypes of adrenergic receptors (three each of  $\alpha_1$ ,  $\alpha_2$ , and  $\beta$ ), of which  $\beta_1$ -receptors are the most abundant in the myocardium.<sup>145</sup> Catecholamine signaling via cardiomyocyte  $\beta$ -adrenoreceptors increases myocardial contractility by stimulatory G protein (*Gas*)-mediated activation of adenylyl cyclase, resulting in cyclic AMP production that activates protein kinase A (Figure 2-5).  $\beta_2$ -adrenoreceptors couple to both *Gas* and the inhibitory G protein *Gai*, which can inhibit adenylyl cyclase and downregulate c-AMP levels. In normal myocardium, the  $\beta_1$ -receptors represent 70% to 80% of all the  $\beta$ -adrenoreceptors. In heart failure, preferential downregulation of  $\beta_1$ -receptors proportionately increases inhibitory *Gai* signaling.<sup>146</sup>

An important mechanism by which  $\beta_1$ -adrenoreceptor/*Gsa*/PKA signaling increases contractility is PKA-mediated phosphorylation of phospholamban (see Figure 2-5) (see Chapter 3). In its unphosphorylated state, phospholamban inhibits SERCA to decrease diastolic calcium uptake into the sarcoplasmic reticulum (SR). Phosphorylation of phospholamban relieves the inhibition of SERCA, resulting in increased SR calcium loading and larger systolic calcium transients, which augments contractility. PKA also phosphorylates L-type calcium channels to enhance calcium entry and ryanodine receptors to enhance calcium release.<sup>147</sup> The mechanism by which catecholamines are toxic to cardiomyocytes has been addressed by genetic manipulation of signaling receptors and effectors. Forced expression of low levels of  $\beta_2$  (60 times normal) enhances cardiac function and rescues genetic cardiomyopathy<sup>148-150</sup> without pathological consequences. However, forced expression of low levels of  $\beta_1$ - or high levels of  $\beta_2$ -adrenoreceptors caused a dilated and fibrotic cardiomyopathy.<sup>148,151</sup> Likewise, transgenic expression of the  $\beta_1$ -adrenoreceptor effector *Gsa* causes myocardial hypertrophy that progresses to an apoptotic and fibrotic cardiomyopathy.<sup>152</sup>

*Gas*-coupled  $\beta_1$ -receptors (but not the  $\beta_2$ -receptors) stimulate cell death via reactive oxygen species and activation of the JNK family of MAPKinases, leading to mitochondrial cytochrome *c* release and mitochondrial permeability transition pore formation.<sup>153</sup>  $\beta_1$ -adrenoreceptor signaling leads to increased SR calcium load via increased L-type calcium channel-mediated calcium influx and disinhibition of SERCA. There is increasing evidence that increased SR calcium levels may enhance contractility at the expense of increasing programmed cell death. The initial observation that intracellular calcium overload can trigger necrosis in cardiac myocytes was made more than 3 decades ago.<sup>154</sup> Intracellular calcium overload may trigger programmed cell death via opening of the mitochondrial permeability transition pore.<sup>155</sup> In transgenic mice with inducible cardiac expression of the  $\beta_2\alpha$  subunit of the L-type calcium channel, increased intracellular and SR calcium provoked widespread cardiomyocyte necrosis with cardiomyopathic decompensation,<sup>156</sup> which could be prevented by L-type calcium channel inhibition by transgene suppression, calcium channel blockade, or ablation of cyclophilin D, a critical component of the mitochondrial permeability transition pore.<sup>157</sup> Increased calcium influx via the L-type calcium channel in response to  $\beta_1$ -adrenergic stimulation also activates calcium/calmodulin kinase (CaMKII), which

**FIGURE 2-5**  $\beta$ -adrenoreceptor signaling in heart failure: Catecholamine binding to the seven transmembrane myocardial  $\beta_1$ -adrenoreceptors activates  $G_{\alpha s}$ , with displacement of bound GDP by GTP. This causes cyclic AMP generation via stimulation of adenylyl cyclase, which activates PKA. PKA phosphorylates the L-type calcium channel, enhancing  $Ca^{2+}$  entry, and phosphorylates RyR, enhancing calcium release from the SR, increasing intracellular calcium ( $Ca^{2+}(i)$ ) available for excitation contraction coupling. PKA phosphorylates phospholamban (PLB) de-repressing SERCA activity with enhanced SR  $Ca^{2+}$  reuptake; and phosphorylates troponin on the myofilaments, with the net effect of enhancing contractility. Termination of G protein signaling occurs with GTPase activity of  $G_{\alpha s}$ , causing GTP hydrolysis and cAMP degradation by phosphodiesterases (not shown). Additionally, activated  $\beta$ -adrenoreceptors are phosphorylated at their cytoplasmic tails by G-protein receptor kinases (GRK), causing receptor endocytosis. Increased  $Ca^{2+}(i)$  with chronic adrenoreceptor signaling causes necrotic cell death via calmodulin-mediated CaMK activation and mitochondrial permeability transition pore formation (MPTP) (see text).  $\beta_2$ -adrenoreceptor activation stimulates  $G_{\alpha i}$  with inhibition of adenylyl cyclase (not shown). A delayed phase of signaling downstream of the  $\beta_1$ -adrenoreceptor is activated by GRK-mediated recruitment of  $\beta$ -arrestin with transactivation of EGF with enhanced survival signaling (see text).

phosphorylates phospholamban, thereby inhibiting its activity further and increasing the SR calcium load, and causing cardiomyocyte apoptosis *in vitro*.<sup>158</sup> Inhibition of CaMKII by forced expression of a dominant negative peptide in the heart results in decreased SR calcium stores, which attenuates cardiomyocyte apoptosis<sup>159</sup> and protects against development of catecholamine-induced cardiomyopathy.<sup>160</sup>

$\beta_2$ -receptors can signal both via  $G_s$  and  $G_i$ , and at physiological levels, primarily mediate cell survival in the heart.<sup>161,162</sup>  $\beta_2$ -adrenoreceptor signaling switches from the stimulatory  $G_{\alpha s}$  pathway to the inhibitory  $G_{\alpha i}$  signaling upon phosphorylation of the receptor by PKA activation downstream of the  $G_{\alpha s}$  subunit.<sup>163</sup> This causes dissociation of the  $G\beta\gamma$  subunit from  $G_{\alpha i}$ , resulting in activation of the PI3K-Akt survival pathway. *In vitro* studies employing selective expression of each  $\beta$ -receptor in cardiac myocytes from mice with combinatorial deletion of both  $\beta_1$ - and  $\beta_2$ -receptors revealed a proapoptotic effect for  $\beta_1$ -signaling and an antiapoptotic PI3K-Akt mediated signaling cascade downstream of the  $\beta_2$ -receptor.<sup>162</sup> Indeed, the  $G_{\alpha i}$  pathway appears to protect against cell death after ischemic reperfusion injury *in vivo*.<sup>164</sup>

The application of insights from experimental mouse models to the human condition is supported by the clinical effects of single nucleotide polymorphisms in genes encoding adrenoreceptor signaling factors. Increased adrenergic signaling downstream of  $\beta_1$ -receptors in individuals carrying an activating polymorphism in the  $\beta_1$ -receptor ( $\beta_1$ Arg389), combined with an inhibitory polymorphism in the presynaptic  $\alpha_2c$  receptor ( $\alpha_2$ CDel322-325), increases the risk of heart failure.<sup>165</sup> Likewise, the gain-of-function polymorphism of the  $\beta_1$ -receptor may alter the response to  $\beta$ -blockers in heart failure.<sup>166</sup>

$\beta$ -adrenoreceptor signaling is downregulated in heart failure due to receptor phosphorylation by G-protein receptor kinases (GRK) (see Figure 2-5). GRK-phosphorylated receptors attract  $\beta$ -arrestins 1 and 2, which terminate the receptor  $G_{\alpha}$  subunit interaction. GRK2 (a.k.a.  $\beta$ -ARK), 5, and 6 are expressed in the myocardium. Forced cardiac expression of

GRK2 and GRK5 blunts the attenuated isoproterenol-mediated increase in contractility, whereas cardiac ablation or dominant negative inhibition enhances the contractile response, suggesting that GRK2 plays an essential role in modulating cardiac function.<sup>24,167</sup> The consequences of GRK2-mediated  $\beta_1$ -adrenoreceptor downregulation in heart failure are not entirely clear. Whereas a GRK2-dominant negative protein ( $\beta$ -ARKct) has improved some genetic and most physiological models of cardiomyopathy,<sup>168,169</sup> cardiac-specific ablation of GRK2 worsened catecholamine-mediated cardiomyopathy<sup>24</sup> but improved cardiac function after myocardial infarction.<sup>170</sup>

Human heart failure is characterized by sympathetic activation with increased circulating catecholamine levels associated with desensitization and downregulation of  $\beta$ -adrenoreceptors.<sup>146</sup>  $\beta_1$ -adrenoreceptors are markedly downregulated and both  $\beta_1$ - and  $\beta_2$ -adrenoreceptors are uncoupled, with elevated myocardial levels of GRK2.  $\beta$ -adrenergic blockers reverse these changes in heart failure and are associated with improved survival and reversal of adverse structural and functional remodeling parameters.<sup>171</sup>

A novel survival pathway may also be triggered downstream from  $\beta_1$ -adrenoreceptor signaling via *EGF receptor transactivation* (see Figure 2-5).  $\beta$ -arrestin coupled with GRK5 and 6 activates a nonreceptor tyrosine kinase, Src, which activates a membrane-bound metalloproteinase, leading to cleavage of a heparin-binding EGF ligand (see later discussion under growth factors) and EGF receptor activation that is protective against catecholamine-induced cardiomyopathy by enhancing survival signaling.<sup>172</sup> Indeed, interindividual differences in  $\beta$ -blocker efficacy may be due to different abilities to activate signaling through this alternate pathway (biased antagonism).<sup>173</sup> These studies are particularly intriguing in the context of genetic studies revealing that a gain-of-function polymorphism in GRK5 is protective in heart failure.<sup>174</sup> Whether the beneficial effects are due to enhanced  $\beta$ -adrenoreceptor desensitization or to increased EGF receptor transactivation is not known.

A major stimulus for hypertrophy after myocardial injury is increased load sensed by individual myocytes and surrounding myocardial fibroblasts. Attempts to isolate the biomechanical sensor of cellular load focused on mechanical deformation or “cell stretch.” Passively stretching cardiomyocytes cultured on deformable substrates provokes reactive hypertrophy with upregulation of early response and fetal genes.<sup>12</sup> One of the mechanisms by which stretch is transduced into a biochemical signal for hypertrophy is activation of integrins, a diverse family of cell surface receptors that link the extracellular milieu to intracellular signaling scaffolds called focal adhesion complexes.<sup>175</sup> Integrins consist of two subunits  $\alpha$  and  $\beta$  in various combinations, each with an extracellular domain to interact with extracellular matrix proteins, a transmembrane part that anchors them, and a short cytoplasmic tail (Figure 2-6). Integrin cytoplasmic tails interact with the cytoskeleton at the focal adhesion complex and serve as adaptors for multiple prohypertrophic signaling proteins (see Figure 2-6): (1) Focal adhesion kinase (FAK), a tyrosine kinase; (2) Srcs, a membrane-bound SH2 domain containing tyrosine kinase; (3) Grb2-associated binder (Gab) family proteins, which are scaffolding proteins that transduce signals downstream of growth factor and cytokine receptors; (4) integrin-linked kinase (ILK), a serine-threonine kinase; and (5) adaptor proteins, such as melusin and vinculin, that link integrins to the cytoskeleton at the focal adhesion complex.

Integrin signaling activated by pressure overload recruits c-Src and FAK leading to activation of ERK1/2 kinases with prohypertrophic signaling.<sup>176</sup> Cardiomyocyte-specific ablation of FAK prevents induction of ANF in response to transverse aortic constriction, without altering the late development of fibrosis and cardiomyopathy.<sup>177</sup> Inhibiting FAK with siRNA prevents and reverses pressure overload hypertrophy and preserves contractile function.<sup>178</sup> The  $\beta_1$  subunit of integrins

activates ILK, small GTPases, and prohypertrophic PI3K and ERK-MAPKinase pathways.<sup>179</sup> Forced expression of ILK causes compensated cardiac hypertrophy in mice, and dominant negative ILK prevents the hypertrophic response to angiotensin stimulation.<sup>179</sup> Cardiac-specific deletion of  $\beta_1$ -integrin or ILK causes spontaneous development of cardiomyopathy.<sup>180</sup>

Other proteins that interact with the cytoplasmic tail of integrins, such as melusin and vinculin, also appear to be essential for mechanotransduction. Ablation of melusin, a striated muscle-specific protein, prevents the myocardial hypertrophic response in response to pressure overload but not neurohormonal infusion, suggesting a specific role for melusin in integrin-mediated mechanotransduction.<sup>181</sup> Cardiac-specific ablation of vinculin, a ubiquitously expressed protein that connects the actin cytoskeleton to the cell membrane, causes progressive development of cardiomyopathy by 6 months of age in mice.<sup>182</sup> Indeed, the  $\beta_1$ -integrin vinculin interface may have a critical homeostatic role in cardiomyocytes as ablation of  $\beta_1$ -integrin causes cardiac defects and periimplantation mortality, and ablation of  $\beta_3$ -integrin causes spontaneous cardiac hypertrophy that was exacerbated with pressure overload.<sup>183</sup>

Another putative mechanical stretch sensor is at the Z-disk, wherein the small LIM-domain protein MLP (muscle LIM protein) is anchored and transduces stress stimuli via interaction with a complex of transducing proteins.<sup>184</sup> Titin, a giant sarcomeric protein component of the thin filament that anchors the Z-disk at one end and extends to the M line at the other, is another candidate, postulated to function as a molecular spring providing passive stiffness to the cell and acting as a biomechanical sensor.<sup>185</sup>

**Autocrine/Paracrine Effects of Neurohormones and Growth Factors.** Mechanical stretch can transduce hypertrophy via autocrine and paracrine release of neurohormones, and activation of respective seven-transmembrane spanning G protein-coupled receptors. Cardiomyocyte deformation induces autocrine secretion of angiotensin II, endothelin 1,

**FIGURE 2-6** Integrin-mediated transduction of biomechanical stress: Integrins are heterodimeric proteins formed by the association of various combinations of single-transmembrane  $\alpha$  and  $\beta$  subunits, which are attached to the extracellular matrix proteins such as laminin and fibronectin. Biomechanical stress induces change in conformation and integrin clustering, resulting in assembly of the focal adhesion complex consisting of the kinases FAK, Src, and ILK, along with adaptor proteins vinculin, paxillin, talin,  $\alpha$ -actinin, and melusin that connect the integrins to the cytoskeletal elements (actin). Stretch-mediated phosphorylation and activation of FAK and ILK causes MAPK (ERK) activation and Akt activation via the SHP2/PI3K pathway, resulting in hypertrophic signaling. Additionally FAK activates small G proteins Rac and Rho (see later discussion), which transduce cytoskeletal reorganization in hypertrophy. Integrin signaling also activates Ras via Shc/Grb2/Gab1/2-mediated Src kinase activation, which transduces hypertrophy signaling via MAPK (ERK) activation.

and peptide growth factors such as FGF.<sup>186</sup> Integrins can also transduce hypertrophic stimuli in part via upregulation of angiotensin II.<sup>187</sup> Interestingly, angiotensin may not be essential for hypertrophy transduced by stretch-induced activation of AT<sub>1</sub>R.<sup>188</sup> Paracrine release of neurohormones, growth factors, and cytokines by nonmyocytes in the mechanically overloaded heart also leads to cardiac fibroblast proliferation,<sup>189</sup> acting as an amplification loop to increase neurohormonal effects on cardiomyocytes. Evidence for simultaneous involvement of multiple growth factors in stretch-induced hypertrophy is consistent with the notion that signaling pathways converge through various neurohormonal receptors.<sup>186</sup>

### Neurohormonal Activation of Hypertrophy Signaling

Norepinephrine, angiotensin II, and endothelin signal via heptahelical transmembrane receptors coupled to the Gq heterotrimeric G protein. G proteins consist of three polypeptide chains— $\alpha$ ,  $\beta$ , and  $\gamma$  (Figure 2-7). The  $\alpha$ -subunits are primarily responsible for determining activation of downstream signaling effectors and are organized into four groups: G $\alpha$ s, G $\alpha$ i, G $\alpha$ q, and G $\alpha$ 12. Inactive G $\alpha$  subunits bind to GDP (guanosine diphosphate) and G $\beta\gamma$  subunits. Upon recruitment to a ligand occupied transmembrane receptor, GTP is exchanged for GDP, resulting in dissociation of the G $\alpha$ -GTP subunit from the  $\beta\gamma$  subunit and activation of downstream signaling cascades. Hydrolysis of GTP by intrinsic GTPase activity (that is augmented by regulators of G protein signaling (RGS) proteins) terminates the signal. G $\alpha$ q-coupled receptors activate phospholipase C, which catalyzes the hydrolysis of phosphatidylinositol 4,5 bisphosphate (PIP<sub>2</sub>) into inositol 1,4,5 triphosphate (IP<sub>3</sub>) and diacylglycerol (DAG). DAG activates the PKC family of growth-stimulating serine-threonine kinases (see Figure 2-7) and IP<sub>3</sub> causes intracellular Ca<sup>2+</sup> release that can activate signaling through calcium-dependent PKCs, calcium-calmodulin dependent kinases (CaMKs), and calcineurin. Another arm of signaling is initiated by the free G $\beta\gamma$

subunits, which recruit PI3K $\gamma$  to the sarcolemma and facilitate interaction with phosphoinositides. This PI3K signaling differs from the activation of the PI3K $\alpha$  isoform in adaptive hypertrophic signaling, which was discussed earlier.

Heart failure causes systemic and myocardial release of catecholamines, leading to G $\alpha$ q activation via  $\alpha_1$ -adrenergic receptors. There are three receptor subtypes:  $\alpha_1$ A/C,  $\alpha_1$ B, and  $\alpha_1$ D, the first two of which are implicated in transducing catecholamine-induced hypertrophy signaling in the heart. In the adult human myocardium, the  $\alpha_1$ A receptor subtype predominates over  $\alpha_1$ B. Norepinephrine and phenylephrine treatment of cardiomyocytes stimulates hypertrophy in vitro with reactivation of the fetal gene program, increased cardiomyocyte size, and protein synthesis.<sup>9</sup> Forced cardiac expression of  $\alpha_1$ B receptors provokes a cardiomyopathy and downregulated  $\beta$ -receptor signaling, but forced expression of  $\alpha_1$ A receptors enhances systolic function without stimulating hypertrophy.<sup>190</sup> Gene ablation of  $\alpha_1$ A/C or  $\alpha_1$ B receptors suggests a role in blood pressure modulation without an effect on cardiac hypertrophy. Combinatorial deletion of both subtypes revealed a modest effect of  $\alpha_1$ -receptor signaling in normal cardiac growth because the double knockout hearts were approximately 13% smaller than wild types.<sup>191</sup> In response to pressure overload, double  $\alpha_1$ -receptor knockout mice developed a cardiomyopathy, with decreased survival, increased cell death, and markedly decreased upregulation of “fetal genes,”<sup>192</sup> likely related to the absence of prosurvival ERK signaling transduced by these receptors.<sup>193</sup> These results indicate that  $\alpha_1$ -receptors signal in normal cardiac growth and cardiomyocyte survival in response to stress and are redundant in the transduction of pressure overload hypertrophy.

Angiotensin II (Ang II), a powerful vasoconstrictor, is a potent inducer of cardiac growth via the AT<sub>1</sub> and AT<sub>2</sub> receptors. There are two AT<sub>1</sub>R subtypes: AT<sub>1a</sub>R and AT<sub>1b</sub>R, which are both coupled to G $\alpha$ q signaling. Forced cardiac expression of AT<sub>1a</sub>R causes cardiac hypertrophy progressing to adverse

**FIGURE 2-7** Neurohormonal signaling via G $\alpha$ q in pathological myocardial hypertrophy. Binding of neurohormones to the cognate neurohormonal receptor causes GTP exchange and activation of the G $\alpha$ q subunit, with dissociation from the G $\beta\gamma$  subunits and recruitment of PLC $\beta$  to the cell membrane. PLC $\beta$  causes hydrolysis of PIP<sub>2</sub> with generation of IP<sub>3</sub> and DAG. IP<sub>3</sub> binds to IP<sub>3</sub> receptors (IP<sub>3</sub>R) on the sarcoplasmic/endoplasmic reticulum causing Ca<sup>2+</sup> release, which causes PKC activation along with DAG for classical PKCs ( $\alpha$  and  $\beta$ ). Novel PKCs ( $\delta$  and  $\epsilon$ ) are activated by DAG alone. See text for details of PKC signaling in heart failure. Classical PKCs activate PKD, which phosphorylates class II HDACs (5 and 9) resulting in export from the nucleus and de-repression of hypertrophy gene transcription.

remodeling and dysfunction<sup>194</sup> and mice lacking AT<sub>1a</sub>R demonstrate attenuated myocardial hypertrophy in response to pressure overload with preserved systolic function.<sup>195</sup> Angiotensin receptor antagonism attenuates hypertrophy in vitro and when given therapeutically to humans with heart failure.<sup>196</sup> However, in vivo, there is no critical requirement for AT<sub>1</sub>R signaling in transducing pressure overload hypertrophy, likely due to angiotensin signaling via AT<sub>1b</sub>R (which is not present in humans) or redundancy in signaling with other neurohormones.<sup>197</sup>

Endothelin-1 (ET-1) is a 21-amino acid polypeptide cleaved from a larger precursor by endothelin converting enzyme. ET-1 is predominantly produced by endothelial cells, although cardiomyocytes and fibroblasts also produce small amounts. ET-1 signals via the ET<sub>1A</sub> and ET<sub>1B</sub> receptors, which are both coupled to G $\alpha$ . ET-1 appears to be a part of the autoregulatory loop with Ang II because ET-1 is produced in response to Ang II stimulation, and the ET-1 receptor blockade antagonizes Ang II-mediated hypertrophy.<sup>198</sup> Endothelin receptor blockade delays, but does not prevent, development of hypertrophy and pathological decompensation in response to pressure overload.<sup>199</sup> Cardiomyocyte-specific deletion of ET-1<sub>A</sub> did not prevent hypertrophy due to Ang II and phenylephrine infusion in vivo,<sup>200</sup> implying that ET-1-induced signaling is redundant in transducing pathological hypertrophy.

**Gq/Phospholipase/Protein Kinase C.** Redundancy in signal transduction at the receptor level in transduction of pathological hypertrophy signals led researchers to look for nodal signaling points that could be inhibited to prevent pathological hypertrophy.<sup>201</sup> The heterotrimeric G proteins, G $\alpha$ q and G $\alpha$ <sub>11</sub>, transduce signals from angiotensin, endothelin, norepinephrine, and other neurohormones.<sup>145</sup> G $\alpha$ q/G $\alpha$ <sub>11</sub> signaling is essential in embryonic cardiac growth because combined ablation of G $\alpha$ q (*gnaq*) and G $\alpha$ <sub>11</sub> (*gna11*) causes embryonic lethality at day 11 with cardiac hypoplasia and failure of ventricular septation.<sup>202</sup> In vivo, unabated G $\alpha$ q signaling by forced cardiac expression was the first nodal signaling molecule shown to recapitulate pathological hypertrophy.<sup>7</sup> Superimposed pressure overload or the hemodynamic stress of pregnancy provokes rapid cardiomyopathic decompensation caused by widespread cardiomyocyte apoptosis.<sup>203,204</sup> Indeed, dominant negative inhibition of G $\alpha$ q,<sup>205</sup> inhibition of G $\alpha$ q signaling by forced expression of inhibitory RGS4,<sup>206</sup> or combined cardiomyocyte-specific ablation of G $\alpha$ q and G $\alpha$ <sub>11</sub>, all prevent pressure overload hypertrophy, establishing a critical role for neurohormonal activation of G $\alpha$ q in transducing the pressure overload stimulus.<sup>207</sup> Polymorphisms in the *gnaq* (G $\alpha$ q) gene promoter that affect G $\alpha$ q expression have been associated with changes in human hypertrophy and heart failure. A common single base pair change from GC to TT at position -694/-695 in the *gnaq* gene promoter eliminates SP-1 transcription factor binding<sup>208,209</sup> and increases G $\alpha$ q promoter activity, which is associated with increased prevalence of left ventricular hypertrophy in normal subjects<sup>209</sup> and increased mortality in African American patients with heart failure.<sup>208</sup>

Phospholipase C $\beta$  (PLC $\beta$ ) is the downstream effector of G $\alpha$ q (see Figure 2-7). Of the four isoforms, PLC $\beta$ <sub>1</sub> and  $\beta$ <sub>3</sub> are expressed in the heart. An essential role for either of these isoforms has not been evaluated for pathological cardiac hypertrophy signaling because the PLC $\beta$ <sub>1</sub> knockout mice develop epilepsy and increased mortality beginning at 3 weeks of age,<sup>210</sup> and PLC $\beta$ <sub>3</sub> knockout mice demonstrate a normal life span with abnormalities in neutrophil chemotaxis and skin ulcers, but no apparent abnormalities in cardiac development.<sup>211</sup> PLC $\epsilon$  is another cardiac expressed phospholipase, levels of which are increased in human dilated cardiomyopathy and in response to experimental isoproterenol treatment or pressure overload.<sup>212</sup> PLC $\epsilon$  is downstream of Ras and regulates  $\beta$ -adrenergic responsiveness in cardiomyopathy. Germline ablation of PLC $\epsilon$  is associated with reduced

ventricular systolic function and diminished  $\beta$ -adrenergic responsiveness and exaggerated hypertrophy and cardiomyopathic decompensation in response to isoproterenol.<sup>212</sup>

Protein kinase C (PKC) is downstream of G $\alpha$ q/PLC $\beta$  and has emerged as a key mediator of altered myocardial contractility and cardiomyocyte survival in pathological hypertrophy (see Figure 2-7). The heart expresses four functionally important PKC isoforms: PKC  $\alpha$  and  $\beta$  ("conventional group," activated by DAG with a requirement for Ca<sup>2+</sup>) and PKC  $\delta$  and  $\epsilon$  ("novel" PKCs, activated by DAG without a requirement for Ca<sup>2+</sup>).<sup>201</sup> PKCs translocate to specific subcellular locations upon activation: PKC $\alpha$  to the membrane from the cytosol, PKC $\beta$  from the cytoplasm to the nucleus, PKC $\epsilon$  from the cytoplasm and nucleus to the myofibrils, and PKC $\delta$  redistributes to the mitochondria and to a perinuclear location.

PKC $\alpha$  is upregulated in rodent pressure overload hypertrophy<sup>7,213</sup> and human heart failure.<sup>214</sup> Treatment of neonatal rat ventricular myocytes with phorbol ester, a nonspecific activator of PKC signaling, causes hypertrophy resembling that of PE and Ang II. Because PKC activation requires translocation to the membrane and binding to specific anchoring proteins (RACKs), studies have interrogated specific PKC effects by transgenic expression of peptides that either facilitate or inhibit PKC translocation, conventional overexpression, or gene ablation. PKC $\alpha$  activation negatively regulates myocardial contractility but not hypertrophy.<sup>215,216</sup> Indeed, inhibition of PKC $\alpha$  prevents contractile dysfunction in pathological hypertrophy.<sup>215,217</sup> PKC $\beta$  overexpression is sufficient to cause myocardial hypertrophy,<sup>218</sup> but it is not necessary since pressure overload hypertrophy is unaltered in PKC $\beta$  knockout mice.<sup>219</sup> PKC $\delta$  appears to be a critical modifier of cell death in response to ischemic injury, without affecting myocardial hypertrophy,<sup>220</sup> whereas PKC $\epsilon$  is both activated in, and sufficient to cause, hypertrophy.<sup>203,221</sup> An additional clue to the adaptive nature of PKC $\epsilon$ -mediated hypertrophy comes from its ability to reduce G $\alpha$ q-mediated pathological hypertrophy and decompensation when activated, and markedly worsen G $\alpha$ q-mediated cardiomyopathic decompensation when inhibited.<sup>222</sup>

Ca<sup>2+</sup>-dependent, nonconventional PKCs also activate protein kinase D (PKD). Protein kinase D directly phosphorylates class II HDACs (histone deacetylases; see Figure 2-7) resulting in their export from the nucleus and de-repression of transcription. Constitutively active PKD1 causes hypertrophy progressing to cardiomyopathy and siRNA-mediated knockdown of PKD1 prevents hypertrophic cardiomyocyte growth by agonists that signal via G $\alpha$ q and Rho GTPase.<sup>223</sup> Cardiomyocyte-specific deletion of PKD1 renders the myocardium insensitive to pressure overload, angiotensin II, and isoproterenol treatment, with preserved cardiac function and prevention of remodeling,<sup>224</sup> secondary to their role in phosphorylating class II HDACs.

### Mitogen Activated Protein Kinases (MAPKs)

Activated G protein-coupled receptors activate mitogen activated protein kinases (MAPKs) via the free G $\beta\gamma$  subunits, either directly or indirectly through cross talk with small Raslike G proteins (Figure 2-8). Multiple other signaling pathways such as receptor tyrosine kinases, receptor serine/threonine kinases (transforming growth factor  $\beta$  [TGF- $\beta$ ]), Janus-activated kinases (JAKs via cardiotrophin-1 [gp130 receptor]), and stress stimuli, such as stretch, also activate mitogen-activated protein kinases (MAPKs) in the heart.<sup>225</sup> MAPK pathways are activated in a cascade manner (see Figure 2-8). There are three major groups of MAPKs: extracellular signal regulated kinases (ERK), JNKs, and p38. Specific MAPKKs activate each MAPK: MAPK1/2 for ERK1/2, MAPK3/6 for p38, and MAPK4/7 for JNK. At the next tier, each MAPKKK can activate different MAPKK-MAPK pathways, providing a mechanism for integration of upstream signaling.

**FIGURE 2-8** Activation of MAPK signaling in pathological hypertrophy. Activated Gαq protein activates small G proteins such as Ras either directly via the released Gβγ subunits or via cross-talk with receptor tyrosine kinases (RTKs), which are activated by growth factors such as EGF, neuregulin, FGF, and IGF-1 (see discussion in text). This leads to stimulation of the mitogen-activated protein kinase (MAPK) signaling cascades. MAPKs are also activated by integrin signaling and TGF receptor-mediated activation of TAK1. MAPK cascades are organized into three tiers: MAPKinase kinase kinases (MAPKKKs) that activate MAPKinase kinases (MAPKKs), which subsequently activate MAPKs. MAPKs signal redundantly via multiple transcription factors (see details in text). Gβγ subunits of the Gαq signaling complex also activate PI3Kγ, resulting in Akt activation and hypertrophy signaling.

The top tier of MAPK pathway consists of the MAPKKKs (see Figure 2-8). One such MAPKKK is Mst1, forced expression of which causes an apoptotic cardiomyopathy.<sup>226</sup> Subsequent stepwise activation of kinases (see Figure 2-8) serially culminates in the activation of the effector kinases. ERK1/2 are activated via Gαq-coupled agonists in response to hypertrophic agonists *in vitro* as Ang II, PE, ET-1, and stretch and *in vivo* by pressure overload.<sup>227</sup> Gαq signaling in response to pressure overload is essential for ERK activation because expression of a truncated Gαq peptide blocks aortic banding-induced ERK activation.<sup>227</sup>

Available evidence suggests a role for the ERK signaling axis in promoting hypertrophy, and p38 and JNK in regulating cell survival and fibrosis. Forced expression of MEK1-ERK1 causes concentric hypertrophy via activation of the calcineurin-NFAT pathway<sup>228</sup> without adverse ventricular remodeling. A critical role for this pathway in hypertrophic signaling is not established because gene ablation either causes no cardiac defects (*Erk1*<sup>-/-</sup>);<sup>229</sup> or has not yet been pursued in a conditional cardiac-specific manner (*Erk2*<sup>-/-</sup> mice are embryonic lethal with lack of trophoblast development).<sup>230</sup> ERK 5 is related to ERK1/2 with a similar activation motif, and is activated in the heart in response to gp130 signaling (by LIF or cardiotrophin 1). Similar to ERK1/2, forced cardiac expression of MEK5 (activator of ERK5, a.k.a. big ERK) causes eccentric cardiac hypertrophy associated with the addition of sarcomeres in series within individual cardiomyocytes,<sup>231</sup> and gene ablation of ERK5 affects embryonic survival.<sup>232</sup>

MAPKs phosphorylate multiple substrates, including enzymes and transcription factors with overlapping specificity that regulate cardiac gene expression (“immediate early response” factors), cell survival, mRNA translation (eIF4E), and mRNA stability.<sup>225</sup> Specificity for downstream substrates is primarily determined via docking interactions. For example, p90RSKs are phosphorylated primarily by ERK1/2, whereas MAPKAPK2 is phosphorylated by p38-MAPK; and Msk1/2 may be phosphorylated by either ERK1/2 or p38-MAPK. Transcription factors activated by MAPKs are nuclear localized, which suggests that MAPKs or downstream kinases translocate into the nucleus to influence gene expression. The differential effects of MAPK signaling on hypertrophy

and/or survival responses may also be related to the timing and duration of the signal and integration with other signaling cascades that crosstalk with MAPK signaling.

p38 and JNK kinases were originally discovered as “stress-responsive kinases” due to their rapid activation in response to stressful stimuli. Of the four genes encoding for p38, p38α is the most abundant in the heart, with minimal p38β detected. p38 and JNK transduce their signals by activating transcription factors c-jun, ATF2, ATF6, Elk-1, p53, and NFAT4. Activation of p38 signaling by forced expression of MKK3 and MKK6 causes early cardiac failure with ventricular fibrosis, whereas forced expression of dominant negative proteins (MKK3, MKK6, p38α, or p38β) and *p38α* gene ablation reveal an antihypertrophic role for p38 in cardiomyocytes.<sup>233</sup> This antihypertrophic effect appears to be mediated via suppression of Akt and calcineurin-NFAT signaling. The effects of p38 activation on cardiomyocyte survival are unclear because nonspecific pharmacological inhibition of p38 inhibits pressure overload and ischemia-reperfusion-induced apoptotic cell death, whereas p38α ablation protects against pressure-overload-induced cardiomyocyte apoptosis.<sup>233</sup> Similarly, JNK signaling (c-Jun N-terminal kinases) appears to be antihypertrophic because mice with either dominant negative inhibition or combined ablation of *JNK1* and 2 show basal and pressure-overload-induced hypertrophy with de-repressed calcineurin-NFAT signaling.<sup>234</sup> Pharmacological inhibition of JNK1 attenuates ischemia-reperfusion-induced cardiomyocyte apoptosis, whereas combinatorial ablation *JNK1,2*, and 3 increases cardiomyocyte apoptosis in response to pressure overload and ischemic reperfusion injury.<sup>233</sup>

Ask-1 is a MAPKKinase, which is upregulated in the myocardium by angiotensin stimulation via AT1R-induced oxidative stress and NF κB activation. *Ask-1* ablation attenuates cardiomyocyte apoptosis and cardiomyopathic decompensation induced by angiotensin infusion<sup>235</sup> in response to pressure overload and coronary artery ligation without an effect on hypertrophy.<sup>236</sup>

**IP<sub>3</sub>-induced Ca<sup>2+</sup>-mediated Signaling.** Gαq signaling causes IP<sub>3</sub> production, which interacts with IP<sub>3</sub> receptors to cause intracellular release of Ca<sup>2+</sup> (see Figures 2-7 and 2-9). In cardiac myocytes, IP<sub>3</sub>-induced Ca<sup>2+</sup> fluxes are localized

**FIGURE 2-9** Neurohormonal activation of calcineurin and CaMK signaling. Gq/G<sub>11</sub>-mediated production of IP<sub>3</sub> via PLCβ causes release of intracellular Ca<sup>2+</sup> via the IP<sub>3</sub>R, leading to activation of the protein phosphatase calcineurin. Calcineurin dephosphorylates NFAT transcription factor, resulting in its nuclear translocation and activation of hypertrophy gene transcription. MCIPs are endogenous inhibitors of calcineurin activity. The increased cytoplasmic calcium concentration (Ca<sup>2+</sup> (i)) also causes activation of CaMKs via interaction with calmodulin. CaMKs phosphorylate class II HDACs, resulting in HDAC translocation out of the nucleus and binding to 14-3-3 protein in the cytoplasm. This allows histone acetylation by HAT p300, de-repressing hypertrophic gene transcription mediated by transcription factors such as MEF2 and CAMTA.

to microdomains, in effect compartmentalizing the Ca<sup>2+</sup>-induced signaling and segregating the signaling effects of local Ca<sup>2+</sup> from the global calcium of excitation–contraction coupling. For example, β<sub>2</sub>-adrenergic receptors are associated with caveolin-3 protein within caveolar microdomains on cardiomyocytes, and this allows for the regulation of L-type calcium channel activity with β<sub>2</sub>-dependent activation, which is prevented by disruption of the caveolar architecture.<sup>237</sup> Other examples of spatially localized IP<sub>3</sub>-induced Ca<sup>2+</sup> release affecting signaling are calsarcin-mediated regulation of Ca<sup>2+</sup>-induced activation of prohypertrophic phosphatase calcineurin at the Z-disk and perinuclear CaMK signaling to influence gene transcription via export of HDACs.<sup>238</sup>

### Calcineurin

IP<sub>3</sub>-mediated release of intracellular calcium activates calcineurin and calcium/calmodulin-dependent kinase (CaMK) pathways that regulate cardiac growth (Figure 2-9).<sup>30</sup> Calcineurin (Cn), a serine-threonine phosphatase also known as protein phosphatase (PP2B), is stimulated by Ca<sup>2+</sup> binding to calmodulin and dephosphorylates the transcription factor Nuclear Factor of Activated T cells (NFAT) at the N-terminal serine residue, allowing its translocation to the nucleus. The functional calcineurin protein is a dimer consisting of two subunits A and B, and is encoded by five genes (CnA by α, β, and γ and CnB by CnB1 and B2), of which the mammalian heart expresses CnAα, CnAβ, and CnB1. In vitro stimulation of cardiomyocytes with hypertrophic stimuli activates calcineurin<sup>239</sup> and calcineurin activity is increased in human compensated hypertrophy and heart failure.<sup>240</sup> Calcineurin activity is also increased in animal models of pressure-overload-induced and exercise-induced cardiac hypertrophy. Forced expression of calcineurin causes myocardial hypertrophy that progresses to heart failure<sup>239</sup> without inducing cardiomyocyte apoptosis.<sup>241</sup> Studies with pharmacological inhibition of calcineurin activity with FK506 and

cyclosporine have suggested that calcineurin transduces pathological hypertrophy signaling in response to PE, Ang II, and ET-1 in vitro, and pressure-overload hypertrophy in vivo (reviewed in Heineke et al<sup>30,242</sup>). Forced expression of dominant negative calcineurin<sup>243</sup> and gene ablation of CnAβ decrease cardiomyocyte hypertrophy in response to pressure-overload stimulus and neurohormones.

Calcineurin is localized at the Z-disk in a complex with calsarcins. Ablation of calsarcin-1 increases calcineurin signaling in pressure overload, resulting in rapid progression to heart failure.<sup>244</sup> Ablation of NFATc1<sup>245</sup> and Nfatc2/c3/c4<sup>246</sup> causes cardiac defects. Forced cardiac expression of constitutively active NFATc4 causes massive cardiac hypertrophy.<sup>239</sup> Ablation of NFATc2 and NFATc3 attenuate pathological hypertrophy by transgenic calcineurin and protect against pressure-overload- and angiotensin-induced hypertrophy without affecting the development of exercise-induced adaptive hypertrophy.<sup>247,248</sup>

Calcineurin signaling is restrained by modulatory calcineurin inhibitory proteins (MCIP) (see Figure 2-9),<sup>249</sup> which bind to calcineurin and inhibit its activity. *MCIP1* gene transcription is activated in the heart by calcineurin-mediated NFAT activation, providing a negative feedback loop for calcineurin signaling, whereas *MCIP2* expression is induced by thyroid hormone signaling.<sup>250</sup> Forced expression of *MCIP1* reduces unstressed heart weight (by 5% to 10%), attenuates calcineurin and swimming-induced hypertrophy, and prevents ventricular remodeling after pressure overload. *MCIP1* overexpression likewise attenuates development of pathological hypertrophy, ventricular remodeling, and cardiomyopathic decompensation after myocardial infarction, suggesting a beneficial effect of preventing pathological hypertrophy in the surviving myocardium.<sup>251</sup> Thus *MCIP1* appears to be anti-hypertrophic in many forms of cardiac growth.

*MCIP1* gene ablation does not result in cardiac abnormalities, indicating that *MCIP1* does not regulate cardiac

developmental growth.<sup>252</sup> However, *MCIP1* ablation sensitizes the heart to calcineurin signaling, resulting in accelerated heart failure in calcineurin transgenic mice, but paradoxically reduces hypertrophy in response to pressure overload and isoproterenol.<sup>252</sup> Indeed, a recent study suggested that MCIPs can act as facilitators of calcineurin activity, thereby having dual functions in hypertrophy signaling.<sup>253</sup>

### Calmodulin-dependent Protein Kinase (CaMK)

Increased cytosolic  $\text{Ca}^{2+}$  activates CaMKs, a family of regulatory enzymes that phosphorylate multiple proteins that modulate myocardial contractility,<sup>254</sup> hypertrophy, and survival signaling (see Figure 2-9). All four CaMKs, I-IV, activate MEF2-mediated transcription of fetal genes<sup>255</sup> that causes cardiomyocyte hypertrophy. Forced cardiac expression of CaMKIV causes eccentric hypertrophy with contractile impairment,<sup>255</sup> but CaMKIV knockout mice develop pressure overload hypertrophy, suggesting that other CaMK isoforms primarily transduce pathological hypertrophy.<sup>256</sup> Indeed, CaMKII is the predominant cardiac isoform<sup>254</sup> and forced expression of CaMKII $\delta$ b (nuclear isoform) or CaMKII $\delta$ c (cytosolic isoform) in cardiomyocytes causes pathological hypertrophy.<sup>257,258</sup> Expression of dominant negative CaMKII $\delta$ b blocks PE-induced cardiomyocyte hypertrophy and pathological gene expression in vitro.<sup>259</sup>

### HAT/HDAC-mediated Transcriptional Regulation via MEF2/CAMTA

CaMKII $\delta$  isoforms bind to and phosphorylate HDAC4, a class II histone deacetylase. The process of histone acetylation-deacetylation controls access of transcription factors, such as MEF2 and CAMTA to the chromatin machinery. Histones are nuclear proteins that constitute the nucleosome, a compact structure of chromatin genomic DNA tightly coiled around histone octamers that prevents access of transcription factors to DNA and represses gene expression. Histone acetyltransferases (HATs) acetylate conserved lysine residues in histone tails, which neutralizes the positive charge, and destabilizes histone-histone and histone-DNA interactions. Thus HATs stimulate gene expression. In contrast, histone deacetylases (HDACs) counter this effect, which promotes chromatin condensation and represses transcription (see Figure 2-9).

HATs belong to five families, and p300 and CREB binding protein (CBP) are the most abundant HAT family members in the cardiac muscle.<sup>260</sup> The HAT activity of p300 appears to play a critical role in cardiac development because targeted gene ablation is lethal between embryonic day 9.5 and 11.5, with failure to develop cardiac trabeculation and upregulate muscle-specific genes such as  $\beta$ MHC and  $\alpha$ -actinin.<sup>261</sup> P300 binds to and acts as a transcriptional coactivator of GATA4, MEF2, and SRF. Activation of p300 and CBP by ERK phosphorylation is required for expression of ANF and  $\beta$ MHC.<sup>262</sup> Forced cardiac expression of these proteins stimulates hypertrophic signaling by facilitating GATA4 acetylation<sup>262</sup> and causes adverse remodeling after myocardial infarction.<sup>263</sup> Dominant negative p300 prevents acetylation and coactivation of GATA-4, which is associated with development of cardiomyopathy.<sup>262</sup> Inhibition of p300 HAT activity by curcumin (a polyphenol abundant in the spice, turmeric) prevents hypertrophy and cardiomyopathic decompensation and regresses established pressure overload.<sup>264</sup>

The HDACs are classified into three categories based on the homology with the yeast HDACs. Class I HDACs primarily consist of a catalytic domain, whereas class II HDACs have phosphorylation sites that serve as targets for signaling pathways, and interact with transcription factors. Class III HDACs require NAD for activity. Class I HDACs (HDAC 1 and 2) stimulate cardiac growth. Forced cardiac expression of HDAC2 causes hypertrophy and HDAC2 null mice are resistant to hypertrophic stimuli.<sup>265</sup> Resistance to hypertrophy in HDAC2 knockout mice is associated with increased expression of the gene encoding for inositol polyphosphate-5-phosphatase f

(Inpp5f), which activates the antihypertrophic kinase GSK3 $\beta$  (see later discussion).

In contrast to class I HDACs, class II HDACs (HDAC4, HDAC5, HDAC7, and HDAC9) inhibit cardiac growth. Forced expression of HDAC5 and HDAC9 prevents hypertrophy in vitro in response to PE and serum, whereas *HDAC5* and *HDAC9* knockout hearts develop spontaneous cardiac hypertrophy<sup>266</sup> and exaggerated hypertrophy in response to pressure overload.<sup>267</sup> In contrast, their response to swimming-induced hypertrophy is not altered, suggesting these HDACs suppress only pathological hypertrophy. Class II HDACs are commonly associated with the MEF2 proteins in the nucleoplasm. MEF2 (myocyte enhancer factor 2) family transcription factors are essential for myogenesis and cardiac development. There are four MEF2 isoforms that bind DNA through a MADS DNA binding domain found on promoters of many cardiac expressed genes as SERCA, aMHC, and MLC2v. MEF2A and MEF2D are the predominant cardiac-expressed transcripts that regulate stress-induced gene expression.<sup>268</sup> MEF2 activity is restrained by binding to class II histone deacetylases (HDAC4, 5, and 7), and this repression is relieved by phosphorylation of HDACs by CaMKs, which induced HDAC nuclear export (see Figure 2-9),<sup>269</sup> and allows p300 to associate with MEF2, promoting gene transcription. By this mechanism, multiple hypertrophy signaling pathways (MAPKs, calcineurin, CaMKII, and protein kinase D) converge on MEF2 activation by class II HDAC export and relieve the transcriptional repression (see Figures 2-1, 2-7, and 2-9). *MEF2D* ablation prevents hypertrophy, ventricular remodeling, and gene dysregulation in response to pressure overload.<sup>270</sup>

Pharmacological inhibition of histone deacetylases inhibits hypertrophy.<sup>271</sup> Treatment of aortic-banded mice subjected with Trichostatin A and Scriptaid (two broad spectrum HDAC inhibitors), or SK7041 (a specific class I HDAC inhibitor),<sup>272</sup> improves survival and myocardial and cardiomyocyte hypertrophy and preserves systolic function. HDAC inhibition also regresses established cardiac hypertrophy and prevents cardiomyocyte apoptosis and myocardial fibrosis in pressure-overloaded animals, accompanied by reversion to the adult myosin gene expression pattern ( $\alpha$ MHC predominant).

Class III HDACs, such as the Sir2 family, regulate life span.<sup>273</sup> Deacetylation by class III HDACs requires NAD<sup>+</sup> and produces 2'-O-acetyl-ADP-ribose (O-AADPR) and nicotinamide. Sirt1 is one of the seven Sir2 kinases or Sirtuins, and can be activated pharmacologically by resveratrol (a component of red wine, consumption of which is associated with cardiovascular benefits). Forced expression of moderate levels of Sirt1 in the heart decreases aging-associated hypertrophy, fibrosis, and diastolic function, associated with reduced oxidative stress,<sup>274</sup> in contrast to higher levels of forced expression, which cause cardiomyopathy.

CaMK signaling also activate calmodulin binding transcription activator (CAMTA) transcription factors. CAMTA2 was discovered as an essential coactivator with Nkx2.5 of ANF gene transcription in cardiomyocytes. CAMTA2 activity is normally repressed by interaction with a class II HDAC (HDAC5). G $\alpha$ q-mediated activation of PKC $\epsilon$  and PKD phosphorylates HDAC5 resulting in export from the nucleus, de-repression of CAMTA2,<sup>275</sup> and activation of hypertrophic signaling. Forced expression of CAMTA2 provokes myocardial hypertrophy, which is enhanced by *HDAC5* gene ablation. *CAMTA2* knockout mice exhibit attenuated hypertrophic response to pressure overload, angiotension, and phenylephrine.<sup>276</sup>

### Cross Talk Between G $\alpha$ q and PI3K/Akt Hypertrophy Signaling Pathways

G $\alpha$ q/phospholipase C pathways cross talk with PI3K/Akt signaling axis in transducing pathological hypertrophy signals. G $\alpha$ q-coupled receptors activate PI3K $\gamma$ , which is distinct from

the  $\alpha$ -isoform activated in physiological hypertrophy signaling. Whereas PI3K $\alpha$  is activated by receptor-mediated tyrosine phosphorylation, PI3K $\gamma$  binds to dissociated G $\beta\gamma$ , providing access to membrane phosphoinositides (see **Figures 2-8 and 2-10**).<sup>277</sup> PI3K $\gamma$  (p110 $\gamma$ ) signaling is processed through Akt, which transduces both physiological and pathological cardiac growth (see **Figure 2-10**), depending upon the duration of activation.<sup>278</sup> There is transient activation of p110 $\alpha$  by exercise, but in pressure-overload/G $\alpha_q$ -mediated signaling, sustained activation of PI3K $\gamma$  occurs with recruitment of additional signaling pathways in the phospholipase C $\beta$  and calcineurin/NFAT axis.

Akt signaling by G $\beta\gamma$ /PI3K $\gamma$  is divergent (see **Figure 2-10**), which may also contribute to whether the hypertrophy is adaptive or maladaptive. One pathway involves activation of mTOR (mammalian target of rapamycin) and induction of protein synthesis. mTOR exists in two complexes (mTORCs)<sup>279</sup>: mTORC1 with Raptor, which is rapamycin sensitive and is the predominant mass-regulating complex downstream of Akt signaling; and mTORC2 with Rictor and Sin, which controls the actin cytoskeleton and determines cell shape. Pharmacological inhibition of mTOR with rapamycin prevents and regresses hypertrophy.<sup>280</sup> The mechanism by which mTOR stimulates protein synthesis is phosphorylation of S6 kinases that induce phosphorylation of ribosomal S6 protein, which recruits eukaryotic elongation factor 4E (eIF4E).<sup>281</sup> Forced expression of S6 kinase 1 (p70/85) causes cardiac hypertrophy.<sup>282</sup> However, combinatorial ablation of S6 kinase 1 (p70/85) and 2 (p54/56) does not alter the degree of hypertrophy in response to pressure overload, swimming, exercise, or transgenic IGFR1 expression, suggesting that activation of the S6 kinase pathway is not absolutely required for induction of protein synthesis in cardiac hypertrophy.<sup>282</sup>

A second Akt pathway leads to phosphorylation and suppression of glycogen synthase kinase (GSK3 $\beta$ , see **Figure 2-10**), and disinhibition of hypertrophy signaling. GSK3 $\beta$

is tonically active in the heart and its phosphorylation by Akt relieves antihypertrophic signaling. In vivo, pressure overload causes rapid phosphorylation of GSK3 $\beta$  within 10 minutes after transverse aortic constriction is applied, suggesting early recruitment of the kinase in the hypertrophic response.<sup>181</sup> Forced cardiac expression of GSK3 $\beta$  suppresses normal growth and causes cardiomyocyte dysfunction<sup>283</sup> and prevents isoproterenol- and pressure-overload-induced hypertrophy.<sup>284</sup> GSK3 $\beta$  phosphorylates and negatively regulates the translation initiation factor eIF2B.<sup>285</sup> GSK3 $\beta$  also counter-regulates the calcineurin NFAT signaling axis by phosphorylating the NFAT residues that are dephosphorylated by calcineurin (see **Figure 2-10**).<sup>284</sup> GSK3 $\beta$  is also phosphorylated by protein kinase A (PKA) activation and G protein-PKC-ERK-p90 ribosomal S6 kinase-based signaling, de-repressing downstream hypertrophic signaling (see **Figure 2-10**).

Like GSK3 $\beta$ , GSK3 $\alpha$  signaling is also antihypertrophic, and its forced expression reduces cardiac mass, while siRNA-based knockdown prevents development of hypertrophy in response to pressure overload by inhibiting ERKs.<sup>286</sup> Forced expression of dominant negative GSK3 $\beta$  increases resting heart size, enhances contractility, and prevents decompensation of pressure overload hypertrophy.<sup>287</sup>

Antihypertrophic effects of GSK3 $\beta$  signaling are transduced in part through the canonical Wnt signaling axis (see **Figure 2-10**). Wnts are extracellular proteins that signal either cell to cell as membrane-bound proteins or as secreted proteins via heptahelical frizzled receptors and single transmembrane-pass coreceptors known as low-density lipoprotein receptor-related proteins (LRPs).<sup>288</sup> Tonic activity of GSK3 $\beta$  phosphorylates  $\beta$ -catenin, a transcription factor in the Wnt pathway, which targets it for degradation by the ubiquitin-proteasome system.<sup>289</sup> When Wnts signal via the frizzled LRP receptors, the entire complex gets recruited to the receptor with the scaffolding protein Dishevelled, resulting

**FIGURE 2-10** Neurohormonal regulation of hypertrophy via Akt/mTOR/GSK3 $\beta$  signaling. G $\beta\gamma$ -mediated PI3K $\gamma$  activation leads to Akt activation and stimulation of protein synthesis via mTOR and suppression of antihypertrophic signaling via GSK3 $\beta$ . Akt also phosphorylates and causes export of FOXO transcription factors from the nucleus, suppressing ubiquitin-proteasome-mediated protein degradation. GSK3 $\alpha/\beta$  exerts a tonic inhibition on multiple prohypertrophic transcription factors and its phosphorylation relieves this inhibition, resulting in hypertrophy signaling. Inhibition of GSK3 is a nodal point for convergence of hypertrophy signaling pathways and also occurs via phosphorylation by PKA (via G $\alpha$ ), PKCs (via G $\alpha_q$ ), ERK/ribosomal S6 kinases (downstream of small G protein signaling), and ILK (downstream of integrin signaling).

in phosphorylation of LRP and Dishevelled, which inhibits GSK3 $\beta$  and prevents GSK3 $\beta$ -mediated phosphorylation of  $\beta$ -catenin.  $\beta$ -catenin therefore accumulates in the nucleus and complexes with a transcription factor TCF/LEF1 (T-cell-specific transcription factor/lymphoid enhancer binding factor 1) by displacing its binding protein Groucho, facilitating gene transcription. The Wnt- $\beta$ -catenin signaling pathway is antihypertrophic in the heart.<sup>290</sup> Cardiomyocyte-specific deletion of  $\beta$ -catenin mildly increases cardiac mass and the cardiomyocyte cross-sectional area and upregulates hypertrophy gene expression.<sup>291</sup> In contrast,  $\beta$ -catenin stabilization decreases cardiomyocyte area, upregulates the atrophy-related protein IGFBP5, and attenuates Ang II-induced hypertrophy.<sup>291</sup> In this instance, the attenuated hypertrophy was associated with cardiomyopathic decompensation, suggesting that the Wnt pathway suppresses adaptive hypertrophy.

Akt also suppresses protein degradation via the ubiquitin-proteasome system. Akt phosphorylates FoxO (O family of forkhead/winged-helix) transcription factors, which suppresses their transcriptional activity by facilitating interaction with 14-3-3 proteins, leading to export out of the nucleus and targeting for ubiquitin-proteasome degradation (see [Figures 2-1 and 2-10](#)). Akt-mediated suppression of FoxO signaling downregulates multiple atrophy-related genes or atrogens.<sup>292</sup> Atrogin-1 is a cardiac- and skeletal muscle-specific F-box protein that regulates skeletal muscle atrophy by binding to Skp1, Cul1, and Roc1, the common components of SCF ubiquitin ligase complexes.<sup>293</sup> Since antihypertrophic FoxO-Atroxin signaling works in opposition to prohypertrophic pathways, in vivo adenoviral transduction of FoxO3 in mice reduces cardiac cell size,<sup>294</sup> and forced cardiac expression of Atrogin-1 suppresses Akt-mediated adaptive hypertrophy signaling<sup>294</sup> and targets calcineurin for proteasome degradation.<sup>295</sup>

**Non-IGF Growth Factors in Hypertrophy.** Cardiac myocytes elaborate peptide growth factors in response to stress.

The role of signaling downstream of two prototypical growth factors, neuregulin, and TGF- $\beta$  are reviewed here in detail.

Neuregulin is a member of the epidermal growth factor (EGF) signaling pathway. As with other growth factors, neuregulins cause dimerization of tyrosine kinase receptors (ErbB2, ErbB3, and ErbB4), leading to tyrosine autophosphorylation and recruitment of downstream signaling effectors<sup>296</sup> ([Figure 2-11](#)). Neuregulin is produced in the heart primarily by the endothelial cells and therefore functions as a paracrine growth factor. All three isoforms of neuregulin are cleaved by membrane-bound metalloproteinases, producing an activated fragment that is released and associates with EGF receptor (juxtacrine signaling) (see [Figure 2-11](#)). Neuregulin-mediated EGF receptor signaling is activated by neurohormonal stimuli via  $\beta$ -arrestin-mediated transactivation of the  $\beta$ -adrenergic receptors.<sup>297</sup> Neuregulin is induced by pressure overload paralleling the development of concentric hypertrophy<sup>298</sup> and its levels decline along with those of ErbB2 and ErbB4 receptors during transition to dilated cardiomyopathy.<sup>299</sup> Ablation of neuregulin 1 or ErbB2 and ErbB4 receptors causes cardiac hypoplasia and loss of trabeculation.<sup>296</sup> Neuregulin signaling via Erb receptors primarily regulates cardiomyocyte survival and not hypertrophy as cardiomyocyte-specific ablation of ErbB2 receptor causes spontaneous development of apoptotic cardiomyopathy,<sup>300,301</sup> which is rescued by adenoviral transduction of the antiapoptotic protein BXL-xl. Also, cardiomyocyte-specific ablation of the ErbB2 receptor markedly increases mortality after pressure overload and decreases cardiomyocyte survival with anthracycline exposure.<sup>301</sup> Exogenously administered recombinant neuregulin improves survival, improves LV function, and retards cardiomyopathic changes in experimental cardiomyopathy.<sup>302</sup> The importance of ErbB2 signaling in provoking cardiac pathology was unexpectedly established when an antibody against ErbB2 (a.k.a. “her2”), which is effective against metastatic breast cancer, caused a high incidence of dilated cardiomyopathy.<sup>303</sup>

**FIGURE 2-11** Neuregulin/EGF signaling in hypertrophy. Neuregulins are transmembrane proteins of the EGF family, present mainly on endothelial cells as three different types (I, II, and III). Proteolytic cleavage by ADAM (a disintegrin and metalloproteinase) family enzyme causes exposure of an EGF-like signaling domain, which interacts with erbB2 and erbB4 receptors resulting in receptor tyrosine kinase activation. EGF signaling is also activated by GRK- $\beta$ -arrestin-mediated EGF cleavage by ligand-occupied seven-transmembrane neurohormonal receptors. Neuregulin/EGF activates Akt and ERK signaling pathways to promote cell survival in the heart.

The transforming growth factor family is a large group of polypeptide growth factors divided into two groups: the TGF/activin subfamily and the bone morphogenic proteins (reviewed in Xiao<sup>304</sup>). TGF- $\beta_1$  is secreted in a latent form and is tethered to the extracellular matrix, whereupon its stimulus-mediated proteolytic cleavage allows interactions with its serine-threonine kinase receptors, TGF- $\beta$ RI and TGF- $\beta$ RII. TGF- $\beta$  is transcriptionally induced during the transition from compensated hypertrophy to failure in the spontaneously hypertensive rat model of pathological hypertrophy. Forced expression of TGF- $\beta_1$  in the heart induces mild hypertrophy,<sup>305</sup> and absence of TGF- $\beta_1$  markedly attenuates hypertrophy but preserves myocardial function in response to Ang II infusion.<sup>306</sup> TGF- $\beta$  signaling activates MAPKs, such as the TAK1 (TGF-activated kinase)-MEK4-JNK1 and TAK1-MEK3/6-p38 axes (see Figure 2-8), and tyrosine kinase pathways, such as Ras/Rho/extracellular signal-regulated kinase (ERK) and RhoA/p160 Rho-associated kinase (ROCK).<sup>307</sup> Increased TAK1 activity is detected in pressure-overload hypertrophy, and forced cardiac expression of TAK1 causes cardiomyocyte hypertrophy with cardiomyopathic decompensation with increased mortality because of heart failure.<sup>308</sup>

Smad 4 is the canonical effector of TGF- $\beta$ , and cardiomyocyte-specific ablation of Smad 4 causes cardiac hypertrophy with reexpression of fetal genes and the activation of the MEK1-ERK1/2 pathway.<sup>309</sup> Thus Smad4 acts in opposition to TGF- $\beta$ -induced MAPK activation. Smad 2 activation is induced by growth differentiation factor 15 (GDF15), a TGF- $\beta$  family member induced by pressure overload<sup>310</sup> and facilitates antihypertrophic signaling. Forced cardiac expression of GDF15 attenuates pressure-overload hypertrophy, without affecting the fetal gene expression program<sup>310</sup> and *GDF15* ablation exaggerates hypertrophy, leading to rapid cardiomyopathic decompensation after pressure overload.

### Small G Proteins

Peptide growth factors and G protein-coupled receptors also transduce neurohormone and stretch-induced hypertrophy by nonreceptor tyrosine kinases such as Src, Ras, and Raf.<sup>311</sup> Ras, a member of the small G protein family (along with Rac, Rho, Rab, Ran, and ADP ribosylation factors) is the prototypical signaling molecule downstream of receptor tyrosine kinases (RTKs) that exist bound to GDP in the inactive state (see Figure 2-8). Upon stimulation, the GDP is exchanged for GTP and followed by a conformational change resulting in stimulation of mitogen-activated protein kinase (MAPK) cascade. Intrinsic GTPase activity then turns the signal off, returning the G protein to its basal state. GEFs are proteins that facilitate GTP exchange, and GAPs promote inactivation by activating the GTPase activity. There are four Ras proteins identified in the mammalian myocardium of which H-Ras has been the most carefully studied. Expression of constitutively active Ras promotes and dominant negative Ras inhibits cardiomyocyte hypertrophy in vitro in response to  $\alpha$ -adrenergic agonists. Forced expression of H-Ras induces cardiomyocyte hypertrophy in vivo with preserved systolic function, myofibrillar disarray, and increased fibrosis with a unique gene expression profile consisting of ANF and BNP upregulation without upregulation of MHC or  $\alpha$ -skeletal actin. Ras signaling also activates multiple MAPK pathways (both ERK and JNK mediated), with the combinatorial effect of its overexpression resulting in cardiomyopathic decompensation.

The Rho family of kinases is constituted by at least 14 members grouped into Rho, Rac, and cdc42 subfamilies. RhoA and Rac1 are activated by G $\alpha_q$  signaling,<sup>312</sup> and this in turn activates Rho kinases, ROCK1 and ROCK2. The Rho signaling pathway does not affect development of hypertrophy but has deleterious effects in pathological hypertrophic signaling. Mice with forced cardiac expression of Rho A develop fatal cardiomyopathy with conduction abnormalities and severe

atrial enlargement.<sup>313</sup> Pharmacological Rho kinase inhibition prevents ventricular dilation and development of fibrosis in response to pressure overload hypertrophy in rats<sup>314</sup> and *ROCK1* deletion markedly reduces fibrosis in mice subjected to pressure overload.<sup>315</sup> Forced expression of constitutively activated Rac1, another Rho family member, causes lethal cardiomyopathy. Rac1 interacts with gp91(phox) and p67(phox) components of NADPH oxidase, and its activation causes increased generation of reactive oxygen species.<sup>316</sup> Cardiomyocyte-specific gene ablation for Rac1<sup>316</sup> attenuates myocardial oxidative stress and hypertrophy in response to Ang II infusion.

Raf kinases are a family of three serine/threonine-specific kinases (A-Raf, B-Raf, and Raf-1) ubiquitously expressed throughout embryonic development. Raf is downstream of Ras signaling and activates the MEK1-ERK axis, with enhanced hypertrophic and prosurvival effects.<sup>317</sup> Cardiac specific ablation of Raf causes apoptotic cardiomyopathy, which is rescued by inhibition of Ask-1 (apoptosis signal-regulating kinase-1),<sup>318</sup> which physically interacts with Raf.

## FUTURE DIRECTIONS

Much of the information described in this chapter has been generated through relatively recent techniques of molecular manipulation in cell-based and murine systems that engendered a revolution in reductionist experimentation (i.e., molecular dissection of pathophysiological processes). As a consequence, the past two decades have produced a literal encyclopedia of individual factors and their functional consequences in hypertrophy and heart failure. Yet, with all this new information, no magic bullet has been identified that prevents or cures heart failure, and a major conclusion from this work seems to be that molecular cross talk and functional redundancy between signaling factors and pathways is so prevalent that achieving a magic bullet is unlikely, if not impossible. It is interesting that two of the current foci of investigational therapeutics—targeting neurohormonal pathways<sup>166,173</sup> and correcting calcium abnormalities<sup>156,159,319</sup>—are the same as when the senior author was a medical student approximately 30 years ago.<sup>146,320-323</sup>

Targeted gain- and loss-of-function approaches that teased out possible roles for individual components of complex biological pathways have helped us develop an essential informational framework describing molecular processes and players in the heart. Now, the reductionist revolution of experimental molecular manipulation may be waning, and the future seems to be bright for integrated molecular studies of the human condition. Aside from the critical need to apply molecular information to human disease, there have been recent technical developments that position the field for a reorientation of approach. One is the availability of experimental platforms permitting high-throughput analysis of massive numbers of endpoints using specimens obtained from individual patients. Examples of currently available and clinically applicable large-scale molecular readouts include comprehensive mRNA and microRNA signatures from cardiac tissue and detailed personal gene polymorphism profiles. Proteomic profiling and analysis of individual exomes and genomes with a resolution down to single nucleotides is within reach in the next few years. The surprising degree of interindividual variability observed in our genetic code<sup>324,325</sup> undoubtedly contributes to observed heterogeneity in cardiac disease and response to therapy. Molecular epidemiology and a systems approach combining clinical investigation and bioinformatics, supported by basic studies, will be needed to determine how differences in gene product expression or function relate to the pathological interplay between factors and pathways.

A second example of the need for an integrated approach to pathway analysis is the promise of regenerative cardiology (see Chapter 4). This is a very new field whose foundation is cell, developmental, and molecular biology. It is obvious that success in rebuilding myocardium from cardiac scar requires creation not just of cardiac myocytes, but also the tissue infrastructure that is essential for myocyte maintenance and function (i.e., cardiac interstitium, myocardial vasculature, intermyocyte physical and electrical connectivity). This is a monumental challenge, and will likely require a highly refined understanding of the interplay between myocyte and vascular growth, death, and contractile signaling. Fortunately, such an understanding is forthcoming.

## Abbreviations Used in This Chapter

Abbreviation	Name	Note
Ang II	Angiotensin II	Hypertrophic agonist
AMPK	Adenosine monophosphate kinase	
ANF	Atrial natriuretic factor	Early response gene
AP-1	Activator protein 1	Transcription factor
AT <sub>1a</sub> R, AT <sub>1b</sub> R	Angiotensin II receptor type Ia or Ib	
Ask-1	Apoptosis signal regulating kinase 1	MAP kinase kinase
ATF-1	Activating transcription factor 1	
β-ARK (GRK2)	β-adrenergic receptor kinase (G-protein receptor kinase 2)	Gβγ dependent, phosphorylates β-adrenergic receptors
BMP	Bone morphogenic proteins	
BNP	Brain natriuretic peptide	TGF-β super family ligands
CAD	Caspase associated DNAase	
CaMK	Ca <sup>2+</sup> calmodulin-dependent kinase	
cAMP	Cyclic adenosine monophosphate	
cAMP kinase	Cyclic 3',5'-adenosine monophosphate kinase	
CREB	cAMP response element-binding protein	cAMP responsive transcription factor
CT-1	Cardiotrophin-1	IL-6 family cytokine
DAG	Diacylglycerol	Endogenous PKC agonist
DISC	Death induced signaling complex	Signaling complex downstream of death receptor
4E-BP	4E-binding protein	
EGF	Epidermal growth factor	
<i>egr-1</i>	Early growth response gene 1	Transcription factor
eIF4F	Eukaryotic initiation factor 4F	Stimulates initiation of translation at a subset of transcripts
ErbB2-4	EGF family tyrosine kinase receptors	Receptors for neuregulins
ET-1	Endothelin 1	
ET <sub>A</sub> , ET <sub>B</sub>	Endothelin receptors A, B	
ECM	Extracellular matrix	
EGF	Epidermal growth factor	
Elk-1	TCF family transcription factor	
Ets1	TCF family transcription factor	
ERK	Extracellular receptor kinase	MAP kinase
FAK	Focal adhesion kinase	Nonreceptor tyrosine kinase
FGF	Fibroblast growth factor	Growth factor
c-fos	c-fos oncogene	Component of transcription factor AP-1
Gα, Gβγ	Subunits of heterotrimeric G proteins	
GAP	GTPase activating proteins	
GATA4	GATA binding protein 4	
GDP	Guanosine diphosphate	
GDF15	Growth differentiation factor 15	TGF-β family protein
GEF	Guanine exchange factor	Activators of small G proteins
gp130	Glycoprotein 130	Receptor for IL-6 family cytokines
GPCR	Heterotrimeric G protein-coupled receptor	
Grb2	Growth factor receptor bound protein 2	Adaptor protein linking RTKs and Ras

Continued

## Abbreviations Used in This Chapter—cont'd

Abbreviation	Name	Note
GRK	G protein receptor kinase	Inhibits G protein signaling and recruits adaptor proteins to stimulate alternate pathways
GSK3 $\beta$	Glycogen synthase kinase 3 $\beta$	Kinase downregulated by hypertrophic stimuli
GTP	Guanosine triphosphate	
HB-EGF	Heparin-binding EGF-like growth factor	
HAT	Histone acetyltransferase	Induces histone acetylation with activation of transcription
HDAC	Histone deacetylase	Represses transcription by inducing histone deacetylation
IGF-1	Insulin-like growth factor	Growth factor
IL-6	Interleukin-6	Cytokine
IP3	Inositol 1,4,5 triphosphate	
ILK	Integrin linked kinase	Serine threonine kinase associated with $\beta$ -integrin
JAK	Janus activating kinase	Tyrosine kinase activated by gp130
JNK	Jun N terminal kinase	MAP kinase
<i>c-jun</i>	<i>jun</i> oncogene	Component of AP-1 transcription factor
LIF	Leukemia inhibitory factor	IL-6 cytokine
MADS domain	DNA binding motif	Present in SRF and MEF2 transcription factors
MAPK	Mitogen-activated protein kinase	
MAPKK	MAPK kinase	Also known as MEK or MK
MAPKKK	MAPK kinase kinase	Also known as MEKK or MKK
MEF2	Myocyte enhancer factor 2	Transcription factor
MEK-1	MAP kinase kinase 1	Activator of ERK MAPKs
MCIP	Modularity calcineurin-inhibitory proteins	Endogenous inhibitor of calcineurin
MHC	Myosin heavy chain	
miRNAs	MicroRNAs	Endogenous RNAs that inhibit mRNA translation/enhance degradation
MLC	Myosin light chain	
MLP	Muscle LIM protein	
mTOR	Mammalian target of rapamycin	Kinase involved in regulation of protein synthesis
<i>c-myc</i>	<i>myc</i> oncogene	Transcription factor
NE	Norepinephrine	Catecholamine
NFAT	Nuclear factor of activated T cells	Transcription factor
PDK1	Phosphoinositide-dependent kinase 1	Downstream effector of PI3K
PE	Phenylephrine	$\alpha$ -adrenergic agonist
PI3K	Phosphoinositide 3-kinase	
PIP2	Phosphatidyl inositol 4,5-bisphosphate	
PIP3	Phosphatidyl inositol 3,4,5-triphosphate	
PKA	Protein kinase A	
PKB	Protein kinase B	Also known as Akt
PKC	Protein kinase C	
PKD	Protein kinase D	
PLC	Phospholipase C	
PMA	Phorbol 12-myristate 13-acetate	PKC agonist
p53	Tumor suppressor gene	Transcription factor
p70S6K	Ribosomal p70 S6 kinase	Protein kinase involved in protein synthesis
Ras	<i>Ras</i> oncogene	Small G protein

Continued

## Abbreviations Used in This Chapter—cont'd

Abbreviation	Name	Note
RTK	Receptor tyrosine kinase	
ROCK	Rho kinases	
RyR	Ryanodine receptor	
SERCA	Sarcoplasmic reticulum $\text{Ca}^{2+}$ ATPase	Pumps $\text{Ca}^{2+}$ from cytoplasm to sarcoplasmic reticulum
SH2	Src homology domain 2	Binds phosphotyrosine residues
SHP2	SH2 domain-containing cytoplasmic protein tyrosine phosphatase	
siRNAs	Short interfering RNAs	Inhibit mRNA translation
SOCS	Suppressors of cytokine signaling	Endogenous repressor of STATs
<i>c-Src</i>	<i>Src</i> oncogene	Nonreceptor tyrosine kinase
SRF	Serum response factor	Transcription factor
STAT	Signal transducer and activator of transcription	Transcription factor regulated by JAKs
TCF	Ternary complex factor	Transcription factor regulated by MAPKs
TAK1	TGF- $\beta$ activated kinase 1	MAPKK activated by TGF- $\beta$
TGF- $\beta$	Transforming growth factor $\beta$	Cytokine
TNF- $\alpha$	Tumor necrosis factor $\alpha$	Cytokine
VEGF	Vascular endothelial growth factor	Angiogenic cytokine

## Conclusions 44

## Future Directions 44

Congestive heart failure (CHF) is a syndrome characterized by deterioration of cardiac pump function. Progressive alterations in the processes that regulate contractility of single ventricular myocytes are thought to be the important contributors to this pump degeneration (see Chapter 2). Those findings that have enhanced our understanding of abnormal electrophysiology, excitation-contraction coupling,  $\text{Ca}^{2+}$  handling, and contractile proteins in relation to the deterioration of ventricular myocyte contractility in the failing heart are the topic of this chapter.

## CHARACTERISTIC ELECTROMECHANICAL ABNORMALITIES OF FAILING MYOCYTES

Prolongation of the action potential duration, a depressed force generating capacity, and slowed contraction and relaxation rates are the hallmark functional changes of the failing human heart. The action potential abnormalities cause prolongation of the surface electrocardiogram (acquired long QT syndrome),<sup>1</sup> which renders the heart prone to arrhythmias and contributes to sudden death.<sup>2</sup> The mechanical abnormalities of the failing heart contribute to its poor pump performance and limit its ability to increase function during daily routine activities.

The cellular and molecular bases of CHF electromechanical abnormalities have been studied both in human tissues and cells and in animal models of human disease. Animal

may even be increased, which would help the heart maintain pump function in the face of increased hemodynamic demands. As the cardiac insult becomes more severe, CHF with LV (LV) dilation and deterioration of pump, muscle, and myocyte performance are induced. The factors that precipitate the transition from compensated to depressed myocyte and pump function are discussed later, as are those issues that are still unresolved and deserving of additional study.

## In Vivo Cardiac Function Versus In Vitro Muscle and Myocyte Contractility

In CHF, the dilated heart has a reduced ejection fraction and ejects blood slowly. These derangements are signs of markedly increased hemodynamic loading (systolic wall stress). Under these conditions the failing heart struggles to maintain blood pressure and cardiac output. Clinical studies have documented that systolic wall stress is increased in the failing heart and is a strong predictor of heart failure severity. This parameter is also inversely related to clinical outcome.<sup>5,6</sup> These clinical data show that the myocytes surrounding the failing ventricle must develop high force (pathologically increased systolic wall stress) to produce ejection. Persistent activation of sympathetic and renin-angiotensin signaling cascades are needed to support this contractile function.<sup>7,8</sup> It is imperative to keep in mind that the in vitro studies performed with muscles or myocytes removed from failing hearts (human or animal models) have largely been conducted in the absence of the altered inotropic environment of the failing heart. As we discuss later, when studied under these conditions many investigators have found that the basal contractile properties of the heart are depressed.<sup>9,10</sup> Collectively these studies show that the poor pump function of the failing heart results from two factors, excessive loading conditions (systolic wall stress) and inherent defects in myocyte contractility. Fixing these structural and functional abnormalities has been a major therapeutic challenge.

CHF has many different causes and yet changes in functional characteristics of the failing heart muscle are surprisingly

models of human disease have been useful for those studies seeking to identify the potential causes and therapies for the cardiac dysfunction seen in hypertrophy and CHF. These animal models in large part mimic human heart disease by increasing hemodynamic loading conditions (pressure and volume overload, interrupting myocardial blood flow (infarction), and by altering the heart rate (rapid pacing or atrioventricular [AV] block). Increasingly, genetically induced deletion or overexpression of specific cardiac myocyte proteins have been used to gain novel insights into the fundamental causes and potential cures of CHF. Chamber remodeling, including increased myocardial mass and left ventricular (LV) chamber dilation, is a common feature of CHF with dilation increasing with CHF severity.<sup>3</sup> Dilation induces increases in systolic wall stress so that muscle cells in the failing heart must develop greater than normal force to develop the pressures required to support a normal blood pressure.

The consensus from most studies performed to date is that mild to moderate cardiac insults are usually followed by a compensatory response that involves hypertrophy and some LV chamber remodeling (see Chapter 15).<sup>4</sup> In these compensatory stages, myocyte function appears to be near normal and

consistent. Slowing of contraction and relaxation rates and prolongation of the action potential duration have consistently been the first changes observed in the early stages of CHF.<sup>11,12</sup> Reduced force production and shortening magnitude and decreases rather than increases in contractility as the heart rate increases (positive versus negative force-frequency relationships) are observed in more advanced CHF.<sup>13</sup>

An important finding of many *in vitro* studies is that nonfailing and failing human myocytes have similar contractile characteristics at low workloads (slow pacing rates, low bath  $\text{Ca}^{2+}$ , absence of catecholamine stimulation).<sup>13</sup> Peak developed force (or shortening) is not significantly different in nonfailing versus failing human left ventricle muscles or in myocytes paced at slow frequencies ( $<30/\text{min}$ ) and the rates of force development (muscles) or shortening (myocytes) are only modestly slower than normal in failing muscles. Changes in heart rate,  $\text{Ca}^{2+}$  influx, or catecholamine exposure all bring out significant differences between nonfailing and failing myocardium and myocytes. Increasing the pacing rate into the physiological range causes contractility to increase in nonfailing myocytes (positive force-frequency) but causes contractility to decrease (or remains constant) in HF myocytes (negative force-frequency relationship). Therefore, at physiological heart rates, the contractility of the failing heart is depressed.

The contractile enhancing effects of high bath  $[\text{Ca}^{2+}]$  and  $\beta$ -adrenergic agonists are also significantly blunted in failing myocytes.<sup>14,15</sup> These results suggest that the phenotypical adaptations of failing myocytes cause preservation of contractility at low workloads (rates) but at the cost of blunted contractile reserve. If a cellular and molecular alteration contributes to the CHF contractile phenotype, it must contribute to these prototypical contractile alterations.

## CALCIUM-DEPENDENT CAUSES OF ELECTROMECHANICAL DYSFUNCTION IN THE FAILING HEART

Morgan and colleagues were the first to observe alterations in the  $\text{Ca}^{2+}$  transient of failing human ventricular muscle.<sup>16</sup> These early studies stimulated a large body of research on the role of deranged  $\text{Ca}^{2+}$  homeostasis in the mechanical abnormalities of the failing heart. Fairly consistent changes in  $\text{Ca}^{2+}$  handling have been observed in studies using large- and small-animal model CHF and in failing human heart muscles and myocytes, as previously reviewed in Houser et al.<sup>9,10</sup>

As mentioned previously, increasing the beating rate of normal human ventricular myocytes causes an increase in the size of the  $\text{Ca}^{2+}$  transient and the force of contraction (positive force-frequency relationship). In myocytes with mild to moderate hypertrophy without CHF, the peak systolic  $\text{Ca}^{2+}$  is normal in the basal state and only becomes depressed when conditions that increase cellular  $\text{Ca}^{2+}$  loading are imposed (faster pacing rates, high bath  $[\text{Ca}^{2+}]$  or catecholamine exposure). As the severity of the inciting hypertrophic stimulus increases and ventricular function begins to change,  $\text{Ca}^{2+}$  transient and contractile abnormalities are found at progressively slower rates of stimulation and in normal bath  $[\text{Ca}^{2+}]$ . When CHF is severe, such as in end-stage human heart failure, peak systolic  $\text{Ca}^{2+}$  and force (or shortening) are both close to normal only at very slow pacing rates. As the beating rate is increased, there is either no change or a decrease in peak systolic  $\text{Ca}^{2+}$  and force of contraction (negative force-frequency relationship) in the failing heart.<sup>15,16</sup> In addition, as CHF progresses, there is an associated increase in diastolic  $\text{Ca}^{2+}$  with increased heart rate.<sup>15</sup> These results strongly support the hypothesis that changes in cellular  $\text{Ca}^{2+}$  handling are a final common pathway for progressive deterioration of cardiac pump function in CHF. The changes in  $\text{Ca}^{2+}$  handling are also likely to be critically involved in the arrhythmias,<sup>7,17</sup>

metabolic disturbances, and activation of cell death pathways<sup>18-21</sup> and hypertrophy<sup>22</sup> that develop during this time. This hypothesis is also strongly supported by studies in animal models that show that the transition from compensated hypertrophy to CHF coincides with the time that myocytes first lose their ability to normally maintain physiological levels of systolic and diastolic  $\text{Ca}^{2+}$ .<sup>23</sup>

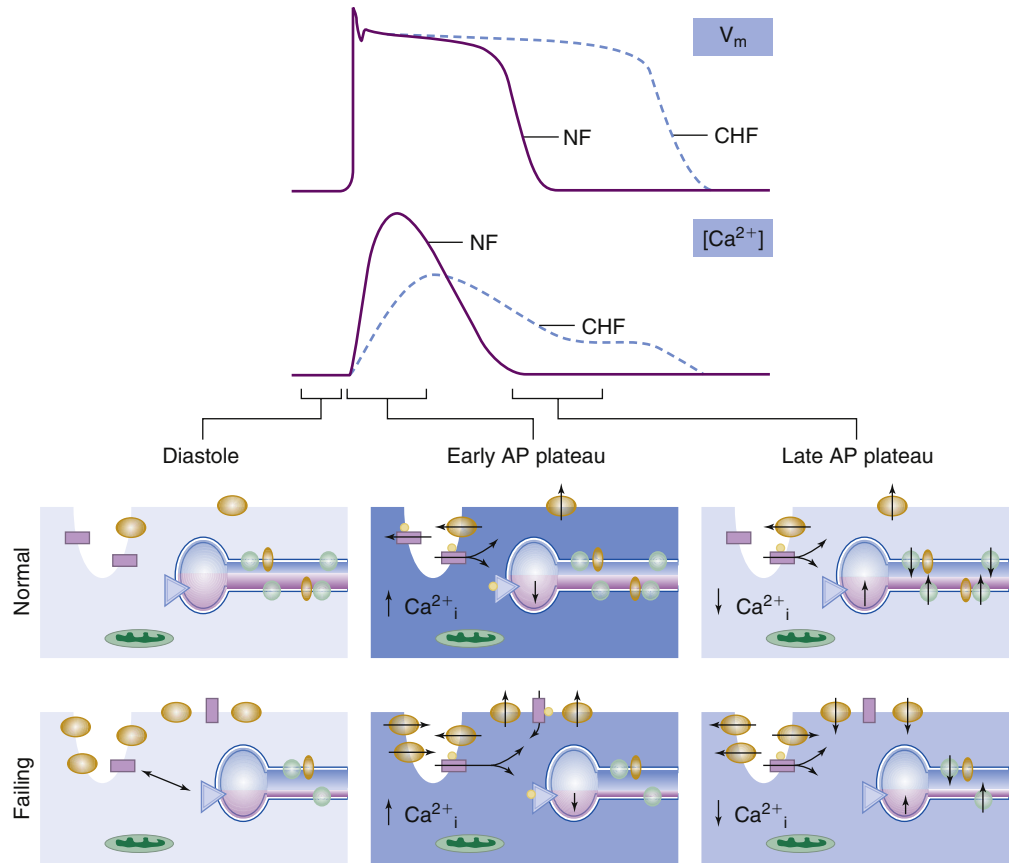

The cellular and molecular bases of the altered  $\text{Ca}^{2+}$  homeostasis of the failing cardiac myocytes have been studied in some detail. Studies performed over the past decade show that changes in the abundance and regulatory state (phosphorylation, nitrosylation, etc.) of critical  $\text{Ca}^{2+}$  regulatory proteins are largely responsible for abnormal  $\text{Ca}^{2+}$  regulation.<sup>24</sup>

In normal myocytes the systolic  $\text{Ca}^{2+}$  transient (rise in cytosolic  $[\text{Ca}^{2+}]$ ) determines the rate and magnitude of contraction. The  $\text{Ca}^{2+}$  transient is derived from two sources:  $\text{Ca}^{2+}$  influx through L-type  $\text{Ca}^{2+}$  channels and  $\text{Ca}^{2+}$  release from the sarcoplasmic reticulum (SR). L-type  $\text{Ca}^{2+}$  channels in the transverse tubules are activated during the early portion of the cardiac action potential.  $\text{Ca}^{2+}$  enters myocytes through these channels and accumulates in diffusion limiting spaces between the T-tubules and the junctional SR.  $\text{Ca}^{2+}$  in this space binds to the cytoplasmic face of the  $\text{Ca}^{2+}$  release channel (ryanodine receptor, RyR), causing it to open.  $\text{Ca}^{2+}$  then moves out of the SR into the cytoplasm. Collectively these processes increase cytoplasmic  $\text{Ca}^{2+}$  and activate contraction. The  $\text{Ca}^{2+}$  transient is terminated when the  $\text{Ca}^{2+}$  entry and release channels close and  $\text{Ca}^{2+}$  efflux ( $\text{Na}/\text{Ca}^{2+}$  exchange) and SR reuptake by the SR  $\text{Ca}^{2+}$  ATPase (SERCA2) reestablish steady-state conditions. The amplitude and duration of the  $\text{Ca}^{2+}$  transient is regulated to modulate the rate, magnitude, and duration of contraction. SR  $\text{Ca}^{2+}$  release is induced and graded by  $\text{Ca}^{2+}$  influx through L-type  $\text{Ca}^{2+}$  channels.<sup>25</sup> The magnitude of SR  $\text{Ca}^{2+}$  release is also determined by the amount of  $\text{Ca}^{2+}$  stored in the SR.<sup>26,27</sup> Alterations in the abundance or activity (by abnormal phosphorylation) of any or all of these  $\text{Ca}^{2+}$  regulatory proteins have been shown to play a role in the abnormal  $\text{Ca}^{2+}$  transients in the failing heart (Figure 3-1). Most studies show that the amount of  $\text{Ca}^{2+}$  released from the SR of failing human (and most animal models) myocytes is smaller than normal and that this difference is accentuated at rapid heart rates.<sup>27,28</sup> The molecular bases of the abnormal  $\text{Ca}^{2+}$  transient are discussed next.

### L-Type $\text{Ca}^{2+}$ Channel

The L-type  $\text{Ca}^{2+}$  channel opens when the membrane potential depolarizes during the upstroke of the cardiac action potential. The subsequent  $\text{Ca}^{2+}$  influx ( $I_{\text{Ca,L}}$ ) contributes to the plateau phase of the action potential, directly elevates cytoplasmic  $[\text{Ca}^{2+}]$ , and induces SR  $\text{Ca}^{2+}$  release<sup>29</sup> (see Figure 3-1).  $\text{Ca}^{2+}$  influx via the L-type  $\text{Ca}^{2+}$  current is also an important source of  $\text{Ca}^{2+}$  to maintain and modify the amount of  $\text{Ca}^{2+}$  stored in the SR.<sup>30</sup> Reductions in the number of these  $\text{Ca}^{2+}$  channels, abnormal localization, or abnormal activity could explain many aspects of disrupted  $\text{Ca}^{2+}$  homeostasis in CHF. Reduced  $I_{\text{Ca,L}}$  density,<sup>31</sup> slow inactivation,<sup>32</sup> and reduced  $\beta$ -adrenergic regulation<sup>33</sup> have all been reported in animal models, but these changes have not been consistently observed in failing human myocytes.<sup>34</sup> An interesting study in failing canine myocytes suggested that the density of L-type  $\text{Ca}^{2+}$  channels is reduced but  $I_{\text{Ca,L}}$  density is maintained.<sup>35</sup> We have shown that the density of the L-type  $\text{Ca}^{2+}$  channel is reduced in failing human myocytes but the  $\text{Ca}^{2+}$  current is maintained by increased PKA-mediated phosphorylation of the channels, which increase their activity.<sup>36</sup> Since the channels are largely phosphorylated in the basal state, sympathetic agonists had little ability to increase the current further. Therefore, blunted adrenergic effects on myocyte contractility are likely to involve a failure to increase  $\text{Ca}^{2+}$  influx and increase SR  $\text{Ca}^{2+}$  loading. These ideas are supported by experiments by

**FIGURE 3-1** The upper panel depicts the differences in the action potential (AP) wave shape and cytosolic free  $\text{Ca}^{2+}$   $[\text{Ca}^{2+}]_i$  between normal (N) and failing (CHF) human ventricular myocytes. The lower panels depict the potential subcellular alterations in CHF that cause abnormal  $[\text{Ca}^{2+}]_i$  transients. The gray level represents the  $[\text{Ca}^{2+}]_i$ . In diastole the  $[\text{Ca}^{2+}]_i$  is similar in N and CHF myocytes. However, SR  $\text{Ca}^{2+}$  loading (depicted by the blue level in the SR) is smaller in the failing myocyte. Also note the difference in the density and location of  $\text{Ca}^{2+}$  regulatory proteins in the N versus CHF myocytes. Peak systolic  $[\text{Ca}^{2+}]_i$  during the early AP plateau phase is lower than normal in the failing myocyte because SR  $\text{Ca}^{2+}$  release is smaller and  $\text{Ca}^{2+}$  efflux via forward mode NCX is greater than normal. SR  $\text{Ca}^{2+}$  release is also reduced in the failing myocyte because of defective EC coupling. During the late phase of the AP plateau  $[\text{Ca}^{2+}]_i$  is greater than normal in the failing myocyte because the prolonged AP duration promotes reverse-mode NCX ( $\text{Ca}^{2+}$  influx) and SR uptake is slower than normal. Repolarization of the membrane potential is required for full recovery of diastolic  $\text{Ca}^{2+}$  in failing myocytes. See text for further discussion.

others in which the open probability of single  $\text{Ca}^{2+}$  channels from failing human ventricular myocytes was shown to be increased, consistent with increased phosphorylation.<sup>37</sup> It is also important to keep in mind that most studies of  $I_{\text{Ca,L}}$  in failing myocytes have been performed at slow pacing rates where differences in inactivation properties would not have an impact on  $\text{Ca}^{2+}$  homeostasis. One study has shown that  $I_{\text{Ca,L}}$  decreases more in failing than in normal myocytes when the beating frequency is increased.<sup>38</sup> These results also suggest that rate-related reduction of  $I_{\text{Ca,L}}$  may be an important component of disrupted rate-dependent regulation of contractility in CHF.

Important questions regarding  $I_{\text{Ca,L}}$  in heart failure that still need to be resolved include (1) whether or not CaMKII-mediated regulation of  $\text{Ca}^{2+}$  channels is altered in human CHF, (2) if restoring  $\text{Ca}^{2+}$  influx in CHF improves pump function or induces cell death by promoting SR  $\text{Ca}^{2+}$  overload and exacerbated pump dysfunction, (3) if L-type  $\text{Ca}^{2+}$  channels are appropriately targeted to junctional regions of the T-tubules where EC coupling occurs, and (4) if changes in  $\text{Ca}^{2+}$  influx are involved in abnormal hypertrophic signaling and structural remodeling.

Abnormalities in the triggered release of  $\text{Ca}^{2+}$  from the SR may contribute to contractility defects and arrhythmias in heart failure.  $\text{Ca}^{2+}$  influx through the L-type  $\text{Ca}^{2+}$  channel during the early portions of the action potential is now known to be the exclusive trigger for the release of  $\text{Ca}^{2+}$  from the SR by activating the  $\text{Ca}^{2+}$  release channel (ryanodine receptor, RyR).<sup>39</sup> There is evidence for the hypothesis that  $I_{\text{Ca,L}}$  is a less effective trigger of SR  $\text{Ca}^{2+}$  release in hypertrophied and failing (rat ventricular) myocytes (decreased EC coupling “gain”).<sup>40</sup> This defective signaling can be rescued in hypertrophied but not failing myocytes by exposure to  $\beta$ -agonists. These studies support the idea that the reduced size of the  $\text{Ca}^{2+}$  transient in failing rat myocytes results from a decrease in the fractional SR  $\text{Ca}^{2+}$  release rather than from a reduction in SR

$\text{Ca}^{2+}$  loading as has been observed in failing human ventricular myocytes.<sup>41</sup> The idea that EC coupling “gain” is reduced in CHF is not supported by our studies in failing human myocytes.<sup>42,43</sup> Our results suggest that the triggered release of  $\text{Ca}^{2+}$  from the SR is reduced in failing human myocytes because SR  $\text{Ca}^{2+}$  stores are depleted rather than because EC coupling is deranged.<sup>43</sup> In addition, a fixed defect in EC coupling “gain” does not adequately explain the fact that  $\text{Ca}^{2+}$  transients are similar in normal and failing human myocytes at slow pacing rates and only become significantly different when the heart rate increases. A frequency-dependent decrease in  $I_{\text{Ca,L}}$  and reduced SR  $\text{Ca}^{2+}$  loading are more likely contributors to the associated reduction in SR  $\text{Ca}^{2+}$  release in failing human myocytes at physiologically relevant heart rates.<sup>38</sup>

Pieske et al<sup>28</sup> have shown that the flattened (or negative) force-frequency relationship of failing human ventricular myocytes results from the fact that SR  $\text{Ca}^{2+}$  loading does not increase normally with stimulation rate.<sup>26</sup> These authors suggest that SR  $\text{Ca}^{2+}$  release decreases at higher stimulation rates in the failing myocardium because the smaller than normal increase in SR  $\text{Ca}^{2+}$  loading cannot offset frequency-dependent EC coupling refractoriness. These findings suggest that abnormal SR  $\text{Ca}^{2+}$  loading and changes in the effectiveness of  $I_{\text{Ca,L}}$  as a trigger for SR  $\text{Ca}^{2+}$  release are centrally involved in the depressed contractility of failing human myocytes.<sup>28</sup> Since publication of this study a number of others have shown that decreased SR  $\text{Ca}^{2+}$  loading is a central feature of deranged  $\text{Ca}^{2+}$  handling in CHF.<sup>10,24</sup>

## Ryanodine Receptor

$\text{Ca}^{2+}$ -induced opening of RyR allows  $\text{Ca}^{2+}$  to be released from the SR with each heart beat. The Marks laboratory has pioneered the idea that abnormal RyR function is involved in dysregulated  $\text{Ca}^{2+}$  in human heart failure.<sup>44</sup> This laboratory has published extensively on the idea that PKA-mediated hyperphosphorylation of RyR at serine 2808 increases

$\text{Ca}^{2+}$ -induced channel opening, thereby inducing what has been termed SR  $\text{Ca}^{2+}$  leak. The idea that RyR behaves abnormally in CHF and can produce a diastolic leak of SR  $\text{Ca}^{2+}$  has been studied extensively by a number of groups.<sup>45-47</sup> While most have been unable to confirm an exclusive role for PKA-mediated phosphorylation,<sup>48</sup> most have shown RyR dysfunction in CHF, and a number of studies have provided very strong new evidence that CaMKII-mediated phosphorylation of RyR at serine 2814 is critical for RyR dysfunction.<sup>49</sup> Important unresolved issues are the precise factors that cause RyR dysfunction in CHF, the specific role of these RyR functional changes in contractile abnormalities, and the role of RyR dysregulation in arrhythmias.

## The Sarcoplasmic Reticulum

The small size and slow decay rate of the  $\text{Ca}^{2+}$  transient in the failing heart is likely to involve slowed  $\text{Ca}^{2+}$  transport by SERCA2. This idea has been examined in numerous studies. SERCA mRNA, protein, and function (in vesicular preparations) have been measured in many models of hypertrophy and failure and in tissue samples from failing human hearts (Table 3-1). Most of these studies have shown that SERCA mRNA and/or protein are reduced in the end-stage failing human heart. However, the few studies that have failed to observe reduced SERCA protein abundance or  $\text{Ca}^{2+}$  uptake rates in failing human hearts<sup>50,51</sup> suggest that the routinely observed derangements in cellular  $\text{Ca}^{2+}$  handling in human myocytes are not always caused by a reduction in the abundance of SERCA protein. In this regard, the activity of the SERCA protein is inhibited by an associated protein, phospholamban (PLN). When PLN is phosphorylated (primarily by PKA-mediated pathways), it disassociates from SERCA and the associated inhibition is relieved. Increases in the PLN/SERCA stoichiometry or reduced PLN phosphorylation could both cause deranged SR  $\text{Ca}^{2+}$  transport without involving a change in SERCA abundance. There is support in the literature for both of these possibilities.<sup>52</sup> These are important issues in light of the in vitro studies showing that the contractility of failing human myocytes is improved when SERCA expression is increased and that heart failure in transgenic (MLP<sup>-/-</sup>) mice can be prevented by eliminating PLN expression and thereby increasing SERCA function.<sup>40</sup> These results suggest that SERCA may be an important therapeutic target in CHF. Most studies have found that the SR  $\text{Ca}^{2+}$  uptake rate is slowed in heart failure and this can lead to increased diastolic  $\text{Ca}^{2+}$  (diastolic dysfunction) and reduced SR  $\text{Ca}^{2+}$  storage (reduced systolic performance). Therefore, improving SR  $\text{Ca}^{2+}$  uptake might normalize abnormal diastolic and systolic  $\text{Ca}^{2+}$  abnormalities. An ongoing clinical trial<sup>53</sup> in which SERCA2 expression is increased in the failing heart via gene therapy should directly test this idea.

The idea that depressed SR function and reduced SR  $\text{Ca}^{2+}$  storage is linked to cardiac decompensation is supported by animal studies showing that increasing SERCA expression (with adenoviral infection techniques) improves the function of the hypertrophied or senescent<sup>54,55</sup> rat hearts and presumably delays the onset of CHF (see Chapter 50). This hypothesis is also supported by recent observations in genetically modified MLP<sup>-/-</sup> mice that develop CHF.<sup>4</sup> When these mice are crossed with either the phospholamban knockout mouse (PLN<sup>-/-</sup>) or a  $\beta$ -ARK-CT mouse, in which downregulation of  $\beta$ -adrenergic signaling is eliminated, the CHF phenotype does not develop over its normal time course.<sup>56,57</sup> The PLN<sup>-/-</sup> and  $\beta$ -ARK-CT mouse hearts and the SERCA-infected rat hearts cause their physiological effects via different  $\text{Ca}^{2+}$  regulatory proteins. However, all have enhanced SR function and improved contractility as their common phenotypical features. These studies suggest that an inability of the SR to take

**TABLE 3-1** Calcium Regulatory Protein Levels in End-Stage Human Heart Failure

Molecule	Assay	Quantity	Reference
Calsequestrin (CSQ)

up and store  $\text{Ca}^{2+}$  is a critical factor in heart failure induction and progression.

## Phospholamban

PLN is an SR protein that associates with SERCA<sup>51</sup> and inhibits its  $\text{Ca}^{2+}$  transport rate. Phosphorylation of PLN by either protein kinase A at serine 16 or  $\text{Ca}^{2+}$ -calmodulin dependent protein kinase at threonine 17<sup>58</sup> causes PLN to disassociate from SERCA and its inhibitory effect is removed. The enhanced SR  $\text{Ca}^{2+}$  transport increases the rate of decay of the  $\text{Ca}^{2+}$  transient and the amount of  $\text{Ca}^{2+}$  stored in the SR. These effects are centrally involved in the increased cardiac function needed to support aerobic exercise and other physiological activities

that require an increase in cardiac output. Alterations in either the abundance of PLN,<sup>23</sup> the PLN/SERCA stoichiometry,<sup>59</sup> reduced basal PLN phosphorylation<sup>60</sup> or a reduced ability of  $\beta$ -adrenergic signaling to phosphorylate PLN<sup>61</sup> could all contribute to the slow  $\text{Ca}^{2+}$  uptake and reduced SR  $\text{Ca}^{2+}$  load in CHF. In mouse studies, elimination of PLN, which will increase SR  $\text{Ca}^{2+}$  uptake, prevents the appearance of CHF in the MLP<sup>-/-</sup> mouse<sup>56</sup> and in some other mouse CHF models. These studies suggest that eliminating the PLN inhibitory effects on SERCA prevents and might even reverse CHF contractile effects. However, recent observations in humans with PLN mutations that reduce the inhibitory effects of PLN on SERCA suggest that in humans these changes cause cardiac dysfunction and premature death.<sup>62</sup> Therefore, at the present time it seems that PLN is a better heart failure therapeutic target in mice than in humans. Future work will need to explore why eliminating PLNs inhibitory effect on SERCA induces fundamentally different effects on the hearts of large and small animals.

### The Sodium-Calcium Exchanger

Under normal conditions,  $\text{Ca}^{2+}$  enters myocytes from the extracellular space down a large, inwardly directed electrochemical gradient. At the normal resting potential of  $-80$  mV and with normal concentrations of intracellular  $\text{Na}^+$  there is sufficient energy in the  $\text{Na}^+$  electrochemical gradient to remove  $\text{Ca}^{2+}$  from the cell via NCX (termed *forward-mode NCX*). This indirect, energy-utilizing active transport is the principal mechanism for  $\text{Ca}^{2+}$  efflux in cardiac myocytes.<sup>10</sup> When the membrane potential is depolarized and/or intracellular  $\text{Na}$  increases, the energy in the  $\text{Ca}^{2+}$  electrochemical gradient can be sufficient to produce  $\text{Ca}^{2+}$  entry coupled to  $\text{Na}^+$  efflux via reverse-mode NCX.<sup>63</sup> This aspect of  $\text{Ca}^{2+}$  transport via the exchanger has been largely ignored in previous studies of  $\text{Ca}^{2+}$  homeostasis in diseased cardiac myocytes.

Increases in the abundance and activity of the NCX in CHF are associated with altered  $\text{Ca}^{2+}$  homeostasis.<sup>64</sup> Some have suggested that the increased NCX activity in CHF is a compensation for the associated reduction in SERCA function.<sup>65</sup> This seems unlikely in myocytes from large mammals (like humans) because SR  $\text{Ca}^{2+}$  release and reuptake occur while the membrane potential is depolarized (during the plateau phase of the action potential) and depolarization reduces and may even eliminate forward-mode NCX activity.<sup>66</sup> Therefore, forward mode NCX and SERCA are unlikely to work in concert to lower cytosolic  $\text{Ca}^{2+}$  in human myocytes. In small mammals such as rats and mice, forward-mode NCX and SERCA function in concert to produce the decay of the  $\text{Ca}^{2+}$  transient because the AP duration in these species is much shorter than that of the  $\text{Ca}^{2+}$  transient.<sup>67</sup> It is also noteworthy that in these species the SERCA/NCX transport rate is large and  $\text{Ca}^{2+}$  efflux via NCX makes a very small contribution to the decay of the  $\text{Ca}^{2+}$  transient, even when the NCX is over-expressed.<sup>68</sup> These fundamental differences in normal  $\text{Ca}^{2+}$  transport mechanisms in large and small mammals point out that extrapolation of finding from one species to another must be done cautiously.

Our studies in human myocytes show that increased  $\text{Ca}^{2+}$  entry via reverse-mode NCX activity contributes to abnormal  $\text{Ca}^{2+}$  handling in failing human ventricular myocytes.<sup>25</sup> It appears that in failing human myocytes  $\text{Ca}^{2+}$  entry via the NCX during the plateau phase of the AP contributes to the slow decay of the  $\text{Ca}^{2+}$  transient and also is the preferential source of  $\text{Ca}^{2+}$  (in place of  $\text{I}_{\text{Ca,L}}$ ) to load the SR (Figure 3-2). These results show that the increased NCX abundance in human CHF actually contributes to the slow decay of the  $\text{Ca}^{2+}$  transient by adding  $\text{Ca}^{2+}$  to the bulk cytoplasm during systole. Our data suggest that  $\text{Ca}^{2+}$  homeostasis is abnormal in

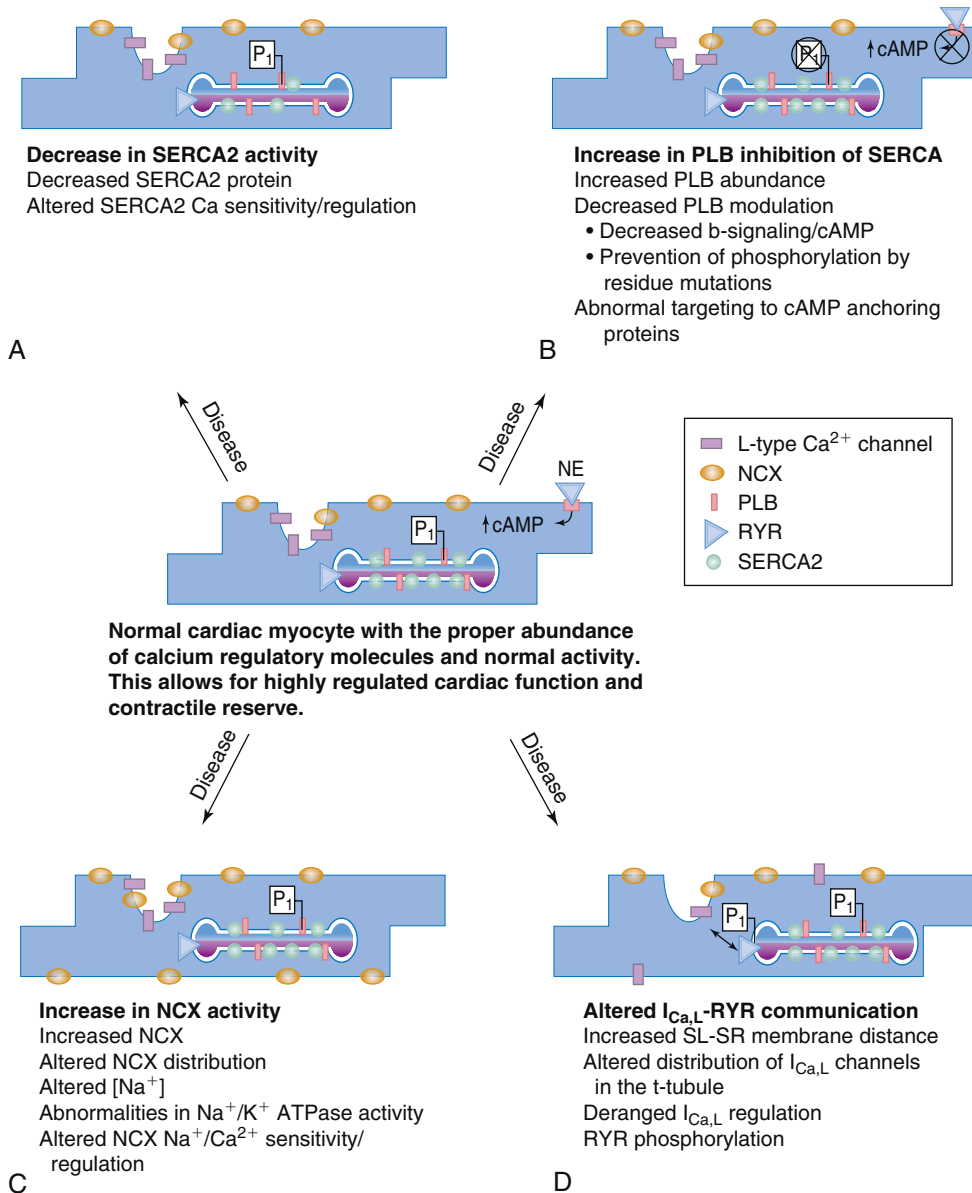

**FIGURE 3-2** Contribution of the L-type  $\text{Ca}^{2+}$  channel and reverse-mode  $\text{Na}^+/\text{Ca}^{2+}$  exchange to sarcoplasmic reticulum  $\text{Ca}^{2+}$  loading: voltage clamp experiments on a failing ventricular myocyte at  $37^\circ\text{C}$  in Tyrode solution with  $1\text{ mM Ca}^{2+}$ . Multiple steps from a holding potential ( $V_{\text{hold}}$ ) of  $-50$  mV to a test potential ( $V_{\text{test}}$ ) after a 1-minute rest period are shown. The left panel shows the steps to  $+10$ -mV-activated  $\text{Ca}^{2+}$  influx and small contractions with very little contractile staircase. The right panel shows the steps to  $+50$ -mV activated larger reverse-mode exchange current, smaller  $\text{Ca}^{2+}$  influx, and larger contractile staircase.

CHF because of a shift in the balance of activity of SERCA and NCX (a decrease in the SERCA/NCX transport capacities). This hypothesis predicts that changes in either the abundance or activity of either of these two  $\text{Ca}^{2+}$  transporters would lead to imbalances in  $\text{Ca}^{2+}$  homeostasis. These ideas are supported by the fact that decreases in the SERCA/NCX abundance are associated with reduced SR  $\text{Ca}^{2+}$  loading, slow decay of the  $\text{Ca}^{2+}$  transient, and a negative force-frequency relationship in the failing human heart.<sup>69</sup> We suggest that when this activity ratio is decreased, the peak systolic  $\text{Ca}^{2+}$  will be blunted because forward-mode NCX will eliminate  $\text{Ca}^{2+}$  from the cytoplasm.<sup>60</sup> This imbalance of SERCA and NCX transport would also produce a persistent unloading of SR  $\text{Ca}^{2+}$  stores that would further reduce the peak level of activator  $\text{Ca}^{2+}$  (Figure 3-3). The resulting lower levels of systolic  $\text{Ca}^{2+}$  coupled with the prolonged AP duration of the failing myocytes would promote reverse-mode NCX activity during the late phases of the AP plateau.<sup>25</sup> These changes slow the decay of the  $\text{Ca}^{2+}$  transient and produce elevated cytosolic  $\text{Ca}^{2+}$  during the terminal phases of the AP, thereby contributing to diastolic dysfunction. Our “balance of activity” hypothesis predicts that there can be many causes for dysfunctional  $\text{Ca}^{2+}$  regulation in CHF (see Figure 3-3) and that there will be multiple unique pharmacological and molecular targets that can prevent or rescue these defects. The ongoing clinical trial with SERCA2<sup>53</sup> should give some insight into these issues. New studies in large animal models of human CHF in which the relative activities of NCX and SERCA are manipulated would also provide important new insights.

### Deranged $\text{Ca}^{2+}$ Metabolism may not be Due to a Change in the Abundance of $\text{Ca}^{2+}$ Regulatory Proteins

The studies summarized previously support the idea that abnormal  $\text{Ca}^{2+}$  handling is a central player in the progressive deterioration of myocyte function in CHF. However, the idea that a change in the abundance of one specific  $\text{Ca}^{2+}$  regulatory protein causes the deranged  $\text{Ca}^{2+}$  metabolism of CHF is not well supported by the literature. There is more support for the idea that changes in the interaction of the  $\text{Ca}^{2+}$  regulatory proteins

**FIGURE 3-3** Potential contributors to deranged  $Ca^{2+}$  homeostasis in congestive heart failure. **A**, Decreased abundance of SERCA2 protein could explain reduced SR  $Ca^{2+}$  loading and slow decay of the  $Ca^{2+}$  transient in CHF. Alterations in SERCA2 protein due to phosphorylation or other modifications needs to be explored. **B**, SR function could be depressed in CHF because of increased expression of PLB (which could inhibit SERCA2) or from abnormal phosphorylation of PLB (which relieves the inhibition). **C**, Increased abundance of NCX (activity) could increase  $Ca^{2+}$  efflux during early phases of the  $Ca^{2+}$  transient and deplete SR calcium stores. Slow decay of the calcium transient could involve  $Ca^{2+}$  influx via reverse-mode NCX. NCX function in CHF could also be abnormal because of increased  $[Na^+]$ , or changes in the transporter distribution in surface and t-tubular membranes. **D**, Reduced SR  $Ca^{2+}$  release in CHF could result from altered junctional microarchitecture, changes in L-type  $Ca^{2+}$  channel distribution, or dysfunctional phosphorylation of the RyR release channels.

that work together to produce and modulate the size and shape of the  $Ca^{2+}$  transient cause the dysfunctional  $Ca^{2+}$  handling of the failing human myocyte. Recent studies clearly show that changes in the phosphorylation or other unrecognized modifications of  $Ca^{2+}$  handling proteins, rather than from a simple change in protein abundance, are likely causes of deranged contractility.<sup>70</sup> Future studies with proteomic (and other) approaches should provide new insights into these issues.

### Is Dysregulated $Ca^{2+}$ the Cause or the Effect of Heart Failure?

$Ca^{2+}$  handling is abnormal in the failing heart and the severity of the derangements increase with the severity of CHF. As heart failure progresses and the heart dilates, systolic wall stress increases and, in turn, increases the demand for contractile activity in the myocyte. Is the generalized blunting of  $Ca^{2+}$  handling in CHF a myocyte reactive response that helps reduce  $Ca^{2+}$  overload and the associated activation of cell death signaling or are these changes primary to the progression of the syndrome? The model systems to address many of these issues have recently been developed and should provide us with novel insights in the future.

Alterations in myocyte  $Ca^{2+}$  handling are centrally involved in the dysfunctional characteristics of the failing heart. The abundance, phosphorylation, and localization of almost all important  $Ca^{2+}$  handling proteins contribute to these defects. No one molecule is uniquely responsible. A major unanswered question is still whether restoring normal  $Ca^{2+}$  handling in the context of the CHF environment will be beneficial or will enhance CHF progression by inducing myocyte death from  $Ca^{2+}$  overload, or cause sudden death via lethal ventricular arrhythmias.

### THE ROLE OF CONTRACTILE PROTEINS IN REGULATING CARDIAC PERFORMANCE

In addition to abnormalities in myocyte calcium cycling, alterations in cardiac myofilament dynamics can contribute to reduced cardiac pump function in the setting of pathological cardiac hypertrophy and heart failure. Accordingly, the remainder of this chapter will highlight the involvement of contractile proteins and related molecules as key determinants of myocyte contractility and the abnormalities observed in failing myocytes. After an overview of basic features of sarcomeric architecture, actin-myosin cross-bridge dynamics, and

length-dependent modulation of contractile performance, we will consider several sarcomeric proteins that have emerged as functionally important regulators of normal and abnormal myocyte contractility. In this context, we will elucidate how naturally occurring mutations, transgenic manipulations, and disease-associated modifications to sarcomeric proteins continue to reveal their physiological and pathophysiological importance. These discussions will highlight the ways in which posttranslational regulation of myofilament activity via phosphorylation of key proteins has increasingly emerged as a critical regulator of cardiac performance in the setting of acute and chronic cardiac insults. Where evidence exists, defects observed in failing human hearts will be highlighted.

At the same time, one must recognize that contractile protein physiology cannot be completely dissociated from cellular  $\text{Ca}^{2+}$  homeostasis. Specifically, it is the cytosolic  $\text{Ca}^{2+}$  transient that triggers actin-myosin cross-bridge cycling that is the fundamental event of cellular shortening. Thus the cellular processes regulating action potential shape, excitation-contraction coupling, and the size and shape of the resulting  $\text{Ca}^{2+}$  transient, as discussed previously, clearly impact responses at the level of the contractile proteins. Conversely, because the contractile proteins themselves are by far the largest  $\text{Ca}^{2+}$  buffer in the cardiac myocyte, changes in the effective calcium sensitivity (affinity) of contractile proteins unavoidably affect the shape of the calcium transient and the ionic fluxes that affect the action potential. Finally, as illustrated by sarcomeric protein mutations, defects in contractile proteins often trigger cardiac hypertrophy and its attendant abnormalities in cardiac electrophysiology, calcium cycling, and neurohumoral regulation.

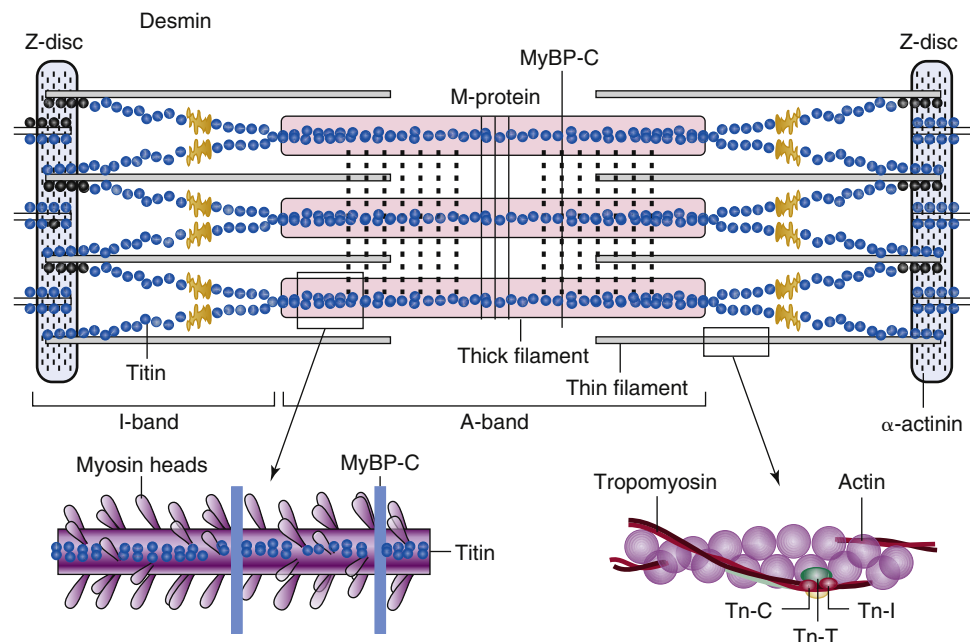

### Normal Contractile Protein Structure and Function

A large body of research has helped elucidate the intricate and truly exquisite molecular dynamics that contribute to the conformational and biochemical changes that ultimately produce actin-myosin cross-bridge cycling. Though space does not permit detailed review of these molecular dynamics, which are reviewed elsewhere,<sup>71</sup> an understanding of the abnormalities observed in failing hearts requires an overview of the major molecules that constitute and regulate the myocyte contractile proteins and their interactions under normal circumstances.

Within each sarcomere, there are two major contractile elements: the thick filament, consisting mainly of myosin and associated proteins, and the thin filament containing actin, tropomyosin, and the troponin complex, as illustrated in Figure 3-4. The thick filament protruding from the M-line consists of myosin, titin, and myosin-binding protein-C (MyBP-C), and myosin consists of the constituent proteins myosin heavy chain (MHC), essential light chain (ELC or MLC-1), and regulatory light chain (RLC or MLC-2). The hexagonal cross section of the thick filament is ideally suited for its interaction with six neighboring thin filaments. Filamentous actin (F-actin) is formed by polymerization of actin monomers. Two tropomyosin (Tm) strands and the troponin complex together regulate the affinity of F-actin for the myosin heads that drive the power stroke for sarcomere shortening. Actomyosin ATPase is the key enzyme driving cross-bridge cycling and this enzyme is regulated by the troponin complex. The troponin complex, in turn, is a heterotrimer composed of the following distinct gene products: troponin C (TnC), the  $\text{Ca}^{2+}$  receptor; troponin I (TnI), an inhibitor of the actin-myosin interaction that shuttles between tight binding to actin and tight binding to the  $\text{Ca}^{2+}$ -bound TnC; and troponin T (TnT) a tropomyosin binding component. The position of tropomyosin, as regulated by TnT, is ultimately the major determinant of the actin-myosin cross-bridge interaction. In systole, increased  $\text{Ca}^{2+}$  binding to TnC leads to conformational changes, including a movement of tropomyosin away from the F-actin groove toward a more peripheral location that exposes the myosin binding site and permits cross-bridge formation. During diastole, decreases in cytosolic  $\text{Ca}^{2+}$  reverse the conformational changes of systole resulting in marked reductions in, and a weakening of, actin-myosin cross-bridges.<sup>71</sup>

As shown in Figure 3-5, the normal relationship between the  $\text{Ca}^{2+}$  concentration and the force generated through cross-bridge interaction is sigmoidal. The relatively steep slope within the middle of this relationship reflects the cooperative nature of the interactions between attached cross-bridges and new thin filament binding of cross-bridges. Even in the absence of calcium, such cooperative binding can be demonstrated in vitro between reconstituted thin filaments and the globular region of myosin.<sup>72</sup> The maximal slope of the  $\text{Ca}^{2+}$ -force relationship is often referred to as the Hill coefficient. Changes in the cooperativity of cross-bridge dynamics are reflected by a change in the Hill coefficient. Recent studies have demonstrated that motifs within the C-terminal region of

**FIGURE 3-4** Diagram of the myocyte sarcomeric proteins. *MyBP-C*, myocyte binding protein-C; *TnC*, Troponin C; *TnI*, Troponin I; *Tn-T*, Troponin T. (Courtesy Granzier H.)

**FIGURE 3-5** Typical force–calcium relationship in an isolated cardiac muscle strip preparation. The dotted line represents a decrease in myofilament  $[Ca^{2+}]_i$  sensitivity such that higher  $[Ca^{2+}]_i$  levels are required to achieve an equivalent tension.

cTnI play a central role in negatively regulating cooperativity such that either natural mutations or purposeful deletions in this region induce increases in cooperative binding between the myosin head and the thin filament.<sup>73</sup> Decreases in myofilament calcium sensitivity are reflected by a shift to the right while increases in calcium sensitivity are reflected by a shift to the left. The main modulators of myofilament calcium sensitivity are sarcomere length and the phosphorylation states of key sarcomeric proteins. Actin-myosin interactions are further regulated by other contractile proteins, such as the myosin light chains and myosin-binding protein C in addition to the large elastic protein titin, as will be discussed later. For both the troponin complex and these other sarcomere-associated proteins, increasing evidence indicates that the balance of kinase-mediated phosphorylation and phosphatase-mediated dephosphorylation represents the major factor regulating myofilament calcium sensitivity in health and disease. Moreover, recently revised models of the spatial limitations within the sarcomere lattice indicate that the interaction between myosin and actin under basal physiological conditions is limited to only one cross-bridge for every seven actin molecules.<sup>74</sup> Accordingly, modulation of myofilament responses above basal conditions represents a source of contractile reserve available to meet increases in hemodynamic demands.

### Length Dependence of Contractility

Normal cardiac muscle exhibits increased contractile performance as preload or resting sarcomere length is increased. This phenomenon, often referred to as the length dependence of cardiac contractility, is the basis for the Frank-Starling relationship and represents one of the most important physiological mechanisms regulating cardiac pump function in vivo. Early studies in mammalian heart muscle demonstrated that alterations in muscle length modulate both the intracellular calcium transient<sup>75</sup> and myofilament  $Ca^{2+}$  sensitivity.<sup>76</sup> While these initial observations have been confirmed repeatedly, the mechanisms underlying the length dependence of calcium sensitivity have been controversial. One proposed mechanism is that the number of interacting cross-bridges is related to the degree of overlap of thick and thin filaments. However, the large increases in force observed with relatively small length changes suggest that other mechanisms are quantitatively more important.<sup>77</sup> A related geometric consideration is that *decreases* in lateral spacing between the thin and thick filaments during cell lengthening lead to enhanced cross-bridge interactions and improvements in contractile performance. However, studies by Konhilas et al indicate that changes in the lateral spacing between myofilaments can be dissociated from length-dependent alterations in force.<sup>78</sup> Other studies had supported a potential role for titin, the giant elastic protein within each sarcomere in converting

altered passive tension to changes in  $Ca^{2+}$  sensitivity.<sup>79</sup> Cazola et al demonstrated reduced length-dependent augmentation in force in mice with targeted deletion of myosin-binding protein; however, the augmented  $Ca^{2+}$  sensitivity at baseline may account for the reduced effect on increased sarcomere length in these in the MBP ablated animals.<sup>80</sup> Most recently, studies have suggested that the inhibitory region on TnI that includes the PKC phosphorylation site (Thr-144) is pivotal for determining the degree of length-dependent augmentation of contractility in cardiac sarcomeres in that replacement of this site with a proline (as in slow skeletal TnI) effectively eliminates myofilament length dependency.<sup>81</sup> Together, these findings suggest that signaling pathways involving troponin, myosin-binding protein and actin, rather than simply spatial relationships between actin and myosin, have a predominating influence on the magnitude of increased force generation in response to increases in sarcomere length.

In contrast to the defects in frequency-dependent increases in contractility and adrenergic responses characteristic of failing hearts, length dependence of contractility and the Frank-Starling mechanism are relatively intact in the failing heart. Beyond animal models supporting this assertion, several studies have used severely failing human hearts, available through cardiac transplantation, to examine the length dependence of contraction. Specifically, in studies using both intact hearts and isolated cardiac muscle strips, Holubarsch et al observed intact preload dependence of contractility in failing human hearts obtained at the time of cardiac transplantation.<sup>82</sup> These investigators and others further demonstrated length-dependent changes in calcium sensitivity in severely failing human hearts. The balance of this chapter will describe the current understanding of the ways in which alterations in sarcomeric proteins contribute to the pathophysiology of heart failure. On a general level, sarcomeric protein mutations, isoform switches, and posttranslational modifications have each emerged as functionally relevant and clinically important factors that can cause and/or contribute to contractile abnormalities observed in failing hearts. While each of these pathophysiological mechanisms will be discussed separately, it is all but certain that interactions among these mechanisms can and do occur in diseased hearts. Indeed, in the midst of substantial new revelations about functionally, significant pathophysiological mechanisms, defining the relative contributions of multiple simultaneous pathological adaptations represent a daunting investigative challenge.

## HEART FAILURE DUE TO MUTATIONS OF SARCOMERIC PROTEINS

A growing number of rare mutations have been shown to produce heritable cardiomyopathies. As discussed in Chapter 27, elucidation of a genetic cause is most frequent for hypertrophic cardiomyopathies with more than 450 different heritable mutations identified as capable of inducing increases in wall thickness in the absence of increased hemodynamic load.<sup>83</sup> Interestingly, most of these mutations involve a single nucleotide within the coding region of a cardiac myocyte sarcomeric protein and exhibit autosomal dominant inheritance with variable penetrance. A primary genetic cause has also been inferred, and sometimes identified, in cases of arrhythmogenic right ventricular dysplasia and LV noncompaction cardiomyopathy. Even in dilated cardiomyopathies with less distinctive morphologies, recent analyses suggest that more than 30% of cases are directly caused by single gene mutations; these are often related to cytoskeletal or metabolic function, with less than 20% linked to sarcomeric protein mutations.<sup>84</sup> The mutations of sarcomeric proteins identified to date in human myocardium are listed in Table 3-2. One interesting observation from this list is that the

**TABLE 3–2     Sarcomeric Protein Mutations Associated with Heritable Cardiomyopathy**

**Mutations Associated with a Familial Hypertrophic Cardiomyopathy<sup>85</sup>**

- Cardiac troponin I (cTnI)

- Cardiac  $\beta$ -myosin heavy chain
- Cardiac myosin-binding protein C (cMBP-C)
- $\alpha$ -tropomyosin
- Actin

morphological and functional phenotype of hearts with distinct mutations involving different sarcomeric protein can be quite similar. For example, defects involving at least 11 different sarcomeric proteins can produce a primary hypertrophic cardiomyopathy in humans.<sup>85</sup> Conversely, alternative point mutations within a single sarcomeric protein such as TnT can be associated with very different phenotypical features depending on the exact location of the mutation.<sup>84</sup> For example, cardiac troponin T, titin, myosin-binding protein C, and tropomyosin mutations can be observed with either hypertrophic or dilated cardiomyopathies. As will be discussed for specific sarcomeric proteins, the ability to create an animal model analogue of mutations producing human genetic cardiomyopathies has increasingly empowered investigations defining how particular sarcomeric protein domains regulate myocyte contractility. Analogously, site-directed mutagenesis in experimental animal models also permits insights into the role of specific coding sequences that have not yet been associated with spontaneous mutations.

The composite body of knowledge from such careful observational and experimental studies is growing rapidly and already permits several interesting and important generalizations about heritable cardiomyopathies. For example, there is a gene-dosage effect for sarcomeric protein mutations such that the phenotypical manifestations can be correlated with the magnitude of pathological gene expression. Finally, it is clear that the full morphological and functional impact of a particular allelic mutation is clearly the result of secondary adaptations to the initial mutation.<sup>84</sup> For example, one specific mutation affecting myofilament  $\text{Ca}^{2+}$  sensitivity may trigger a compensatory concentric hypertrophy and be associated with a primary diastolic abnormality, while another mutation affecting cross-bridge cycling may alter force transmission and be manifested as a dilated cardiomyopathy phenotype with systolic dysfunction. These stereotyped secondary adaptations to sarcomeric mutations likely explain why there are relatively few distinct phenotypes associated with a wide variety of single gene mutations.

**SARCOMERIC PROTEIN ISOFORM SWITCHES IN FAILING HEARTS**

Independent of either total or relative myofibrillar protein abundance in failing human hearts, several studies have also reported changes in contractile protein isoforms, some

of which are analogous to isoform shifts observed in animal models of heart failure. For example, normal adult rat hearts express almost entirely the  $\alpha$ -isoform of myosin heavy chain ( $\alpha$ -MHC), while rats with experimental hypothyroidism or heart failure develop an almost complete conversion to  $\beta$ -MHC.<sup>86</sup> In failing human hearts, multiple studies have reported qualitatively similar, but quantitatively lesser, shifts with  $\alpha$ -MHC expression decreasing from 5% to 15% in the normal myocardium to values up to 2% in the failing human myocardium.<sup>87</sup> Other studies using animals with experimental hypothyroidism and in vitro constructs have demonstrated that such relatively small shifts in  $\alpha$ -MHC abundance can be functionally significant with greater  $\alpha$ -MHC expression allowing faster contraction.<sup>88</sup> Using a similar approach, Metzger et al also showed that increased  $\beta$ -MHC was associated with a decrease in myofilament calcium sensitivity.<sup>89</sup> From a mechanistic standpoint, recent studies demonstrated that a highly conserved miRNA (miR-208) encoded by an intron of an  $\alpha$ -myosin heavy chain (MHC) gene plays a pivotal role in regulating the balance of  $\alpha$ - and  $\beta$ -MHC experimental hypothyroidism and pressure overload.<sup>90</sup> Interestingly, miRNA-208 knockout mice unable to upregulate  $\beta$ -MHC were resistant to hypertrophy and fibrosis during chronic pressure overload, but developed age-dependent defects in sarcomere structure and cardiac performance. These studies demonstrate a functionally significant role for a cardiac-specific miRNA in the elegant coordination of contractile protein expression in normal and stressed hearts and also suggest that the pathological  $\alpha$ - to  $\beta$ -MHC isoform switch might have an adaptive role in the setting of sustained hemodynamic overload.

Analogous shifts to fetal isoforms during heart failure have also been observed for other contractile proteins. For example, smooth muscle  $\alpha$ -actin is normally expressed during cardiac myogenesis, but is absent in the normal adult mammalian heart that expresses only the skeletal and cardiac actin isoforms. However, during cardiac hypertrophy triggered by pressure overload in rats or dilated cardiomyopathy in humans, smooth muscle  $\alpha$ -actin is reexpressed in the heart.<sup>91</sup> Similar pathological expression of an atrial isoform of the cardiac myosin essential light chain (cMLC-1) has been reported in failing human hearts with congenital heart disease.<sup>92</sup> In the latter case, the magnitude of atrial MLC expression in the right ventricular myocardium of patients with tetralogy of Fallot was positively correlated with shortening velocity at a variety of different afterloads.<sup>92</sup> Investigators from the Morano laboratory have also observed a similar correlation between myocardial atrial MLC content and both in vitro and in vivo measures of contractility among patients with hypertrophic cardiomyopathy.<sup>93</sup> Moreover, in these studies investigators demonstrated a gene-dose response in human myocardium with greater “pathological” ventricular expression of the atrial MLC-1 expression associated with faster rates of contraction, suggesting that some isoform switches in failing hearts may be adaptive. More recently, developmental isoform switches have also been observed for titin, the large elastic filament that plays a prominent role in regulating myocyte passive tension. In the developing heart, the longer, more compliant titin isoform (N2BA) predominates in cardiac myocytes.<sup>94</sup> After birth, there is a transition to greater representation of the stiffer N2B isoform, which ultimately becomes the dominant isoform in the left ventricle. In the setting of advanced systolic heart failure with a severely reduced ejection fraction, there is a relative increase in the N2BA isoform associated with increased myofibrillar compliance.<sup>95</sup> On the other hand, in patients with heart failure and preserved ejection fraction, sometimes called diastolic heart failure, a lower ratio N2BA:N2B has been reported in association with a relative increase in stiffness,<sup>96</sup> as shown in Figure 3-6. Despite these compelling results, a challenge to interpreting the overall functional significance of isoform

switches in human myocardium derives from the fact that multiple isoform shifts typically occur concurrently in the same muscle preparation.

## PHOSPHORYLATION-DEPENDENT REGULATION OF SARCOMERIC PROTEINS

Some of the most important and dynamic ways in which sarcomeric protein function is regulated in normal and failing hearts are via posttranslational modifications. In particular, it has been increasingly evident that the regulation of contractile protein function and interactions by the phosphorylation state of several key molecules is as important as the regulation of  $\text{Ca}^{2+}$  cycling dynamics in regulating contractility. Indeed, coordinated regulation of both  $\text{Ca}^{2+}$  cycling and  $\text{Ca}^{2+}$  sensitivity is a defining feature of physiological signaling while distortions in both processes conspire to produce the characteristic defects observed in myocytes from diseased hearts. Further complicating the situation is the fact that multiple different signaling pathways and kinases are involved in phosphorylation of sarcomeric proteins and at least two of these proteins (cTnI and titin) are phosphorylated via more than one kinase. Table 3-3 summarizes the current understanding of the types and functional effects of sarcomeric protein phosphorylation in normal hearts and the alterations observed in failing mammalian hearts.

**FIGURE 3-6** Functional impact of titin isoform switching. Shown are exemplary passive sarcomere length-tension relationships of cardiac myofibrils. Titin-based mechanical signaling in normal and failing myocardium. *J Mol Cell Cardiol* 2009;46:490-498.)

## PKA-mediated Phosphorylation

Myocardial contractile performance is augmented when  $\beta$ -adrenergic receptors are stimulated by catecholamines, resulting in activation of protein kinase A (PKA) and PKA-mediated phosphorylation of several myocyte proteins. Specifically, combined with phosphorylation of the L-type calcium channel, the ryanodine receptor, and phospholamban, PKA-mediated phosphorylation of key myofibrillar proteins permits the inotropy and faster relaxation required for achievement of enhanced stroke volume and faster heart rates required during physiological stress. It is well established that PKA-dependent phosphorylation of three molecules, cardiac TnI, myosin-binding protein C, and titin, can affect myofilament calcium sensitivity, cross-bridge dynamics, passive stiffness, and overall contractile performance.

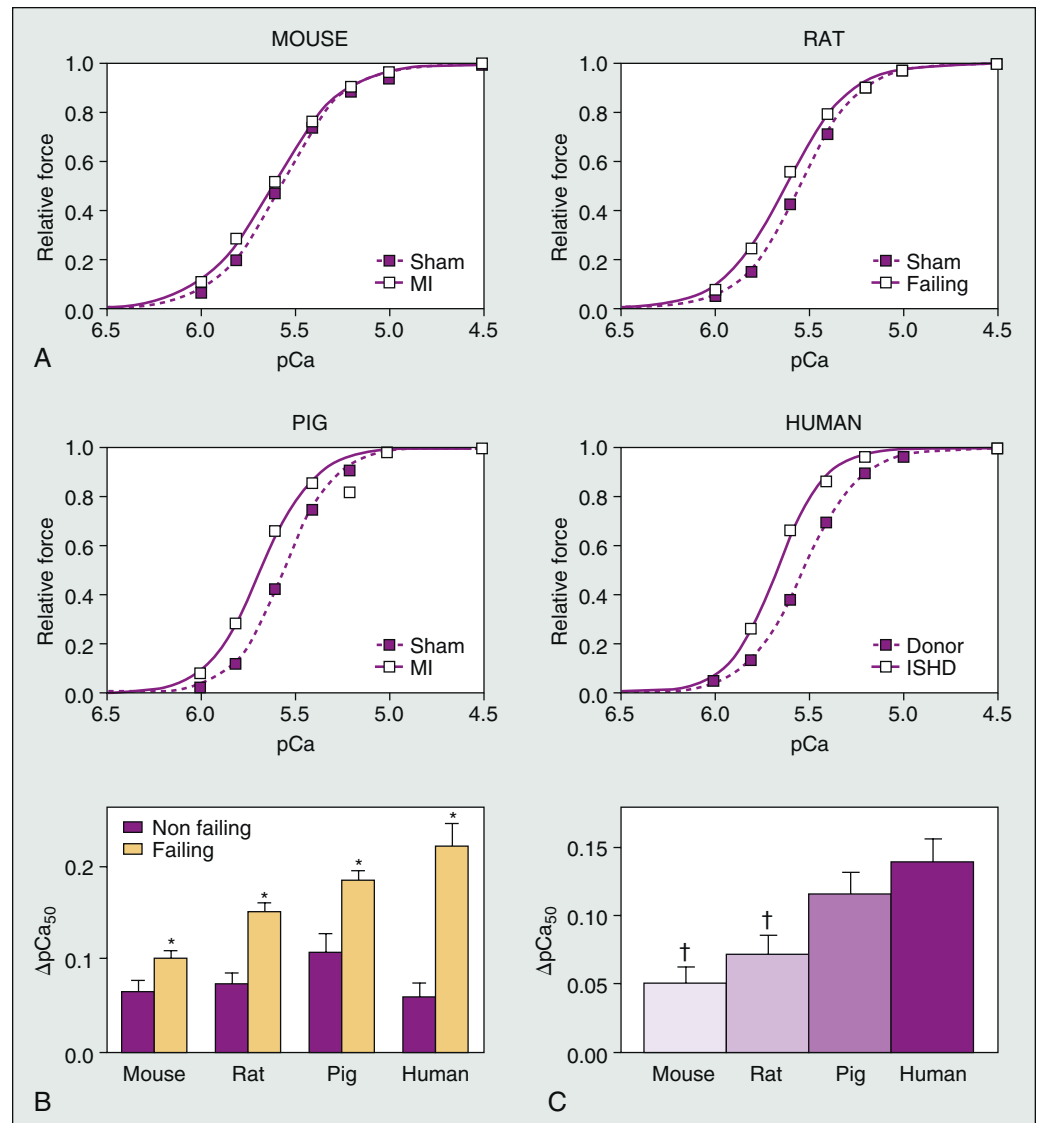

Under normal circumstances, increased adrenergic stimulation leads to *decreased* myofibrillar calcium sensitivity via PKA-dependent phosphorylation of cTnI and cMBP-C.<sup>80,97</sup> PKA-dependent stimulation of cTnI involves phosphorylation of two serine residues in the N-terminal region of cardiac TnI,<sup>98</sup> which lowers the affinity of TnC for  $\text{Ca}^{2+}$ . PKA-dependent stimulation of cMBP-C involves phosphorylation of three separate serine residues resulting in greater interaction between the thick filament and actin and enhanced force generation.<sup>99</sup> PKA-dependent phosphorylation of cMBP-C also accelerates actin-myosin cross-bridge kinetics and augments in vivo myocardial contractile performance both in vitro and in vivo.<sup>100</sup> Under loaded conditions, the net effect of cTnI and cMBP-C phosphorylation via PKA is increased force-generating capacity and increased absolute power output, likely reflecting a predominating effect of cMBP-C on cross-bridge cycling.<sup>101,102</sup>

Recognizing that the syndrome of heart failure is characterized by chronic increases in cardiac adrenergic stimulation (see Chapter 10), several groups have examined the state of PKA-mediated regulation of myofibrillar function in failing human hearts and animal models of heart failure. Despite the potential effect of increased cTnI phosphorylation to decrease  $\text{Ca}^{2+}$  sensitivity, greater myofibrillar  $\text{Ca}^{2+}$  sensitivity has been reported in failing mouse, rat, dog, pig, and human hearts compared with nonfailing controls,<sup>103</sup> as shown in Figure 3-7. In each of these models, there was an intact or enhanced response to direct (receptor-independent) PKA stimulation in vitro and a decreased level of in vivo cTnI phosphorylation despite increased ambient adrenergic tone, suggesting uncoupling of the adrenergic stimulation cascade. In interspecies comparisons, it is particularly noteworthy that the greatest degree of enhanced  $\text{Ca}^{2+}$  sensitivity and uncoupling was observed in failing human myocardium, with rodent models of heart failure tending to substantially underestimate the defects. These

**TABLE 3-3** Summary of Sarcomeric Protein Phosphorylation in Mammalian Hearts

Sarcomeric Protein	Kinase	No. of Sites	Normal Phosphorylation Effect	HF Abnormality
Troponin I (cTnI)	PKA	2	Reduces $\text{Ca}$ sensitivity and increases cross-bridge kinetics <sup>147</sup>	Reduced phosphorylation <sup>103</sup>
	PKC	1	Reduces $\text{Ca}$ sensitivity <sup>148</sup>	Increased phosphorylation <sup>112</sup>
Troponin T (cTnT)	PKC	4	Reduces $\text{Ca}$ sensitivity and slows cross-bridge kinetics <sup>109</sup>	Increased phosphorylation <sup>110</sup>
Myosin-binding protein C (cMBP-C)	PKA	3	Speeds force activation and force decay <sup>100</sup>	Reduced phosphorylation <sup>80</sup>
Myosin essential light chain (cMLC1)	MLCK	2	Reduces contractility <sup>149</sup>	Unknown
Myosin regulatory light chain (cMLC2)	MLCK	2	Increases peak force and $\text{Ca}$ sensitivity, slows rate of force decay <sup>150</sup>	Reduced phosphorylation <sup>151</sup>
Titin	PKA	1	Decreases passive stiffness <sup>113</sup>	Reduced phosphorylation <sup>116</sup>
	PKG	1	Decreases passive stiffness <sup>114</sup>	Reduced phosphorylation <sup>114</sup>

**FIGURE 3-7**  $\text{Ca}^{2+}$ -sensitivity of myofilaments in different species. **A**,  $\text{Ca}^{2+}$ -sensitivity of the myofilaments was significantly higher in failing compared with nonfailing controls in all studies. **B**, A reduction in maximal force generating capacity was observed in postinfarct remodeled myocardium.  $P < .05$ , animal versus human in Bonferroni posttest analysis. **C**, Force measurements in cardiomyocytes from human catheter biopsies revealed enhanced cardiomyocyte stiffness in heart failure patients with reduced left ventricular ejection fraction (HFREF) compared with controls.  $*P < .05$ , failing versus nonfailing in unpaired Student  $t$ -test;  $\#P < .05$ , effect of PKA in paired Student  $t$ -test. (From Hamdani N, de Waard M, Messer AE, et al. Myofilament dysfunction in cardiac disease from mice to men. *J Muscle Res Cell Motil* 2008;29:189-201.)

differences could reflect the relatively small dynamic range of adrenergic responses in rodents,<sup>103</sup> or the fact that failing human tissue is typically obtained from profoundly diseased hearts at the time of cardiac transplantation. Complementing these findings, several investigators have demonstrated reduced baseline phosphorylation of cTnI and cMBP-C in failing human hearts compared with nonfailing controls.<sup>103,104</sup>

### PKC-mediated Phosphorylation

Analogous to PKA-dependent phosphorylation involved with adrenergic stimulation, it is well established that many of cellular actions of vasoactive peptides like angiotensin II and endothelin are mediated via PKC-dependent signaling processes. Gwathmey and Hajjar demonstrated that PKC-dependent phosphorylation can modulate the  $\text{Ca}^{2+}$ /force relationship in both failing and nonfailing human myocardium.<sup>105</sup> Specifically, these investigators observed that phorbol ester reduces the peak force development and the slope of the  $\text{Ca}^{2+}$ /force relationship, consistent with PKC-mediated reductions in  $\text{Ca}^{2+}$  sensitivity. These findings were complemented by studies demonstrating that phosphorylation of both cTnI and/or cTnT by direct PKC stimulation causes inhibition of Mg ATPase activity.<sup>106</sup> Moreover, studies using transgenic mutants lacking sites for PKC-mediated phosphorylation of troponins have defined the relative roles of these regulatory

molecules. In this manner, Noland et al have demonstrated that phosphorylation of cardiac cTnI at Ser-43/Ser-45 is responsible for PKC-mediated decreases in  $\text{Ca}^{2+}$  sensitivity while cTnI phosphorylation at Ser-23/Ser-24 is responsible for regulation of actomyosin MgATPase.<sup>107</sup> In addition, PKC-dependent phosphorylation of cardiac cTnT may amplify the myofilament desensitization induced by PKC-mediated phosphorylation of cTnI.<sup>108</sup> Other studies demonstrate that the Thr-206 phosphorylation site on cTnT is capable of reducing maximum  $\text{Ca}^{2+}$ -saturated force, myofilament  $\text{Ca}^{2+}$  sensitivity, and the rate of cross-bridge cycling.<sup>109</sup>

Recent studies indicate that increased PKC-dependent phosphorylation of myofilament target proteins contributes to altered contractility in failing hearts. For example, Noguchi et al linked PKC phosphorylation of thin filaments from failing human hearts to decreased maximal force development despite increased shortening velocity.<sup>110</sup> In isolated cardiac myocytes from human hearts, van der Velden et al reported a PKC-mediated decrease in  $\text{Ca}^{2+}$  sensitivity with minimal effects on peak force development.<sup>111</sup> By examining PKC-mediated effects with and without antecedent PKA activation, these studies demonstrated that intact PKC-dependent phosphorylation of both cTnI and cTnT may serve to improve diastolic function in failing human myocardium in which PKA-mediated TnI phosphorylation is decreased. These studies also implicated specific upregulation of PKC $\alpha$  and PKC $\beta$

isoforms as contributors to increased PKC-dependent activity in heart failure with reduced expression of these isoforms observed after LVAD-support. Complementary studies by Belin et al also demonstrated significant increases in PKC $\alpha$  content and activity in severely failing hearts following either myocardial infarction or pressure-overload hypertrophy in rats, but observed no change in PKC $\alpha$  activity in animals with compensated hypertrophy.<sup>112</sup> By demonstrating that PKC $\alpha$  stimulation had an enhanced effect on normal myocardium while dephosphorylation via protein phosphatase 1A had an enhanced effect on failing myocardium (Figure 3-8), these studies support a functionally important role for PKC-dependent hyperphosphorylation of myofilament proteins in severely failing hearts.

## Titin Phosphorylation and Passive Properties of Myocytes

Although preload-dependent modulation of contractility is relatively intact in failing hearts, a key potential regulator of preload-dependent contractility in vivo is the passive stiffness of the myocardium. In multicellular preparations from failing human hearts, a greater increase in resting tension is typically required to achieve any given increment in muscle length (increased stiffness) so that the ratio of increased developed force to increased passive force is somewhat decreased. Though not excluding an additional role for extracellular matrix components in causing increased passive stiffness, recent studies demonstrate that increased passive stiffness of cardiac myocytes themselves is a characteristic of hearts with severely reduced systolic dysfunction.<sup>103</sup>

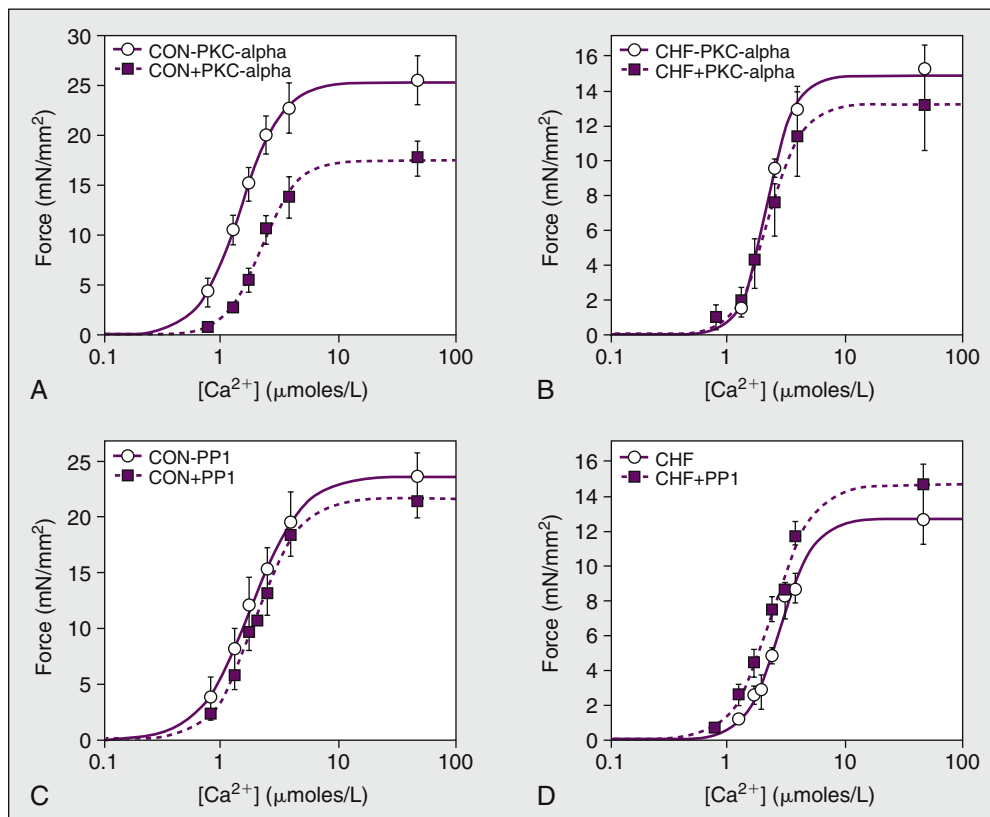

Recent studies demonstrate that titin phosphorylation via either a cAMP/PKA-dependent mechanism<sup>113</sup> or cGMP/PKG-dependent signaling<sup>114</sup> may alter this sarcomeric protein's contribution to cardiac myocyte passive stiffness in failing hearts. In contrast to the titin isoform switches discussed previously, these adaptations can occur on a beat-to-beat basis. Under

normal circumstances, the decrease in passive tension induced by titin phosphorylation is greater following PKA phosphorylation than following PKG phosphorylation<sup>115</sup> as illustrated in Figure 3-9. In this context, the observation that increased myocyte passive stiffness with systolic dysfunction can be abrogated by direct PKA activation supports a role for impaired adrenergic signaling as an underlying mechanism for this pathophysiological defect.<sup>103</sup> Other studies suggest that defects in adrenergic signaling contribute even more to increased myocyte passive stiffness in failing hearts with preserved systolic function that is often referred to as "diastolic function".<sup>96,116</sup>

Defects in PKG-mediated titin phosphorylation, as is activated by nitric oxide or natriuretic peptide signaling, have likewise been implicated as contributing to increased myocyte passive stiffness in failing human and canine hearts.<sup>114</sup> In these studies, reductions in both PKA- and PKG-dependent titin phosphorylations were observed in failing hearts compared with nonfailing controls. These studies raise the therapeutic possibility that pathological increases in myocardial stiffness could be abrogated by interventions that enhance PKA- or PKG-dependent signaling in failing hearts. Supporting this possibility, two separate groups have demonstrated that sustained inhibition of cGMP proteolysis via phosphodiesterase 5 inhibition improves indices of LV diastolic function in murine hearts.<sup>117,118</sup>

## LIMITED PROTEOLYSIS OF CONTRACTILE PROTEINS

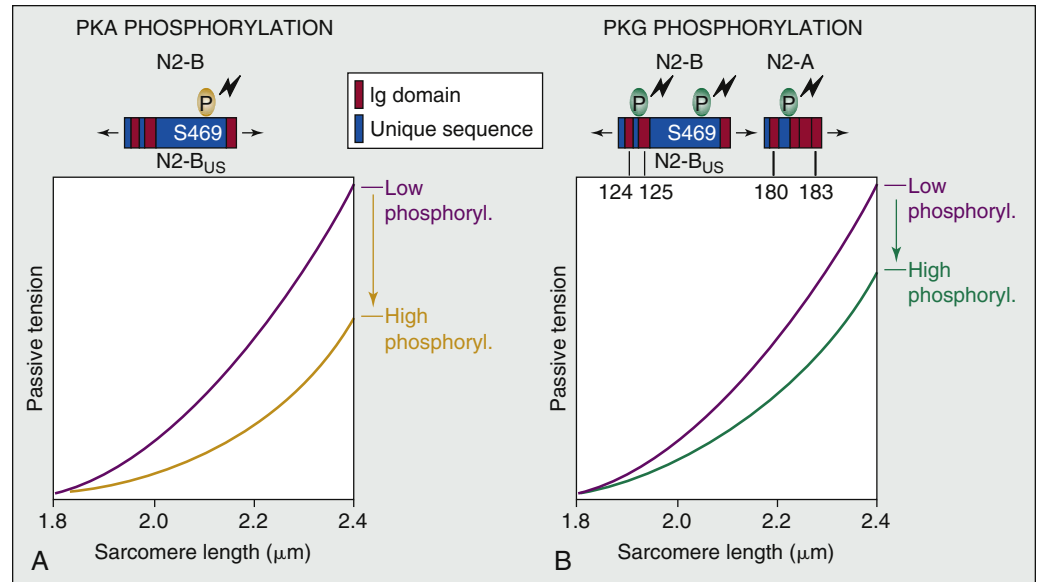

Another potentially important posttranslational modification of contractile proteins contributing to contractile dysfunction is proteolysis of myofilaments themselves or key regulatory proteins. Using explanted human heart tissue, studies by Hein et al have demonstrated that contractile proteins manifest clear-cut structural changes by immunohistochemistry after only 10 minutes of ex vivo warm ischemia.<sup>119</sup> In this

**FIGURE 3-8** Functional effects of PKC phosphorylation in isolated myocytes. **A**, Average force- $[Ca^{2+}]$  relations for control (CON) myocytes ( $n = 10$ ) before (CON-PKC) and after (CON+PKC) incubation with recombinant PKC-. **B**, Average force- $[Ca^{2+}]$  relations for CHF myocytes ( $n = 7$ ) before (CHF-PKC) and after (CHF+PKC) incubation with recombinant PKC-. **C**, Average force- $[Ca^{2+}]$  relations for control (CON) myocytes ( $n = 9$ ) before (CON-PP1) and after (CON+PP1) incubation with the catalytic subunit of protein PP1 (0.15 U/mL). **D**, Average force- $[Ca^{2+}]$  relations for CHF myocytes ( $n = 8$ ) before (CHF-PP1) and after (CHF+PP1) incubation with the catalytic subunit of protein PP1 (0.15 U/mL). (From Belin RJ, Suman-dea MP, Allen EJ, et al. Augmented protein kinase C- $\alpha$ -induced myofilament protein phosphorylation contributes to myofilament dysfunction in experimental congestive heart failure. *Circ Res* 2007;101:195-204.)

**FIGURE 3-9** Functional impact of titin phosphorylation. Shown are exemplary passive sarcomere length-tension relationships of cardiac myofibrils. *N2-B<sub>US</sub>*, unique sequence of the cardiac N2-B titin domain; *S469*, serine residue 469 of the human N2-B<sub>US</sub>; 124, 125, 180, 183, I-band titin Ig-domains. (From Kruger M, Linke WA. Titin-based mechanical signalling in normal and failing myocardium. *J Mol Cell Cardiol* 2009;46:490-498.)

context, a growing body of literature has demonstrated that limited proteolysis of contractile proteins plays a pivotal role in the pathophysiology of myocardial stunning, a phenomenon in which a transient ischemic insult, followed by reperfusion, produces a sustained decrease in contractile dysfunction. In one representative study, Gao et al reported that rat cardiac trabeculae exposed to 20 minutes of ischemia and reperfusion before isolation exhibited relatively intact cytosolic  $\text{Ca}^{2+}$  transients in association with a severe contractile defect, suggesting decreased thin filament  $\text{Ca}^{2+}$  sensitivity.<sup>120</sup> Subsequent studies by McDonough et al correlated thin filament dysfunction with stepwise degradation of cTnI during progressive increases in the duration of transient cardiac ischemia.<sup>121</sup> With more severe ischemia, there is release of TnI fragments (e.g., TnI<sub>1-193</sub>) from myocytes enabling detection of myonecrosis by plasma assays. Interestingly, a subpopulation of phosphorylated TnI appears to be more resistant to ischemia-induced proteolysis demonstrating one of many interactions among posttranslational modifications of contractile proteins.

Building on these observations, some investigators have suggested that limited proteolysis of myofibrils with associated changes in  $\text{Ca}^{2+}$  sensitivity and force generation could be an important initiating or propagating pathophysiological process within the failing heart.<sup>122</sup> In this context, Feng et al demonstrated that increased preload during transient ischemia is a key factor mediating limited proteolysis and that significantly elevated preload can induce limited TnI proteolysis even in the absence of frank ischemia.<sup>123</sup> These studies further implicated activation of  $\mu$ -calpains as key degradative enzymes mediating TnI proteolysis during increased preload. These findings suggest the hypothesis that sustained increases in LV end-diastolic pressure, as are often observed among patients with advanced heart failure, could contribute to contractile dysfunction via thin filament proteolysis. Potential therapeutic opportunities related to these mechanisms are suggested by recent studies demonstrating that heat shock protein 27 (Hsp27) activation via overexpression protects cTnI, cTnT, and other sarcomeric proteins against proteolysis during transient ischemia or acute calcium overload.<sup>124</sup>

## CONCLUSIONS

Advanced physiological and molecular assays combined with a rapidly increasing array of informative transgenic models have accelerated the pace of new insights into the cellular

basis of myocardial contractile dysfunction. Although these new insights have helped define the mechanisms behind many previously unexplained physiological and pathological phenomena, they have also highlighted previously unanticipated levels of complexity relevant to cardiac myocyte signaling and biophysics. These complexities include varied mechanisms of control and interaction that raise many new and important questions concerning the hierarchy pathological mechanisms operating within cardiac myocytes from failing human hearts.

Alterations in myocyte  $\text{Ca}^{2+}$  handling appear to be centrally involved in the dysfunctional characteristics of the failing heart. Indeed, the literature suggests that changes in the abundance or activity of almost all of the important  $\text{Ca}^{2+}$  regulatory molecules contribute to deranged  $\text{Ca}^{2+}$  homeostasis in the failing heart. However, it is unlikely that a change in the abundance of a single  $\text{Ca}^{2+}$  regulatory molecule is consistently responsible for contractile defects in failing hearts. At the same time, there is little doubt that alterations at the level of the sarcomeric proteins contribute to the pathophysiology of advanced heart failure in humans. While studies of patients with familial cardiomyopathies demonstrate how single allelic mutations affecting sarcomeric proteins can be sufficient to induce profound phenotypical manifestations, such disease-causing mutations represent only a small fraction of the functionally important changes in sarcomeric proteins observed in failing hearts. Indeed, recent studies have increasingly identified pathological changes in myofilament isoforms and phosphorylation that are both functionally significant and potential targets with therapeutic interventions.

## FUTURE DIRECTIONS

A major unanswered question is still whether restoring normal  $\text{Ca}^{2+}$  handling in the context of the CHF environment will be beneficial or will enhance CHF progression by inducing myocyte death from  $\text{Ca}^{2+}$  overload or cause sudden death via lethal ventricular arrhythmias. Likewise, as we address current gaps in our knowledge of pathological changes in myofilament proteins, we will need to define which isoform switches and posttranslational modifications are adaptive, rather than detrimental. In addition, future studies will need to include improved integration of findings to determine the net effects of the multiple simultaneous abnormalities of isoforms and phosphorylation states that are typically observed

in failing hearts. These and other studies characterizing HF-associated defects, particularly those examining human hearts, must move beyond the most extreme comparisons of end-stage hearts with nonfailing hearts to better reflect the full spectrum of abnormalities, including hearts with mild and moderate systolic dysfunction and failing hearts with preserved systolic ejection. In this regard, the clinical impact of new information will be particularly enhanced by studies clarifying whether particular cellular targets of therapy are relevant across a wide spectrum of disease or only applicable to a particular etiology or disease stage. Though not usually an initial step, such therapeutic interventions should ultimately be examined in the context of established clinical pharmacotherapy. For example, to what extent do  $\beta$ -blockers obviate the need for targeting abnormalities of PKA-dependent signaling observed at the level of  $\text{Ca}^{2+}$  cycling and myofilament proteins?

uncontrolled deleterious events. However, the scar does not possess the properties of the uninjured tissue and therefore negatively affects the overall performance of the organ. Despite the presence of resident adult stem cells in several organs, tissue repair involves scar formation.<sup>1-3</sup> Tissue repair in embryos is rapid, efficient, and scar-free.<sup>4-7</sup> Skin wounds in the early mammalian embryo heal with *restitutio ad integrum*, whereas wounds in adults result in scarring. The most important difference between these two conditions involves the inflammatory response. In embryonic wounds, a lower number of less differentiated inflammatory cells is present in the damaged region and the growth factors that accumulate at the site of healing are different from those in the adult.<sup>4,7,8</sup> Therefore, modulation of the inflammatory response may improve repair in adult organs but the removal of these extrinsic signals may interfere with long-term regeneration. Resident stem cells or exogenous progenitor cells administered in proximity of the lesion can modify the microenvironment by secreting cytokines that favor cell homing, growth, and differentiation.<sup>9-12</sup> Enhancement of intrinsic growth by resident or nonresident stem cells constitutes the basis of myocardial regeneration. Although 11 independent laboratories have identified cardiac progenitor cells (CPCs) in the adult heart,<sup>13-25</sup> the controversy concerning myocyte regeneration has not been resolved yet.<sup>26-28</sup> Questions continue to be posed regarding CPC function and the mechanisms modulating myocyte turnover with aging and cardiac repair in the presence of pathological states. Similarly, the plasticity of bone marrow-derived progenitor cells (BMPCs) and in particular their ability to transdifferentiate and acquire the myocyte lineage has been challenged and data in favor<sup>12,29-36</sup> or against<sup>37-44</sup> this possibility continue to appear in the literature (for review see Leri<sup>45</sup>).

## CELL THERAPY

Endothelial progenitor cells, mononuclear bone marrow cells, and CD34-positive cells have been administered to patients affected by acute myocardial infarction, chronic ischemic heart failure, and refractory angina.<sup>46-62</sup> These interventions have had positive outcomes documenting not only the feasibility and safety of this therapeutic approach but also beneficial effects on cardiac function.<sup>63-65</sup> While patients are currently enrolled in large clinical trials (see Chapter 51), the documentation of cardiac-specific adult progenitor cells has created great expectations concerning the use of this new cell for the management of human disease. Theoretically, the most logic and potentially powerful cell to be employed for cardiac repair is the CPC.<sup>66-68</sup> It is intuitively apparent that if the adult heart possesses a pool of primitive, undifferentiated, multipotent cells, these cells must be tested first before more complex and unknown cells are explored. The attraction of this approach is its simplicity. Cardiac regeneration would be accomplished by enhancing the normal turnover of

myocardial cells. However, difficulties exist in the acquisition of myocardial samples in humans, and in the isolation and expansion of CPCs in quantities that can be employed therapeutically. Conversely, BMPCs constitute an appealing form of cell intervention; BMPCs can be easily collected from bone marrow aspirates or the peripheral blood upon their mobilization from the bone marrow with cytokines.<sup>32</sup> At present, it is unknown whether CPCs and BMPCs are similarly effective in reconstituting necrotic myocardium after infarction or limitations exist in CPC growth and BMPC transdifferentiation resulting in inadequate restoration of lost tissue. Also, BMPCs may constitute a necessary initial form of intervention for the infarcted heart, whereas CPCs might be employed later during the chronic evolution of the cardiac myopathy.<sup>45,53-65</sup> Thus a fundamental question that remains to be addressed initially experimentally and later clinically is whether BMPCs are superior, equal, or inferior to CPCs for the regeneration of cardiomyocytes and coronary vessels in ischemic heart failure (Figure 4-1).

Cardiac repair after infarction is mediated by several factors including (1) number of cells to be administered, (2) cell death and survival in the hostile milieu of the infarct and periinfarcted region, (3) cell engraftment, and (4) cell growth and differentiation. An additional variable of BMPCs is their level of plasticity, which is dictated by their ability to acquire the myocyte, and vascular smooth muscle (SMC) and endothelial cell (EC) lineages. In an identical manner, CPCs have to promote the formation of a proportional number of parenchymal cells and coronary vessels. Moreover, the injected CPCs and BMPCs can contribute indirectly to cardiac regeneration by releasing a variety of peptides that exert a paracrine action on the myocardium and its resident CPCs.<sup>12,69-74</sup> These mechanisms are not mutually exclusive and both progenitor cell populations may participate directly and indirectly in the repair process. In all cases, progenitor cells have to engage themselves in homing into the myocardium to perform specific functions. These biological processes depend on a successful interaction between progenitor cell classes and tissue microenvironment.

**FIGURE 4-1** CPCs, BMPCs, and myocardial regeneration. **A** and **B**, The positive or negative outcome of myocardial regeneration mediated by the injection of human CPCs and BMPCs with distinct growth and/or differentiation potential is illustrated schematically in a model of acute (**A**) and chronic (**B**) myocardial infarction in immunodeficient animals. *MI*, myocardial infarction.

Importantly, the unfavorable microenvironment of the infarct varies with time and infarct healing. Apoptotic myocytes and vascular cells are replaced by diffuse cell necrosis, inflammation, and myocardial scarring. These evolving characteristics of the dead myocardium may have different consequences on CPC and BMPC homing, survival, growth, and differentiation. Cardiac repair may be severely blunted in chronic postinfarct heart failure with both BMPCs and CPCs, or one cell type might be less powerful than the other. The continuous debate in the field in terms of variety of cells being implemented and the difficulty in defining the destiny of the delivered cells has not favored a common effort in the scientific community; these critical questions have not been addressed in a collaborative, comprehensive manner. Dissimilarities in experimental designs, cell characteristics, and

modality of delivery, together with substantial differences in the method of analysis of the myocardium, have further clouded understanding of the actual effects of the injected cells on the structure and function of the damaged heart. Very positive results are contrasted by completely negative findings, adding a significant level of confusion to an already rather complex and confusing new area of research and therapy.<sup>34,41,43,67</sup>

### The Controversy

The possibility that cardiomyocytes and coronary vessels are formed by endogenous and/or exogenous progenitor cells has promoted a profound shift in paradigm of the heart, which has been viewed for decades as a terminally differentiated

postmitotic organ. This dramatic change in understanding of cardiac behavior and function originated from observations made in the 1940s, which have continued to accumulate over the years.<sup>75,76</sup> However, the disagreement that persists among the members of the scientific community today was present then and has continued for nearly 70 years. The reason for the controversy is unclear, but it seems to reflect unshakable positions based on preconceived beliefs more than on careful analysis and proper consideration of published results.<sup>66,67,75</sup> In the course of the controversy, recurrent statements have been made to undermine the technical protocols used in studies supporting the existence of cardiac regeneration. Consistently, the data in favor of myocardial regeneration are claimed to be the product of methodological artifacts,<sup>41,76-79</sup> which precludes any constructive interaction among laboratories with divergent results.

Unfortunately, the old dogma has profoundly conditioned basic and clinical research in cardiology for the past 35 years.<sup>45,66</sup> The premise of this work is that cardiomyocytes undergo cellular hypertrophy only and cannot be replaced either by the entry into the cell cycle of a subpopulation of nonterminally differentiated myocytes or by the activation of a pool of primitive cells that become committed to the myocyte lineage. However, the efforts made to introduce a highly dynamic perspective of the heart has led to the identification and characterization of a resident pool of stem cells that can generate myocytes and ECs and SMCs organized in coronary vessels.<sup>14</sup> This discovery has created a new heated dispute concerning the implementation of adult cardiac stem cells in the treatment of heart failure of ischemic and nonischemic origin. Collectively, the substrate that governs the debate involves the inability of BMPCs to transdifferentiate and the limited therapeutic potential of adult CPCs for myocardial regeneration.

## CELL THERAPY AND MYOCARDIAL INFARCTION

Results from our laboratory\* and others† have documented that autologous BMPCs and CPCs promote cardiac repair after acute myocardial infarction, suggesting that both cell types may have important clinical implications for the management of the human disease. The stem cell antigen c-kit is expressed in a population of BMPCs that are capable of differentiating into cardiomyocytes, SMCs, and ECs restoring in large part myocardial infarcts and ventricular performance.<sup>29,30,33,35</sup> Similarly, c-kit is present in resident CPCs that are self-renewing, clonogenic, and multipotent in vitro and replace dead tissue with functional myocardium in vivo.<sup>14,25,80-83</sup> Therefore the stem cell epitope c-kit has been employed to isolate progenitor cells from the bone marrow and the heart; c-kit provides a uniform reference point for comparison between BMPCs and CPCs. The presence of the stem cell antigen c-kit has previously been found to be associated with comparable functional behavior of progenitor cells whether they derive from the heart or bone marrow. Although this approach allows us to obtain a reasonably homogeneous preparation of progenitor cells, it has limitations related to the uncommitted or early committed state of the cells, their quiescent or cycling condition, and their migratory properties. However, the collection of progenitor cell classes by stem cell antigens remains the most reasonable and sensitive strategy to date.

The mechanisms that guide stem cell homing in the myocardium are not completely understood. Cardiac injury may be necessary for migration and long-term engraftment of stem cells in the myocardium. In the absence of tissue damage,

the implanted stem cells are at a growth disadvantage with respect to the endogenous stem cells. The ischemic myocardium provides a microenvironment that is particularly rich in cytokines, favoring seeding, survival, and growth of progenitor cells. The binding of SDF-1 to its receptor CXCR4 is critical in promoting homing of BMPCs to the bone marrow and distant organs,<sup>88-98</sup> although IGF-1 and HGF may be crucial in opposing death signals and facilitating migration, respectively.<sup>80,81,99</sup> SDF-1, IGF-1, and HGF are upregulated in the border zone acutely after infarction and may enhance BMPC and CPC viability, translocation, and homing (Figure 4-2).<sup>92,100-102</sup>

How unfavorable the scarred myocardium becomes for cell seeding is unknown and an important question. Engraftment of CPCs and BMPCs necessitates the formation of adherens and gap junctions with resident myocytes and fibroblasts, which are the supporting cells in the niches and anchor the injected cells to the host myocardium (Figure 4-3).<sup>25,35,82,83,103</sup> Interaction between integrin receptors on progenitor cells and extracellular matrix proteins is fundamental for cell lodging, division, and maturation.<sup>103,104</sup> CPCs may be better equipped than BMPCs to colonize the heart, but BMPCs may possess a high degree of plasticity adapting rapidly their phenotype to the cardiac microenvironment. Scarring may modify in an unpredictable way the possibility of cardiac regeneration. The process of transdifferentiation may alter the growth behavior of BMPCs, which may lose in part their ability to divide after the acquisition of the myocyte phenotype. Similarly, myocytes derived from BMPCs may possess inherent limitations in the acquisition of the adult phenotype. BMPCs may have a growth potential, which is superior to CPCs but transdifferentiation could affect this characteristic and CPCs may constitute a more powerful form of therapy for cardiac repair. The opposite may also be true and BMPCs may retain even after transdifferentiation a stronger regenerative capacity than CPCs representing the most appropriate cells for the damaged heart. These are all critical issues in need of resolution, which have only been partially investigated so far.

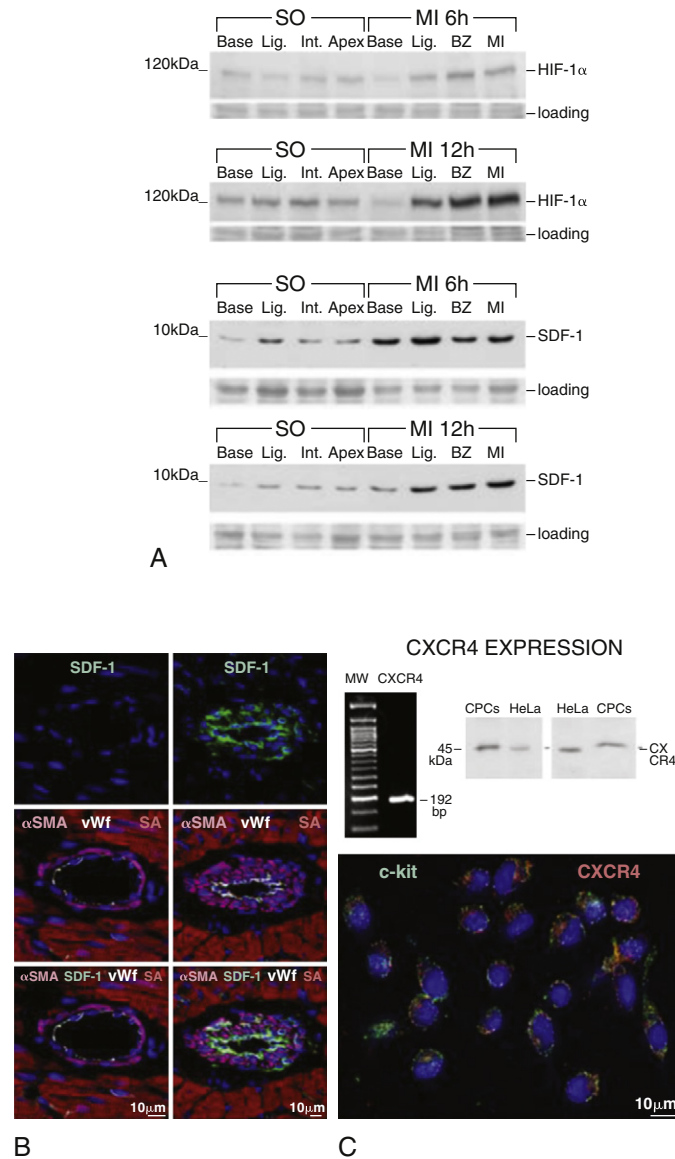

Later sections summarize current information on the growth properties of BMPCs and derived myocytes and CPCs and myocyte progeny to establish the efficacy of these progenitor cell classes for cardiac repair after infarction. A direct comparison between these two cell populations for myocardial regeneration has not been performed yet but significant knowledge has been acquired regarding their ability to engraft and form cardiomyocytes that are integrated structurally and functionally with the recipient myocardium. Additionally, limitations in the capacity of BMPCs and CPCs to differentiate and acquire the adult cardiomyocyte phenotype have been identified, pointing to crucial new areas of investigation to understand the fundamental biological processes that regulate progenitor cell function.

## Progenitor Cell Homing

The movement of hematopoietic stem cells (HSCs) from the peripheral blood to the bone marrow is termed homing and is characterized by the active translocation of HSCs across the blood/bone marrow endothelial barrier and their lodging into bone marrow niches.<sup>105-113</sup> Following homing, engraftment occurs.<sup>91,93,107,112</sup> Although homing and engraftment are regulated by common mechanisms, engraftment is a long-term process that requires cell division and commitment of the stem cell progeny.<sup>93,112</sup> Here, homing does not refer to migration of cells from the blood and across the coronary endothelium to the myocardium, but to the migration of the delivered cells within the tissue through interstitial tunnels by the interaction of integrin receptors with extracellular matrix proteins (Figure 4-4).<sup>80,83</sup> This process conditions the fraction of progenitor cells that ultimately lodge within the heart and lead to

**FIGURE 4-2** Myocardial ischemia and the HIF-1 $\alpha$ -SDF-1 pathway. **A**, With respect to sham-operated rats (SO), the expression of HIF-1 $\alpha$  and SDF-1 is enhanced in the ischemic myocardium at 6 and 12 hours after infarction. *MI*, myocardial infarct. **B**, In a model of permanent occlusion of the left anterior descending coronary artery, SDF-1 (green) was negligible in resistance arterioles located above the ligature (*left panels*), but was highly expressed in arterioles below the ligature (*right panels*). Central panels show myocytes ( $\alpha$ -sarcomeric actin, red), ECs (von Willebrand factor, white), and SMCs ( $\alpha$ -smooth muscle actin, magenta). **C**, CPCs express CXCR4 at the mRNA and protein levels. The presence of CXCR4 (red) in c-kit-positive (green) CPCs was confirmed by immunocytochemistry.

myocardial regeneration. Importantly, engraftment requires the expression of surface proteins involved in cell-to-cell contact and the connection between the delivered cells and the interstitial compartment.<sup>93,103,112,114,115</sup> Cell homing is characterized by the formation of adherens junctions (N-cadherin, E-cadherin) and gap junctions (connexin 43, connexin 45) between progenitor cells and supporting cells.

The heart typically shows discrete structures in the interstitium where CPCs are clustered together forming cardiac niches. The documentation that stem cell niches are present in the adult myocardium has been based on the identification of pockets of CPCs and the detection of cell-to-cell contact between CPCs and myocytes and fibroblasts. In the heart and in other self-renewing organs, stem cells are connected structurally and functionally to the supporting cells by junctional and adhesion proteins represented by connexins and cadherins.<sup>108,114-117</sup> Connexins are gap junction channel proteins that mediate passage of small molecules involved in cell-to-cell communication.<sup>116,117</sup> Cadherins are calcium-dependent

transmembrane adhesion molecules, which have a dual function; they anchor stem cells to the microenvironment and promote a cross talk between stem cells and between stem cells and supporting cells.<sup>108,114,115</sup> Cardiac niches create the necessary permissive milieu for the long-term residence, survival and growth of CPCs.<sup>103</sup> The arrangement of CPCs and supporting cells in the cardiac niches is similar to that found in the bone marrow<sup>109-111,113,118,119</sup> and the brain,<sup>120-122</sup> providing elements of analogy for these organs. In the bone marrow, osteoblasts and stromal cells function as supporting cells.<sup>109,111</sup> They can be considered the equivalent of myocytes and fibroblasts found in the heart.

To date, the hematopoietic stem cell appears to be the most versatile stem cell in crossing lineage boundaries and the most prone to break the law of tissue fidelity.<sup>123</sup> Early studies on c-kit-positive BMPC differentiation into myocardium have generated great enthusiasm<sup>29,30</sup> but other observations have rejected the initial positive results<sup>38-40</sup> and promoted a wave of skepticism about the therapeutic potential of BMPCs

**FIGURE 4-2, cont'd** **D**, By immunolabeling, HIF-1 $\alpha$  (upper panels; green, arrowheads) was detected rarely above the ligature (left panel) and in numerous nuclei below the ligature (right panel). HIF-1 $\alpha$  is expressed in nuclei of ECs (von Willebrand factor, white) and myocytes ( $\alpha$ -sarcomeric actin, red) (lower panels). **E**, SDF-1 (green, arrowheads) was restricted to coronary vessels; it was minimally detectable above the ligature (left panel) but was apparent in the border zone at 6 hours after infarction (right panel). Lower panels show SDF-1 together with ECs and myocytes. (From Tillmanns J, Rota M, Hosoda T, et al. Formation of large coronary arteries by cardiac progenitor cells. *Proc Natl Acad Sci U S A* 2008;105:1668–1673.)

for the injured heart. The center of the controversy is the lack of unequivocal evidence in favor of myocardial regeneration by the injection of bone marrow cells in the infarcted heart. Because of the great interest in cell-based therapy for heart failure, several approaches including gene reporter assay, genetic tagging, cell genotyping, PCR-based detection of donor genes, and direct immunofluorescence with quantum dots have recently been employed to prove or disprove bone marrow cell transdifferentiation into functionally competent myocardium after permanent coronary occlusion. To demonstrate reproducibility of results, four laboratories with complementary expertise decided to undertake a series of joined experiments to acquire unequivocal information on the plasticity of BMPCs and their therapeutic potential for the infarcted heart.<sup>35</sup>

A necessary premise of BMPC transdifferentiation with acquisition of the cardiogenic fate involves the engraftment of the donor cells within the host myocardium. Shortly after cell implantation, donor BMPCs seed within the viable myocardium of the border zone and integrate structurally within the surrounding tissue (Figure 4-5). Junctional and adhesion complexes form between BMPCs and between BMPCs and adjacent myocytes and fibroblasts.<sup>35</sup> In the absence of engraftment, BMPCs die by apoptosis; cell death is restricted to BMPCs that fail to express connexin 43 and N-cadherin and are unable to take residence in the host myocardium. This aspect of cell death is termed *anoikis* and is triggered by the lack of cell-to-cell contact.<sup>124–126</sup> This is one of the aspects of programmed cell death initiated by the inability of cells to make proper interconnections with adjacent cells; *anoikis* is a Greek word that means “homelessness.” Conversely, at 48 hours, most engrafted BMPCs are proliferating. There is a time-dependent decrease in the rate of cell death and a time-dependent increase in the rate of cell division of the injected BMPCs. Because of these two variables, approximately 25% of the injected BMPCs are present in the border zone at 2 days. Importantly, similar results have been obtained following the intramyocardial injection of CPCs.<sup>25,82,83</sup>

Thus, adult BMPCs implanted in the infarcted heart integrate within the host myocardium by establishing temporary niches, which create the microenvironment necessary for the engrafted cells to lose the hematopoietic fate, adopt the cardiac destiny, and form *de novo* myocardium. By this

mechanism, the engrafted cells can then exert a regenerative effect, a paracrine effect, or both. Similarly, adult CPCs engraft, survive, and grow within the myocardium, forming junctional complexes with resident myocytes and fibroblasts; they lose their primitive undifferentiated phenotype and commit to cardiac cell lineages.

### Formation of Temporary Niches

As discussed and documented previously, the surviving myocardium after infarction contains niches that can host BMPCs and CPCs, but putative new niches may be formed within the thin layer of viable myocytes—interstitium surrounding the infarct. Clustering of engrafted prelabeled CPCs or BMPCs together with unlabeled recipient progenitor cells joined together by adherens junctions and gap junctions has allowed us to define expanded niches while pockets of labeled progenitor cells and labeled early committed cells have reflected the generation of putative new niches within the remaining noninfarcted myocardium. These mechanisms of CPC or BMPC engraftment may not be operative in the normal intact heart. Because of the absence of damage and need to regenerate dead myocardium, BMPCs and CPCs delivered to control intact hearts are expected to undergo apoptosis. A few cells may persist shortly after injection but they are at a growth disadvantage and subsequently die without dividing or differentiating.<sup>82,83</sup> Competitive repopulation studies with HSCs from different mouse strains have shown in a bone marrow transplantation protocol the behavior postulated for CPCs and BMPCs. In nonmyeloablated C57BL/6 recipients, DBA/2 HSCs become quiescent and do not show clonal growth or contribute to hematopoiesis.<sup>127,128</sup>

The spared myocardium after infarction contains functional niches and despite the apparent structural integrity, it is not a “normal” tissue, particularly the region bordering the infarct.<sup>129–131</sup> The increased wall stress and functional demand trigger myocyte hypertrophy and regeneration together with activation of interstitial fibroblasts, collagen accumulation, and capillary formation.<sup>132</sup> Acutely and chronically after infarction, the distant myocardium is less affected by these abnormalities creating a gradient in the reaction of the heart to ischemic damage.<sup>133</sup> The tissue response, however, does

**FIGURE 4-3** Engraftment of CPCs injected in proximity of the occluded coronary artery in infarcted rats. **A**, Site of injection of EGFP-positive CPCs (green) 24 hours after infarction. **B-E**, Connexin 43 (Cx43, yellow) and E-cadherin (E-cadh, yellow) are expressed between the injected CPCs (EGFP, green) and the recipient myocytes (B,  $\alpha$ -sarcomeric actin; white) and fibroblasts (D, procollagen; red). Gap and adherens junctions are shown at higher magnifications in the insets (arrowheads). Cardiomyocytes and coronary vessels were employed as positive controls for connexin 43 and E-cadherin labeling. (From Tillmanns J, Rota M, Hosoda T, et al. Formation of large coronary arteries by cardiac progenitor cells. *Proc Natl Acad Sci U S A* 2008;105:1668–1673.)

not counteract the loss in muscle mass; ventricular dilation, wall thinning, myocyte death, and inadequate vascular growth supervene, leading to a severely decompensated myopathy.<sup>134</sup> These alterations in combination with local accumulation of growth factors and cytokines may favor a similar gradient in engraftment of BMPCs and CPCs. However, BMPCs and CPCs may not behave in a comparable manner and may have a different capacity to lodge within the infarcted hearts, conditioning distinct degrees of myocardial regeneration and tissue repair.

To document the formation of cardiac niches, we have performed studies in which EGFP-positive-c-kit-positive CPCs were injected in proximity of the border zone after infarction (Figure 4-6). Cells homed to this region and occasionally to the remote myocardium. Cells were distributed in the interstitium as doublets or triplets and continued to express c-kit. CPCs engrafted within preexisting pockets of CPCs; cadherins

**FIGURE 4-4** CPC migration towards a chemotactic gradient. Hepatocyte growth factor (HGF) was injected in the border zone of a myocardial infarct 5 hours after coronary artery ligation. EGFP-positive cells (green, arrowheads) translocate within interstitial tunnels made of fibronectin (yellow). The large open arrow indicates the direction of migration. (From Urbanek K, Rota M, Cascapera S. Cardiac stem cells possess growth factor-receptor systems that after activation regenerate the infarcted myocardium, improving ventricular function and long-term survival. *Circ Res* 2005;97:663–673.)

and connexins were present between EGFP-positive-c-kit-positive CPCs and fibroblasts or myocytes, which are the supporting cells of the cardiac niches.<sup>103</sup> A different phenomenon occurs when, shortly after coronary artery ligation, progenitor cells are injected locally within the myocardium at the base of the heart, far away from the border zone and the infarct. The lack of injury together with a relatively intact microenvironment appears to act against CPC homing and engraftment activating predominantly the apoptotic pathway.<sup>124–126</sup> These heterogeneous myocardial environments allow comparing distinct regions of the infarcted heart and identify substrates favoring homing and engraftment of implanted CPCs and BMPCs or activating the cell death pathway. Whether CPCs and BMPCs similarly adapt to these variable conditions of the myocardium is unknown and critically relevant to stem cell therapy. Currently, there is no systematic analysis of the ability of BMPCs and CPCs to expand or create niche structures within the infarcted heart.

Engraftment of BMPCs and CPCs locally within the myocardium is mediated by SDF-1. The hypoxia-inducible factor-1 (HIF-1) is a transcriptional regulator of the SDF-1 chemokine.<sup>94,135,136</sup> HIF-1 and SDF-1 are upregulated with ischemia and correlate with the oxygen gradient within the tissue.<sup>136</sup> This myocardial response may create a gradient in which hypoxia increases progressively from the border zone to the apex of the infarcted ventricle. Such distribution of oxygen may be seen in longitudinal sections of the infarcted heart (Figure 4-7). Ischemia activates a rapid response characterized by upregulation of HIF-1 protein in vascular ECs coupled with SDF-1 synthesis and accumulation in the interstitium. CPCs and BMPCs express CXCR4,<sup>82,90,96,137,138</sup> the receptor of SDF-1 suggesting that progenitor cell engraftment may be triggered by the local formation of SDF-1 followed by the activation of CXCR4 receptors on progenitor cells.<sup>139–141</sup> SDF-1 binding to CXCR4 is required for successful engraftment of CPCs or BMPCs into the myocardium (see Figure 4-2);<sup>35,82,83</sup> this may lead to the generation of temporary niches, the expansion of existing niches or both, before the acquisition of specific cell phenotypes and the formation of functionally competent cardiac cells.

**FIGURE 4-5** Engraftment of BMPCs in the acutely infarcted heart. EGFP-positive male BMPCs were injected in the border zone shortly after coronary occlusion. **A** and **B**, Within 12 to 24 hours, clusters of BMPCs engraft within the recipient myocardium. BMPCs are c-kit-positive (green) and carry the Y chromosome (Y-chr, white dots). Connexin 43 (A, Cx43; yellow dots) and N-cadherin (B, N-cadh; yellow dots) are present between male BMPCs (arrows), and between male BMPCs and Y-chromosome-negative female myocytes ( $\alpha$ -sarcomeric-actin, red; arrows) and fibroblasts (procollagen, col, magenta; arrows). **C**, Apoptosis (TdT, magenta) involves exclusively nonengrafted EGFP-positive (white) BMPCs (c-kit, green). Connexin 43 (Cx43, yellow dots) is absent in apoptotic BMPCs. (From Rota M, Kajstura J, Hosoda T. Bone marrow cells adopt the cardiomyogenic fate in vivo. *Proc Natl Acad Sci U S A* 2007;104:17783–17788.)

**FIGURE 4-6** Formation of niches in the viable myocardium after infarction. Following injection in the border zone, EGFP-positive c-kit-positive CPCs can engraft within preexisting niches (A-C, G-I, expanded niches) or form new niches (D-F). **A-C**, Five c-kit-positive CPCs (A, C, white), two of which are EGFP-positive (B, C, green) are present in the same niche. **D-F**, Four c-kit-positive CPCs (D, F, white), which are all EGFP-positive (E, F, green) are present in the same niche. **G-I**, One EGFP-positive CPC (G, I, green) lodged into a cluster of CPCs expressing the Notch1 receptor (H, I, red). **J**, One EGFP-positive CPC engrafted and differentiated into a myocyte. Note the presence of connexin 43 (yellow dots, arrows) between the EGFP-positive and EGFP-negative myocytes.

## Regulation of Progenitor Cell Growth

A critical aspect of cell therapy involves the characterization of the growth properties of the cells to be administered. It is rather surprising that this fundamental factor of cell function with great clinical import has been largely neglected. Comments in this regard are frequently made but, with some exceptions,<sup>68</sup> no specific protocols have been defined or proposed. Proliferation of CPCs and BMPCs is regulated by telomerase activity and telomeric length.<sup>142-146</sup> Replicative senescence corresponds to G1 growth arrest triggered by shortening of telomeres beyond a critical length.<sup>147-150</sup> Currently, it is unknown whether in the same organism BMPCs and CPCs have similar telomerase activity and telomeric length and, thereby, similar growth reserve.

Defects in hematopoiesis<sup>151-154</sup> and cardiomyogenesis<sup>155</sup> are present in telomerase null mice but a direct comparison between BMPC and CPC growth remains to be performed. For effective cardiac repair, BMPCs have to engraft and commit to the myocyte phenotype and this process requires transdifferentiation of BMPCs to a lineage distinct from the organ

of origin.<sup>45,123,156</sup> Defects in telomerase activity and telomere length oppose lodging of progenitor cells.<sup>154,157</sup> Also the transdifferentiated progeny could have a limited capacity to divide and form functionally competent cardiomyocytes. Importantly, telomere dysfunction can occur by abnormalities in the expression and/or DNA-binding properties of telomere-related proteins.<sup>158-160</sup> We have found that defects in TRF1, TRF2, DNAPKcs, Ku86, Ku70, and PARP develop together with telomeric shortening and the expression of the senescent proteins<sup>147-150,160-162</sup> p53 and p16<sup>INK4a</sup> in CPCs and amplifying myocytes with heart failure in animal models and humans (Figure 4-8).<sup>99,163-166</sup> Therefore measurements of telomerase activity and telomere integrity and function are crucial for the recognition of the potential therapeutic efficacy of BMPCs and CPCs before their injection within the myocardium. This baseline information has to be complemented with in situ measurements of the cell cycle and telomeric length in engrafted cells to define cell division and telomere length at the single cell level. Additionally, the distribution of these parameters needs to be integrated with the assessment of cellular senescence by detection of p53 and

**FIGURE 4-7** Hypoxia in the infarcted heart. After coronary artery ligation, a gradient is formed in which hypoxia increases progressively from the border zone to the apex of the ventricle. The distribution of oxygen is shown in longitudinal sections of the infarcted heart 12 hours after the injection of a pimonidazole probe. Ischemic areas are depicted in green and fluorescence intensity corresponds to the degree of hypoxia. BZ, Border zone.

p16<sup>INK4a</sup>.<sup>155,163-166</sup> Similar analyses have to be done in the population of amplifying myocytes to establish the reparative potential of progenitor cell categories and their committed progeny (see Figure 4-8).

By this integrated approach, the therapeutic efficacy of BMPCs and CPCs can be determined before their delivery to the myocardium. These parameters condition the outcome of the treatment and may be employed to vary the number of cells to be administered in each patient to optimize cell therapy. The relevance of the telomerase-telomere axis and cellular senescence of progenitor cells for understanding cell turnover and regeneration in the normal and diseased heart has recently been emphasized.<sup>68,167,168</sup>

### Fate of the Engrafted Cells

Successful engraftment of CPCs and BMPCs in proximity or within the infarct is the initial fundamental process of tissue repair. However, this is only the first part of the complex and long journey of progenitor cells. In proximity of the infarct, the engrafted cells have to survive within the myocardium and migrate from the seeding site to the border of the damaged area, invade the infarct, and ultimately grow and differentiate. The concentration of HGF and IGF-1 increases after infarction and this mimics the response of HIF-1 and SDF-1, suggesting that the local levels of HGF and IGF-1 may play a critical role in the ability of progenitor cells to counteract death signals and translocate to the infarct or remain viable within the dead tissue.<sup>80,81</sup> Myocardial reconstitution necessitates the generation of a cardiomyocyte compartment and a well-balanced coronary vasculature. Myocytes alone in the absence of adequate blood supply cannot perform their function and generate force, and coronary vessels alone without

muscle mass cannot restore ventricular performance.<sup>45,169</sup> The question is whether commitment of engrafted progenitor cells leads to a coordinated growth response in which cardiomyocytes, resistance arterioles, and capillary profiles are concurrently developed to engender functionally competent myocardium. Coronary blood flow is regulated by resistance to coronary arterioles,<sup>170</sup> while oxygen availability and diffusion are controlled by the capillary network.<sup>133,171,172</sup> The effects that CXCR4-SDF-1, c-Met-HGF, and IGF-1R-IGF-1 growth factor systems have on CPC and BMPC engraftment, survival, growth, and differentiation have only been partially elucidated.<sup>80,81,137-140,173-175</sup>

Results obtained in our laboratory suggest that local activation of resident CPCs by growth factors acutely after infarction results in a significant recovery of muscle mass and approximately 20% of the regenerated myocytes acquire the adult phenotype over a period of 4 months.<sup>80</sup> Shorter intervals lead to the formation of a minimal number of myocytes with volumes comparable to those present in the adult heart. Similarly, the intramyocardial injection of CPCs induces a substantial recovery of the infarcted myocardium but also in this case, the regenerated myocytes are small and resemble fetal-neonatal cells.<sup>14</sup> Whether this is a time-dependent process or constitutes an intrinsic biological defect in CPC differentiation is unknown. This problem is even more apparent when BMPCs are employed for myocardial repair. The mobilization of BMPCs with cytokines<sup>30</sup> or the direct implantation of BMPCs in proximity of the infarcted myocardium<sup>29,33,35</sup> is not associated with the development of adult myocytes. And this phenomenon persists up to 3 months with either treatment. The possible superior efficacy of resident CPCs has also been suggested by their ability to rescue animals with infarcts commonly incompatible with life in rodents,<sup>80</sup> a phenomenon that was not observed with BMPCs.<sup>29,30,33,35</sup> However, it is difficult to make appropriate comparisons between CPCs and BMPCs with available work. None of the experiments was designed to analyze the therapeutic impact of CPCs versus BMPCs. The number of injected or activated cells was not controlled in the two conditions, and parallel studies were not performed. This is of crucial import because if BMPCs and CPCs have similar beneficial effects on cardiac repair and myocyte differentiation, BMPCs may become the most appropriate form of cell therapy for the infarcted heart. BMPCs have been well characterized biologically<sup>176</sup> and, most importantly, have been employed clinically for nearly 3 decades.<sup>177,178</sup> They are easy to obtain, they are safe, and they do not generate malignant neoplasms when injected in the systemic circulation.

To establish whether CPCs and BMPCs have comparable or dissimilar efficacy in cardiac repair after infarction, the number and phenotypic properties of generated myocytes will have to be characterized. If we assume that the physiological postnatal maturation of the heart<sup>132,143,179</sup> represents the gold standard paradigm for effective and successful myocardial regeneration, several criteria will have to be met: (1) Shortly after engraftment, progenitor cells would be expected to generate a large number of myocytes resembling neonatal cells, approximately 1000  $\mu\text{m}^3$  in volume;<sup>\*</sup> (2) myocyte proliferation should decrease rapidly and cellular enlargement should become the predominant form of expansion of muscle mass, reaching the adult phenotype approximately 20,000 to 25,000  $\mu\text{m}^3$ ;<sup>†</sup> (3) myocyte apoptosis should be relatively high in the early phases of cardiac repair and minimal when the myocytes have fully matured<sup>‡</sup>; (4) because of the small size of cardiomyocytes, there should be approximately one capillary every 10 to 15 myocytes early during regeneration, but a ratio of nearly one capillary to one myocyte should be reached in a

**FIGURE 4-8** Heart failure and CPCs. **A**, Telomerase activity was measured by the telomeric repeat amplification protocol assay in control human hearts and in human hearts affected by acute (acute MI) and chronic (chronic MI) ischemic cardiomyopathy. Products of telomerase activity start at 50 bp and display a 6-bp periodicity. Samples treated with RNase (+) were used as a negative control and HeLa cells as a positive control. Serial dilutions of proteins (0.5 and 1.0  $\mu$ g) were used to confirm the specificity of the reaction. The band at 36 bp corresponds to an internal control for PCR efficiency. **B**, Expression of the telomere-related proteins, TRF-1, TRF-2, and DNA-PK (DNA-PKs, Ku86, and Ku70), and full-length and cleaved poly (ADP-ribose) polymerase. The expression of cell cycle inhibitors and markers of cellular senescence was also measured.

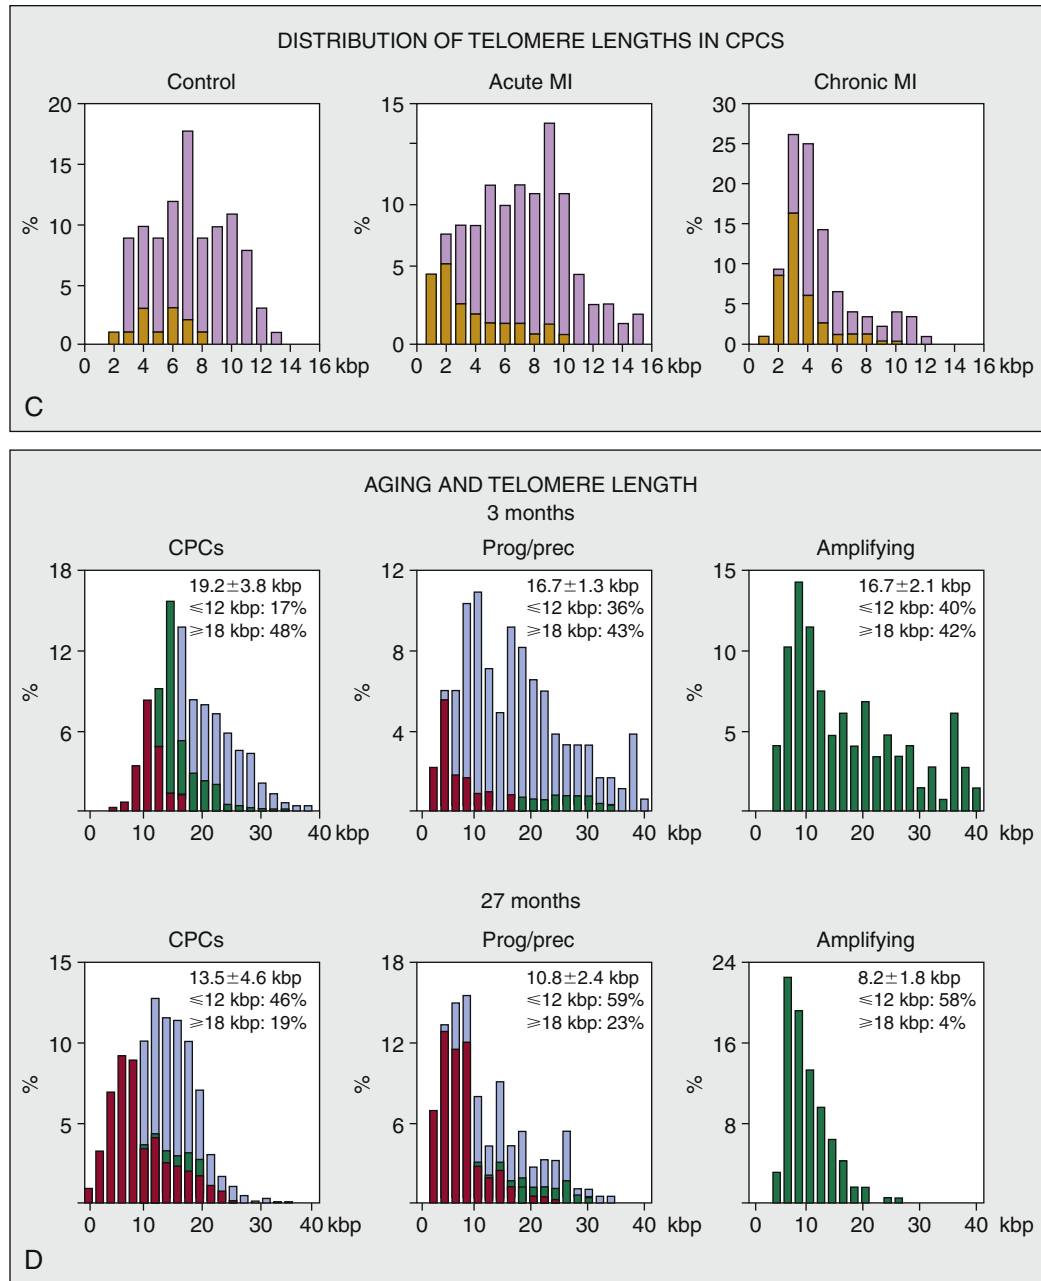

period of 4 to 6 weeks;<sup>§</sup> and (5) numerous coronary resistance arterioles should develop to decrease coronary resistance, and promote the integration of the new coronary vasculature with the remaining coronary circulation. <sup>||</sup>

Local hypoxia is commonly present during organogenesis and in adult tissues where it induces the formation of niches that protect and preserve the biological properties of stem cells in an unfavorable environment.<sup>92,97,180-182</sup> Hypoxia in vitro promotes survival and growth, and maintains multipotentiality of hematopoietic and neural progenitor cells.<sup>183-185</sup> Hypoxia also inhibits myogenesis of skeletal muscle satellite cells.<sup>186</sup> If myocardial regeneration recapitulates the fetal program, inadequate oxygenation of the forming myocardium

may favor myocyte replication rather than differentiation. This seems to be the case since there are only a few capillaries within the regenerating myocardium and HIF-1 is upregulated in the developing myocyte nuclei and interstitial cell nuclei (Figure 4-9). In the embryonic heart, activation of the Notch receptor affects cardiomyogenesis,<sup>187-191</sup> pointing to the Notch pathway as a modulator of progenitor cell fate, a condition which might be mimicked in the forming myocardium. And hypoxia-induced HIF-1 expression may result in increased stability of the intracellular domain of Notch, NICD, and expression of RBP-Jk.<sup>192</sup>

The components of the Notch pathway, which include Notch receptors, NICD, and RBP-Jk, are present in BMPCs and in CPCs as well.<sup>193,194</sup> Notch interferes with BMPC maturation<sup>195</sup> and skeletal myogenesis<sup>196</sup> but favors muscle regeneration with aging.<sup>197-199</sup> Our recent results indicate

**FIGURE 4-8, cont'd** **C**, Telomere length in hCPCs is shifted to the left to shorter telomeres in chronic MI. The filled portion of the bars corresponds to p16<sup>INK4a</sup> and/or p53-positive CPCs; they increase in acute and chronic infarcts but more dramatically in chronic infarcts. **D**, Telomere length was measured in lineage negative CPCs, myocyte progenitors-precursors, and amplifying myocytes in young (*upper panels*) and old (*lower panels*) rat hearts. Average telomere length is listed together with the percentage of cells with telomeres  $\leq 12$  kbp and  $\geq 18$  kbp. Green solid bars correspond to the fractions of cycling Ki-67-positive cells while red solid bars indicate the fractions of senescent p16<sup>INK4a</sup>-positive-cells. (From Gonzalez A, Rota M, Nuszynska D. Activation of cardiac progenitor cells reverses the failing heart senescent phenotype and prolongs life span. *Circ Res* 2008;102:597-606; and Urbanek K, Torella D, Sheikh RF. Myocardial regeneration by activation of multipotent cardiac stem cells in ischemic heart failure. *Proc Natl Acad Sci U S A* 2005;102:8692-8697.)

that Notch is operative in early myocyte differentiation.<sup>194</sup> In the search for the molecular control of CPC differentiation, we have found that a perfect consensus site for RBP-Jk is present in the promoter region of Nkx2.5, suggesting that Nkx2.5 is a novel target gene of Notch1; band-shift assays and chromatin immunoprecipitation experiments are consistent with this possibility (Figure 4-10). Reporter gene assays have documented that the physical interaction between RBP-Jk protein and Nkx2.5 DNA leads to upregulation of Nkx2.5 function.

Importantly, Nkx2.5 recruits GATA4 to the promoter regions of several genes that are essential for the progression of myocyte growth from the early stages of myocyte

differentiation to the acquisition of the adult myocyte phenotype.<sup>200</sup> Complete null mutation of Nkx2.5 in the mouse does not abolish myocyte formation and initial heart looping. Nkx2.5 is required for late myocyte differentiation and Nkx2.5 deletion results in the arrest of heart development at 10 days pc.<sup>200</sup> GATA4 expression appears to follow the attenuation in Nkx2.5 mRNA, suggesting that the transcriptional regulation of Notch and Nkx2.5 is linked to the preservation of the pool of highly dividing amplifying myocytes while GATA4 promotes their further differentiation.<sup>194</sup>

Collectively, these observations suggest that HIF-1 may lead to a prolonged activation of Nkx2.5 Notch in CPCs and BMPCs, sustaining their early committed state. Myocyte

**FIGURE 4-9** Properties of regenerated myocytes. Newly formed myocytes in the regenerating myocardium 3 weeks after CPC implantation are small in size and express HIF-1 (white) in their nuclei. Myocytes are recognized by the red fluorescence of  $\alpha$ -sarcomeric actin.

maturation may be a time-dependent process regulated by oxygen availability to the forming cells. When vasculogenesis provides sufficient coronary blood flow, normoxia is reestablished, inhibition of differentiation may be relieved, and myocytes acquire the adult phenotype. However, whether CPCs and BMPCs are both capable of generating adult myocytes or whether one progenitor cell possesses a higher and/or faster differentiation potential than the other remains to be determined. This unresolved biological problem has tremendous clinical implications; it defines the efficacy and limit of these two forms of cell therapy for the infarcted heart. The forthcoming clinical implementation of autologous CPCs in patients affected by ischemic cardiomyopathy imposes the resolution of this dilemma.

### Mechanics of Progenitor Cells Derived Cardiomyocytes

A relevant aspect of BMPC and CPC differentiation is whether the formed myocytes are functionally competent electrically and mechanically.\* Work performed in our laboratory following the injection of these progenitor cell classes has addressed this issue. Because of the controversy in the field, we are illustrating data collected with the intramyocardial delivery of BMPCs.<sup>35</sup> Shortly after treatment, cells positive for the stem cell antigen c-kit or the reporter gene EGFP have been identified, but these cells fail to show electrical properties of

developing myocytes and to contract in response to electrical stimulation. At 15 to 30 days after infarction and cell implantation, small new myocytes have been found and these cells exhibit membrane currents similar to those of mature cells. However, regenerated myocytes show a prolongation of the action potential and enhanced cell shortening (Figure 4-11).

The recognition that BMPCs differentiate into myocytes that contract in vitro raised the question whether these new cells are integrated structurally and functionally in vivo participating in ventricular performance. In this regard, connexin 43 has been detected between spared and developing myocytes, documenting the structural integration between these two cell populations (see Figure 4-11). Additionally, synchronicity in calcium transients between new and resident myocytes has been documented by an ex vivo preparation and two-photon microscopy (see Figure 4-11). Collectively, these observations provide strong evidence in favor of the functional coupling of old and regenerated cardiomyocytes.

The structural and functional integration of the restored myocardium has multiple positive effects on the anatomical characteristics and hemodynamic performance of the infarcted heart. The injection of BMPCs restores in part the loss of contraction in the infarcted region of the ventricular wall (Figure 4-12). Moreover, cardiac repair decreases chamber volume and increases the wall thickness-to-chamber radius ratio and the ventricular mass-to-chamber volume ratio (see Figure 4-12). Hemodynamically, infarcted untreated hearts show a marked increase in left ventricular end-diastolic pressure (LVEDP) and a decrease in LVDP and  $\pm$ dp/dt. Conversely, myocardial regeneration attenuates the increase in LVEDP and improves LVDP and  $\pm$ dp/dt. Together with the reduction in ventricular dilation, the amelioration in cardiac function by cell therapy produces a significant decrease in diastolic wall stress (see Figure 4-12). Thus, c-kit-positive-BMPCs adopt the cardiomyogenic fate structurally, electrically, and mechanically, improving the performance of the infarcted heart. Similar findings have been obtained with CPCs,<sup>14,25,80-83</sup> although we do not know yet whether one progenitor cell is superior to the other.

### CELL THERAPY AND CHRONIC INFARCT

The use of progenitor cell therapy acutely after infarction has been introduced in several small clinical trials (see chapter 51).<sup>62-64</sup> Ischemic heart failure in humans is typically characterized by segmental losses of myocardium with scar formation and collagen accumulation in the interstitial compartment.<sup>45</sup> Although areas of spontaneous regeneration have been found,<sup>166,201</sup> these regions are minute and do not reduce significantly infarct size. Myocyte formation occurs acutely<sup>201</sup> and chronically<sup>166</sup> but the addition of new cells is mostly restricted to the viable myocardium. If we consider the evolution of the postinfarcted heart, the size of the infarct is not an infallible predictor of the short-, mid-, and long-term outcome of the disease.<sup>133</sup> Negative remodeling and

accumulation of damage in the surviving myocardium may become the critical determinants of the onset of cardiac deterioration and its progression to terminal failure. The number of acute events differs in the patient population, and by the nature of the damage the chronically postinfarcted heart necessitates therapeutic approaches that are by far more complex than those required by acute infarcts. Recent observations in humans suggest that BMPCs may be effective in long-term ischemic heart disease and this beneficial impact

appears to be mediated by reduction of the originally scarred myocardium.<sup>53,56</sup> In this regard, it is relevant to determine whether BMPCs and CPCs can replace regions of scarring with functionally competent myocardium and whether the mechanisms postulated to be involved in acute infarcts are operative in the chronic disease.

Although data on BMPCs are not currently available in terms of the ability of these cells to invade and replace the scarred tissue with mechanically active myocardium, recent

C

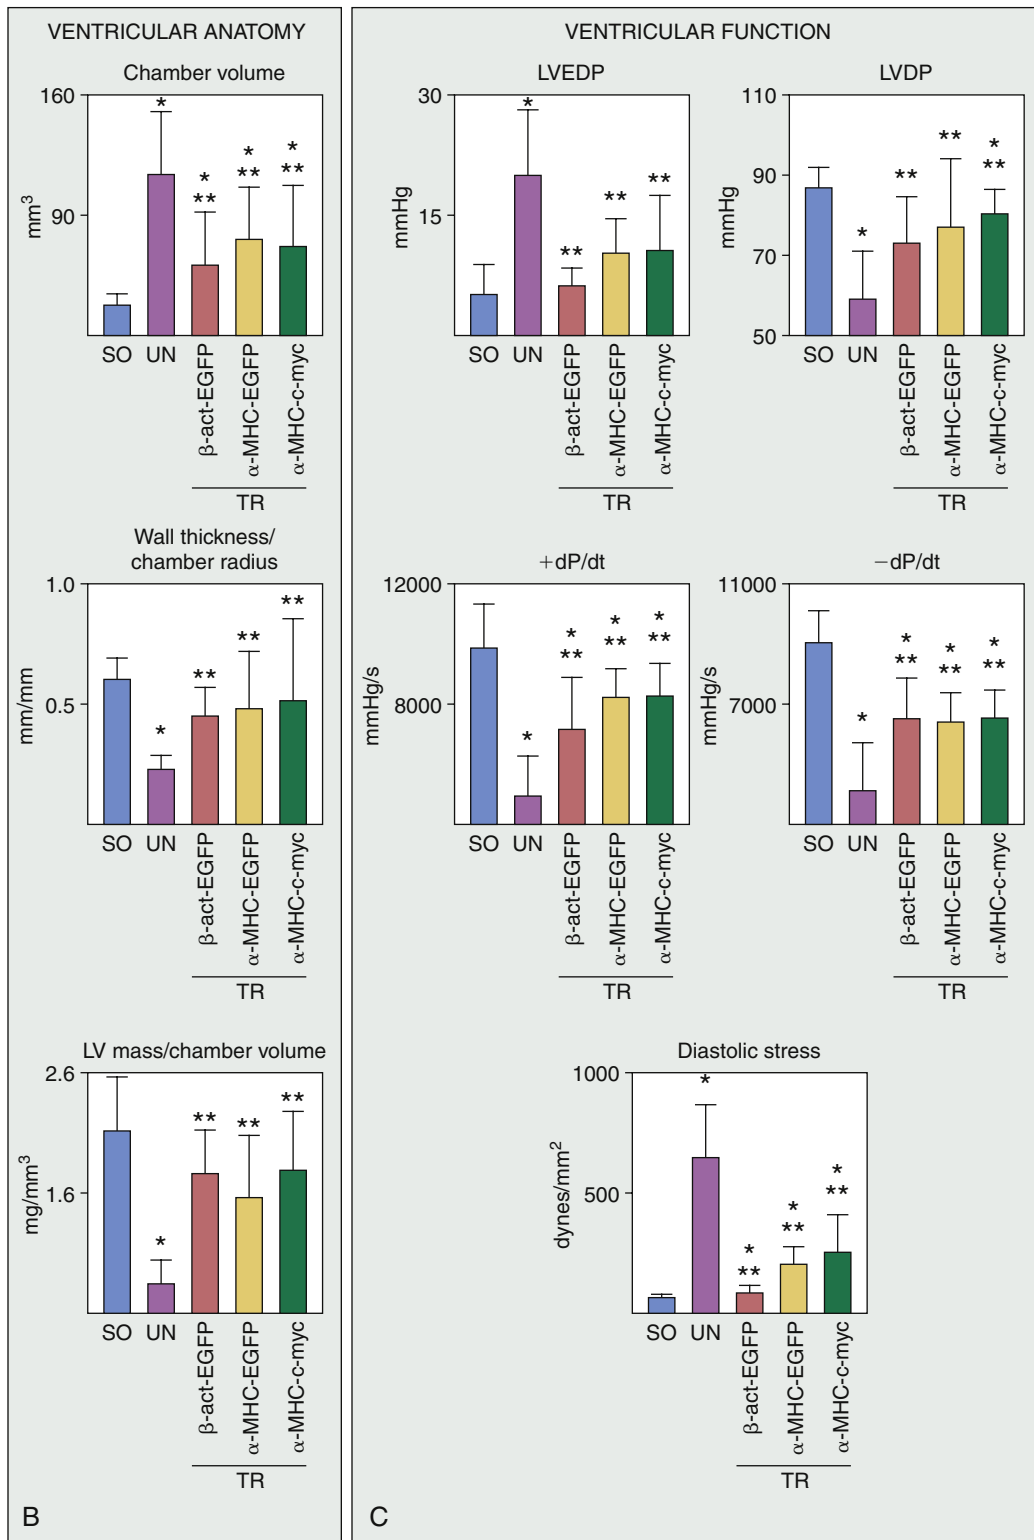

**FIGURE 4-11, cont'd C**, The functional integration of regenerated EGFP-positive-myocytes with the surrounding myocardium has been documented by an ex vivo preparation and two-photon microscopy in hearts at 1 month after coronary artery ligation. The heart is perfused retrogradely through the aorta with an oxygenated Tyrode solution containing the calcium indicator Rhod-2 and then stimulated at 1 Hz. Calcium transient is detected in EGFP-positive BMPC-derived myocytes and EGFP-negative mouse myocytes. The synchronicity in calcium transients between these two myocyte populations provides strong evidence in favor of the functional coupling of old and new myocytes. (From Rota M, Kajstura J, Hosoda T. Bone marrow cells adopt the cardiomyogenic fate in vivo. *Proc Natl Acad Sci U S A* 2007;104:17783-17788.)

Bone marrow cells adopt the cardiomyogenic fate in vivo. *Proc Natl Acad Sci USA* 2007;104:17783-17788.)

results have been obtained in our laboratory concerning the therapeutic efficacy of CPCs in healed infarcts in rodents.<sup>83</sup> In this study, rats with a healed myocardial infarct were treated with implantation of CPCs or with intramyocardial delivery of HGF and IGF-1. These growth factors (GFs) were employed because CPCs express c-Met and IGF-1 receptors and HGF is a powerful chemoattractant of CPCs while IGF-1 promotes their division and survival.<sup>80,81</sup>

Resident CPCs locally activated by GFs or injected directly in proximity of a healed infarct can rescue nearly 45% of the infarct by replacing fibrotic tissue with functionally competent myocardium.<sup>83</sup> Myocardial regeneration protects the infarcted heart from the progressive increase in cavity dilation, decrease in wall thickness, and deterioration in ventricular function with time. Together with observations in the acutely infarcted heart,<sup>14,25,80-82,202-204</sup> these findings strongly suggest that CPCs are a powerful form of cell therapy for ischemic cardiomyopathy. CPCs are effective whether administered intramyocardially<sup>14,25</sup> via the coronary route<sup>202</sup> or activated in situ with HGF and IGF-1, which trigger their growth and mobilization shortly after an ischemic event<sup>80,81</sup> and chronically at the completion of healing. CPCs migrate through the myocardial interstitium, reaching areas of necrotic and scarred myocardium where they home, divide, and differentiate into myocytes and vascular structures. From a clinical perspective, CPCs appear to represent an ideal candidate for cardiac repair in patients with chronic heart failure in which discrete areas of damage are present in combination with multiple foci of replacement fibrosis across the ventricular wall.<sup>45</sup> Potentially, CPCs may be isolated from endomyocardial biopsy or surgical samples and, following their expansion in vitro, administered back to patients avoiding the inevitable and threatening adverse effects of rejection and other complications with nonautologous transplantation. Alternatively, GFs can be delivered locally to stimulate resident CPCs and promote myocardial regeneration. Importantly, these strategies may be repeated to reduce further myocardial scarring and expand the working myocardium.

Myocardial scarring interferes with the migration and engraftment of locally injected or GF-activated CPCs. Acute infarcts are more amenable to CPC translocation and homing, providing a milieu in which CPCs rapidly accumulate and generate a committed progeny (Figure 4-13).<sup>80</sup> Despite the less favorable environment dictated by collagen deposition chronically after infarction, CPCs retained the ability to infiltrate the scar, digest part of the connective tissue, and form cardiomyocytes and coronary vessels. The comparable effects on myocardial regeneration obtained by local CPC-delivery and GF-activation of resident CPCs may be explained by the pattern of migration of these cells within the scar; the higher number of cells found with intramyocardial injection of CPCs was compensated by the faster speed of migration of GF-activated CPCs. When these two variables are considered, i.e., speed and cell number, the accumulation of cells under these conditions is remarkably similar.<sup>83</sup> However, this was not the case in acute infarcts in which cell infiltration was more efficient following CPC-implantation than after CPC-activation by GFs (see Figure 4-13).

The invasion of the scarred tissue by CPCs appeared to be mediated by enhanced activity of MMP-9 and possibly MMP-14. MMP-9 is critical for the recruitment of bone marrow stem cells and their mobilization from quiescent to proliferative niches,<sup>205</sup> and a similar mechanism may be operative in the translocation to the chronically infarcted heart of GF-treated resident CPCs or delivered CPCs. The upregulation of MMP-9 expression and activity in CPCs is dependent on HGF.<sup>80,81,99</sup> Additionally, SDF-1, which is highly expressed in myocytes and endothelial cells after ischemic injury, acts on MMP-9 and promotes the differentiation of CPCs into vascular cells and cardiomyocytes.<sup>82</sup> The lack of increase

in MMP-2 activity observed here may favor the stability of SDF-1, which is degraded by this protease.<sup>206</sup>

Importantly, with respect to the intact heart, the content of cytokines and growth factors differed in the scarred myocardium (Figure 4-14).<sup>83</sup> The enhanced expression of the chemotactic factors sICAM-1, CXCL7, and bFGF in chronic infarcts may have created a condition facilitating migration and homing of CPCs.<sup>207</sup> Additionally, the presence of sICAM-1, CXCL7, and TIMP-1 in the scar could have promoted CPC mobilization, EC migration and differentiation, and vessel formation.<sup>208</sup> The increases in CXCL7 and TIMP-1 were restricted to chronic infarcts. As expected, the acutely infarcted myocardium displayed a cytokine profile that reflected an inflammatory response and tissue reaction to acute injury (see Figure 4-14). However, the higher levels of sICAM-1 and bFGF within the scar are particularly relevant for myocardial regeneration since sICAM-1 may have created a niche structure that supported the engraftment of CPCs and bFGF is critical for the differentiation of resident CPCs into myocytes.<sup>21</sup>

The analysis of cytokine and growth factor expression in acute and chronic infarcted hearts<sup>83</sup> offers the possibility to establish whether the delivery of CPCs participates in the synthesis and secretion of soluble proteins, which exert an autocrine or paracrine effect on myocardial regeneration. The presence of CPCs in the scar attenuates, at least in part, the differences in cytokine profile with acute infarcts by increasing the quantities of LIX that are involved in stem cell maintenance and proliferation<sup>209</sup> and IP-10 that modulates vessel homeostasis and growth.<sup>210</sup> Thus acute and chronic myocardial damage leads to the expression of genes that create a microenvironment that conditions the activation, migration, and growth of CPCs, ultimately controlling the regenerative response of the pathological heart.

Whether these results have implications for the treatment of chronic human heart failure is difficult to predict. Risk factors such as aging and diabetes are frequently present in patients with ischemic cardiomyopathy, and they have profound negative consequences on the number and function of CPCs.<sup>68</sup> However, functionally competent human CPCs have been isolated from a variety of patients undergoing open heart surgery<sup>25</sup> or endomyocardial biopsy<sup>23</sup> and the activation of CPCs by GFs in senescent rats with severe ventricular decompensation reverses the cardiac phenotype and prolongs lifespan.<sup>99</sup>

## Progenitor Cells and Fusion Events

In all studies performed so far in our laboratory with BMPCs or CPCs,\* the collected data indicate that progenitor cells undergo lineage commitment and give rise to myocytes and coronary vessels within the acutely and chronically infarcted myocardium in the absence of cell fusion. Heart homeostasis is modulated by CPCs that continuously differentiate into new younger cells replacing old dying cells. This mechanism of cardiac cell turnover is operative in animals<sup>14,16,19,81</sup> and humans<sup>25</sup> and does not involve cell fusion. Similarly, BMPCs acquire cardiac cell lineages independent of cell fusion.<sup>33,35</sup>

However, the generation of cardiomyocytes by CPCs<sup>15</sup> or BMPCs<sup>40</sup> has been postulated to be largely the product of cell fusion. If this were to occur, the process of cell fusion would require the merging of a CPC or BMPC with a terminally differentiated, binucleated myocyte, approximately 25,000  $\mu\text{m}^3$  in volume or larger. Thus, a trinucleated heterokaryon, a binucleated hyperploid synkaryon, restricted to one of the two nuclei, or a binucleated hyperploid synkaryon with a proportional partition of the DNA of the BMPC to each of the myocyte nuclei would be formed.<sup>45,123</sup> The unusual trinucleated myocyte heterokaryon will be no longer terminally

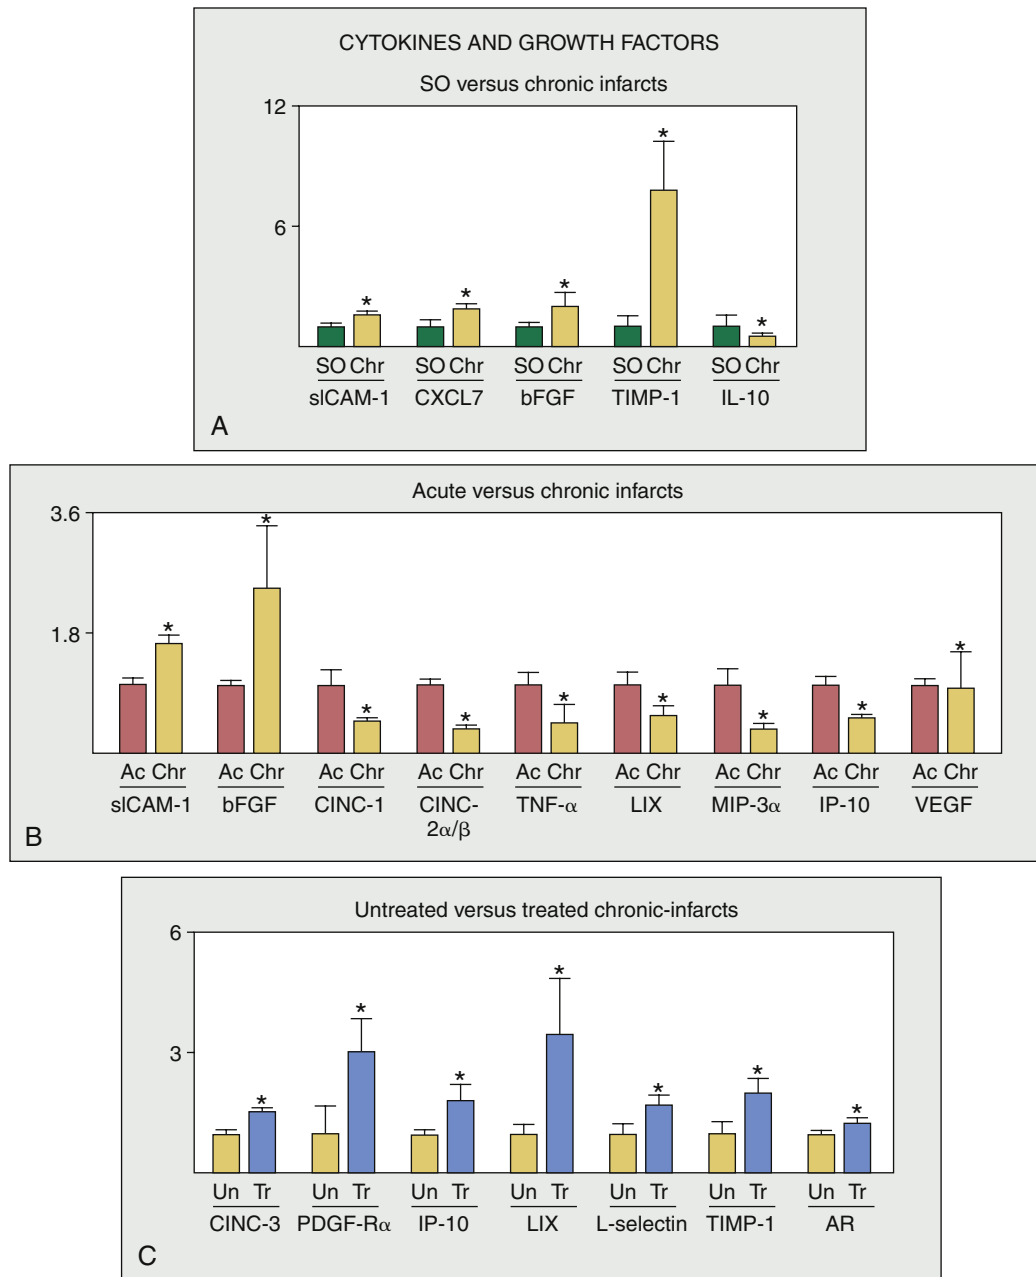

**FIGURE 4-13** Migration of CPCs in the infarct. **A-E**, Translocation of EGFP-positive CPCs at 24 hours after cell implantation in an acute infarct. The same field, examined at 1-hour intervals is illustrated. Green: EGFP-positive cells; red: coronary vasculature perfused with rhodamine-labeled-dextran. Blue: collagen. White circles in A indicate the position of selected cells at the beginning of observation. White arrows reflect the direction of migration and the distance covered by the cells in 1 to 4 hours. **F-J**, Translocation of EGFP-positive CPCs at 24 hours after cell implantation in a chronic infarct. The movement of cells is illustrated as described above. (From Rota M, Padin-Iruegas E, Misao Y, et al. Local activation or implantation of cardiac progenitor cells rescues scarred infarcted myocardium improving cardiac function. *Circ Res*. 2008;103:107-116.)

differentiated; it will reenter the cell cycle, become approximately  $50,000 \mu\text{m}^3$  in volume, and then divide, creating two trinucleated daughter cells, approximately  $25,000 \mu\text{m}^3$  each. When cell fusion is accompanied by nuclear fusion, the high DNA content leads to genetic instability and minimal or null replicative potential.<sup>211</sup> However, the replicating and nonreplicating myocytes originated from BMPCs or CPCs are predominantly mononucleated, at times binucleated and never trinucleated. Nearly 80% of these cells vary from  $500 \mu\text{m}^3$  to  $3000 \mu\text{m}^3$ ; only a minimal fraction reaches a volume of  $10,000$

$\mu\text{m}^3$  or larger. All cells have a  $2n$  karyotype, and possess two sex chromosomes.<sup>25,33,35</sup>

Surprisingly, the differentiation of CPCs into myocytes and the possibility of a phenotype conversion of adult BMPCs have been challenged in favor of the complex mechanism of cell fusion.<sup>212</sup> This rather unrealistic model of myocyte biology has been claimed to be operative based on results obtained with the Cre-Lox genetic system, which has been accepted at face value and viewed today as the gold standard for studies of myocardial regeneration and BMPC

**FIGURE 4-14** Cytokines and growth factors regulate homing of CPCs in the infarct. A cytokine and growth factor array was performed to identify the signals involved in the migration and engraftment of CPCs in the acute and chronic infarcted heart. The content of cytokines and growth factors was analyzed in myocardial tissue samples. The different expression profile in acute and chronic infarcts indicates that distinct environmental cues characterize the cardiac milieu in the two conditions. **A-E**, Fold changes in protein quantities. transdifferentiation.<sup>15,40,212</sup> Cre is a recombinase enzyme that cuts DNA segments flanked by binding sequences termed LoxP sites. The Cre recombinase gene is driven by a cell-specific promoter, such as the  $\alpha$ -myosin heavy chain. The LoxP sequences flank the stop codon, which is located between the *LacZ* or *EGFP* gene and its promoter, repressing the expression of *LacZ* or *EGFP* (LoxP mouse). When cells that contain this construct fuse with cells carrying the Cre recombinase gene, the LoxP and stop codon sequences are recognized and excised by the Cre recombinase. Therefore, the *LacZ* or *EGFP*

gene is expressed in the fused cells and  $\beta$ -Gal or EGFP is synthesized under the control of the cell-specific promoter.

Unfortunately, the Cre-Lox model is not perfect. The unmodified Cre-recombinase present in progenitor cells can cross the membrane of the recipient cell,<sup>213</sup> mimicking fusion events. Also, the formation of nanotubes<sup>214</sup> may lead to the transfer of Cre recombinase to the cell carrying the *LacZ* gene, resulting in a  $\beta$ -Gal positive cell in the absence of cell fusion.<sup>45</sup> Fusion of a CPC or BMPC with a mature myocyte cannot trigger the division of the recipient terminally differentiated cell.

FIGURE 4-14, cont'd.

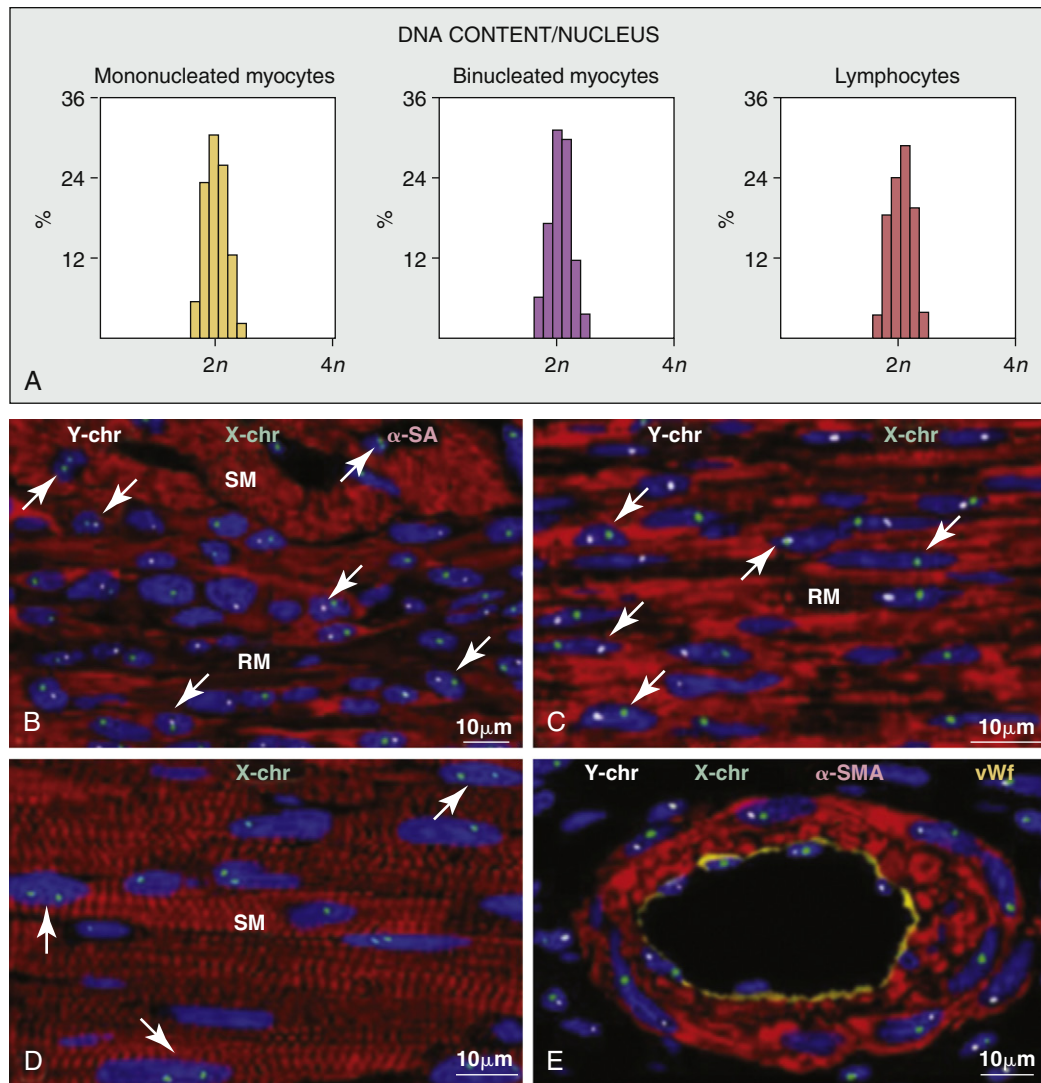

The hybrid cell loses the ability to proliferate, abrogating the fundamental role of CPCs or BMPCs. The generation of nanotubules between BMPCs<sup>214</sup> strongly suggests that expression of an enzyme cannot be interpreted as proof of cell fusion. The recognition that nanotubules are formed between cells explains the translocation of enzymes between adjacent cells and the migration of organelles from one cell to the neighboring cell. By inference, the cross talk between cells is not limited to membrane-to-membrane interaction but involves a more sophisticated network of structural and functional bridges. Therefore, cell fusion has to be studied by analyzing DNA content together with the number of sex chromosomes in nuclei of newly formed myocytes (Figure 4-15). So far, the collected findings challenge cell fusion as a mechanism of myocardial regeneration by differentiation of CPCs and BMPCs.<sup>34,45,67,123</sup>

FUTURE DIRECTIONS

The field of cardiac stem cell biology is in its infancy and we have little understanding of the mechanisms involved in the homeostasis and repair of the adult human heart. Historically,

the foundations for the view of the heart as a terminally differentiated postmitotic organ incapable of regeneration can be traced back to the mid-1920s.<sup>215</sup> The dogma was established that the postnatal heart is composed of a fixed number of myocytes and that, if myocytes die, they are permanently lost and the myocardium must maintain its vital role with a reduced number of cells. The remaining myocytes cannot be triggered into the replicating phase;<sup>216</sup> they continue to perform their physiological function, undergo cellular hypertrophy, and ultimately die.<sup>217</sup> Based on this paradigm, the age of myocytes, the organ, and organism were assumed to coincide, implying that myocytes in humans may have a life span that exceeds 100 years.<sup>167</sup> For several decades, no effort was made to reexamine this rather unusual view of the biology of the heart and cardiac homeostasis. Remarkably, there is not a single piece of evidence that demonstrates the inability of the heart to replace its dying myocytes. It seems rather extravagant that cardiomyocytes can contract 70 times per minute over 100 years and continue to be functional. During this period, they would have contracted 3.7 billion times and still be operative. If this were to be the case, adult myocytes would be essentially immortal cells. This unrealistic view of the heart forms the basis of our limited knowledge on the

**FIGURE 4-15** Cell fusion. **A**, A 2n DNA content per nucleus was found in newly formed myocytes, ECs, and SMCs originated from BMPCs injected in the border zone of an acute infarct. Lymphocytes were used as control. **B-D**, Sections illustrating the interface between the surviving (SM) and regenerated myocardium (RM) at low (**B**) and higher (**C** and **D**) magnification. At 30 days, newly formed myocytes (arrows) have at most one Y-chr (white) and one X-chr (green), indicating their diploid male genotype. Spared myocytes (arrowheads) showed, at most, two X-chr, indicating their diploid female genotype. **E**, SMCs in a regenerated arteriole possess, at most, one Y-chr and one X-chr, documenting their diploid male genotype. (From Rota M, Kajstura J, Hosoda T. Bone marrow cells adopt the cardiomyogenic fate in vivo. *Proc Natl Acad Sci USA* 2007;104:17783-17788.)

function of resident human CPCs and their potential role in cardiac cell turnover and regeneration.

Human myocytes larger than 30,000  $\mu\text{m}^3$  cannot reenter the cell cycle and proliferate.<sup>163</sup> Cycling myocytes are small and mononucleated. It would be inefficient for large myocytes to divide once or at most twice to expand the cardiac mass. Heart weight in humans can increase nearly threefold, reaching values of 1000 g or larger.<sup>218-221</sup> Heart failure typically shows increases in myocyte number that vary from 20% to 100% or more.<sup>218-223</sup> This phenomenon is not affected by age; in an analysis of 7112 human hearts, from birth to 110 years of age, Linzbach has shown that extreme forms of organ hypertrophy are detectable up to the ninth decade of life, and heart weights of 500 and 600 g are present in patients at 100 years of age and older.<sup>224</sup> Collectively, these observations point to the CPC as the controlling cells of cardiac homeostasis and repair. Surprisingly, despite the fact that the controversy on myocardial regeneration persists, several distinct types of CPCs have been claimed by different laboratories with values that would transform the heart from a postmitotic organ to the most self-renewing organ in the organism.

These uncertainties strengthen the need for the acquisition of fundamental knowledge on the growth and differentiation of CPCs.

Understanding CPC function is critical for the implementation of CPCs in the daily treatment of the chronically decompensated human heart. In fact, the heart now belongs to the group of constantly renewing organs, where the capacity to replace cells depends on the persistence of a stem cell compartment.<sup>109,110,225-231</sup> Regeneration conforms to a hierarchical archetype in which slowly dividing stem cells give rise to proliferating, lineage-restricted progenitor-precursor cells, which then become highly dividing amplifying cells, which eventually reach terminal differentiation and growth arrest.<sup>231-234</sup> Stem cells have a high propensity for cell division and this property is maintained throughout the life span of the organ and organism.<sup>227,228,230,233,234</sup> In contrast, the less primitive, transient amplifying cells represent a group of dividing cells that have a limited proliferation capacity. Amplifying cells divide and concurrently differentiate,<sup>225,228,235-237</sup> and when complete differentiation is reached, the ability to replicate is permanently lost. This forms the foundation of a new

**FIGURE 4-16** Hierarchy of cardiac stem cell (CSC) growth and differentiation. Asymmetrical division of a CSC into a daughter CSC and a daughter cardiac progenitor (CPg). CPg gives rise to myocyte progenitor (MPg) and precursor (MPr), EC progenitor (EPg) and precursor (EPr), and SMC progenitor (SMPg) and precursor (SMPr). Precursors become transient amplifying cells, which divide and differentiate into mature myocytes, ECs, and SMCs. CSCs are lineage-negative cells that express only c-kit, MDR1, or Sca-1. Progenitors express stem cell antigens and transcription factors of cardiac cells but do not exhibit specific cytoplasmic proteins. Precursors possess stem cell antigens, transcription factors, and membrane and cytoplasmic proteins typical of myocytes, ECs, and SMCs. Amplifying cells have nuclear, cytoplasmic, and membrane proteins of cardiac cell lineages but are negative for stem cell antigens. TGF- $\beta$ , transforming growth factor  $\beta$ -receptor. (From Anversa P, Kajstura J, Leri A, et al. Life and death of cardiac stem cells: a paradigm shift in cardiac biology. *Circulation* 2006;113:1451-1463.)

paradigm of the heart in which multipotent resident CPCs are implicated in the constant turnover of myocytes, ECs, SMCs, and fibroblasts (Figure 4-16). The recognition that activated CPCs translocate to areas of need where they grow and differentiate makes the possibility of myocardial regeneration a feasible reality. Theoretically, in a manner comparable to HSCs that repopulate and completely reconstitute the ablated bone marrow,<sup>238,239</sup> CPCs may be capable of rebuilding the damaged myocardium and converting a severely diseased heart into a physiologically functional heart.

The recognition that the adult atrial and ventricular myocardium contains a pool of CPC that are self-renewing, clonogenic, and multipotent in vitro and regenerate cardiomyocytes and coronary vessels in vivo has raised the unprecedented opportunity to repair the diseased heart.<sup>13-25</sup> Hypothetically, CPCs can be isolated from biopsy samples and, following their expansion, can be implanted within regions of damage where they reconstitute the lost myocardium.<sup>25</sup> Alternatively, portions of infarcted or injured myocardium can be restored by cytokine activation of resident CPCs, which

migrate to the site of injury where subsequently they form myocytes and vascular structures.<sup>80,81</sup> At last, the injured tissue is replaced by new functionally competent myocardium. These two forms of therapy are not mutually exclusive and in fact complement each other. In a heart severely depleted of its CPC compartment, the identification and expansion of the remaining CPCs may be a preferable option while, in the presence of a relatively intact CPC pool, the administration of cytokines may be as effective as direct cell implantation. Collectively, the findings in small and large animals are encouraging but have left unanswered the question whether the cells currently available for myocardial regeneration possess the inherent property to mature into adult myocytes and form the vascular framework necessary for the oxygenation of the developing myocardium. These important issues constitute the target of future research, which aims at the identification of novel strategies for the treatment of chronic heart failure of ischemic and nonischemic origin.

# Myocardial Basis for Heart Failure: Role of the Cardiac Interstitium

Ashleigh A. Owen and Francis G. Spinale

With a prolonged cardiovascular stress or pathophysiological stimuli, a cascade of compensatory structural events occurs within the myocardium. This process occurs as a continuum and has been defined as myocardial remodeling (see Chapter 15). This remodeling process has been demonstrated within the myocardial compartment following myocardial infarction (MI), with hypertrophy, or cardiomyopathic disease. A commonly employed index of the left ventricular (LV) remodeling process is quantitation of chamber volumes.<sup>1-5</sup> Progressive LV dilation in patients with chronic heart failure (CHF) is associated with a greater incidence of morbidity and mortality.<sup>3,4</sup> Furthermore, pharmacological treatments that provide a beneficial effect on survival in CHF patients are very often associated with an attenuation in the rate and extent of LV dilation.<sup>1-7</sup> These observational data suggest that interventions that directly alter the LV myocardial remodeling process hold therapeutic promise in the setting of CHF. A number of cellular and extracellular factors likely contribute to the complex process of myocardial remodeling. For example, myocardial remodeling following MI includes

signaling and cellular pathways that may be potential therapeutic targets for modulating ECM structure and function in the context of CHF.

## MYOCARDIAL EXTRACELLULAR MATRIX STRUCTURE AND COMPOSITION

The myocardial ECM contains a fibrillar collagen network, a basement membrane, proteoglycans, and glycosaminoglycans, and bioactive signaling molecules. The myocardial fibrillar collagens such as collagen types I and III ensure structural integrity of adjoining myocytes, provide the means by which myocyte shortening is translated into overall LV pump function, and is essential for maintaining alignment of myofibrils within the myocyte through a collagen-integrin-cytoskeletal-myofibril relation.<sup>8,10,32-36</sup> While the fibrillar collagen matrix was initially considered to form a relatively static complex, it is now recognized that these structural proteins can undergo rapid degradation and fairly rapid turnover. The complex fibrillar collagen weave, which surrounds individual myocytes within the myocardium, is demonstrated in [Figure 5-1](#). Collagen fibril formation entails posttranslational modification. The carboxyterminal of the procollagen fibril is cleaved by a proteolytic reaction, which results in a conformational change necessary for collagen fibril cross-linking and triple helix formation.<sup>37</sup> A critical step in the proper formation and structural orientation of the fibrillar collagen matrix is collagen cross-linking. Interruption of collagen cross-linking has been clearly demonstrated to alter myocardial ECM structure and in turn LV geometry and function.<sup>38-40</sup> Furthermore, alterations in fibrillar collagen cross-linking have been identified in myocardial samples taken from patients with end-stage CHF.<sup>15</sup> While the newly formed, uncross-linked collagen fibrils are vulnerable to degradation, the triple helical collagen fiber is resistant to nonspecific proteolysis and further degradation requires specific enzymatic cleavage. During collagen cross-link formation, the carboxyterminal peptide is released into the vascular space.<sup>41-43</sup> Collagen type I

changes in coronary vascular structure and function, myocyte loss, hypertrophy of remaining myocytes, and increased size and number of nonmyocyte cells, all of which result in nonuniform changes in LV myocardial wall geometry. While myocardial remodeling is accompanied by changes in the cellular constituents of the LV myocardium, significant alterations in the structure and composition of the extracellular matrix (ECM) occurs.<sup>8-12</sup> Moreover, it has become increasingly evident that the myocardial ECM is not a static structure, but rather a dynamic entity that may play a fundamental role in myocardial adaptation to a pathological stress and thereby facilitate the remodeling process.<sup>8-27</sup> A greater appreciation for the highly complex and dynamic nature of the ECM can be realized by myocardial imaging and direct interrogation of the interstitium.<sup>28-30</sup> An example of the complexity of the ECM and the tight interface with respect to tissue structure and function is exemplified by the freeze-etched electron microscopic studies illustrated in [Figure 5-1](#).<sup>31</sup> These imaging studies underscore how the ECM environment is tightly coupled to the cell membrane and intracellular structures. In both human and animal studies, it has been reported that alterations in the collagen interface, both in structure and composition, occur within the LV myocardium, which in turn may influence LV geometry.<sup>14-28,32-36</sup> Therefore, identification and understanding of the biological systems responsible for ECM synthesis and degradation within the myocardium hold particular relevance in the progression of CHF. Accordingly, the purpose of this chapter is fourfold. First, present a brief overview of myocardial ECM structure and biosynthesis. Second, briefly demonstrate how the ECM is altered in important disease states that cause CHF: MI, hypertension, and cardiomyopathy. Third, discuss how increased activation of an interstitial proteolytic system likely contributes to ECM remodeling in CHF. Fourth, define

**FIGURE 5-1** **A**, An example of the complex nature of the ECM and the tightly coupled interrelationship to the cell membrane and intracellular structures is exemplified in this micrograph of a chondrocyte and the ECM obtained by quick-freeze, deep-etched microscopy.<sup>31</sup> The ECM is densely filled with a highly structured architecture that directly interfaces with the plasma membrane (PM), and in turn the intracellular (IN) space. The nuclear pores are evident on the nuclear membrane (NM) and emphasize the tightly coupled arrangement between the nucleus to the ECM. This image reinforces the concept that changes in ECM structure and function will directly affect cellular processes. **B**, Sections of myocardium were perfusion fixed and then subjected to maceration digestion and scanning electron microscopy to remove cellular constituents and provide a greater relief of the fibrillar collagen matrix.<sup>179</sup> The fibrillar collagen weave surrounding individual myocyte profiles and the degree of complexity regarding the 3-dimensional ECM network can be readily appreciated through this process. (**A**, Image courtesy of Dr. Robert Mecham, Washington University School of Medicine. **B**, Reproduced from Rossi MA. Connective tissue skeleton in the normal left ventricle and in hypertensive left ventricular hypertrophy and chronic chagasic myocarditis. *Med Sci Monit* 2001;7:820–832.)

fiber formation results in the release of a 100-kDa procollagen type I carboxyterminal propeptide (PIP).<sup>43–45</sup> Similarly, the formation of mature collagen III fibers results in the release of a 42 kDa procollagen peptide (PIIP).<sup>43,44</sup>

The integrins are a family of transmembrane proteins that serve multiple functions with respect to myocardial structure and function.<sup>32–34</sup> Integrins form the binding interface with proteins comprising the basement membrane and therefore directly influence myocyte growth and geometry. Moreover, the integrins coalesce at important structural sites within the myocyte called costameres, which are composed of cytoskeletal proteins such as  $\alpha$ -actinin and vinculin which form a key intracellular support network for contractile protein assembly and maintaining sarcomeric alignment.<sup>32–34,46,47</sup> The myocyte costamere is also where the integrins appear to cluster and interdigitate with an intracellular signaling cascade system such as focal adhesion kinase. Thus disruption of normal integrin-ECM interactions will likely result in significant changes in myocyte structure and function.

There are a number of extracellular proteins that comprise the basement membrane, such as collagen IV, fibronectin, and laminin. It is the basement membrane that forms the anchoring points for the fibrillar matrix and contact points for other proteoglycans such as chondroitin sulfate within the ECM. For example, the abundant binding of negatively charged unbranched glycosaminoglycans within chondroitin sulfate results in a molecule with a very high osmotic activity.<sup>48</sup> Accordingly, changes in the content and distribution of these proteoglycans will affect hydration within the extracellular space and in turn directly influence myocardial compliance characteristics. Moreover, these highly charged molecules within the ECM result in the formation of a hydrated gel, which serves as a reservoir for signaling molecules and bioactive peptides. Therefore, the ECM is an important determinant of extracellular receptor-ligand interactions. Another important function of the myocardial ECM is that it serves as a reservoir for critical biological signaling molecules that regulate myocardial structure and function. For example, tumor necrosis

factor  $\alpha$  (TNF- $\alpha$ ) is initially a membrane-bound molecule that requires proteolytic processing and release into the interstitial space to form ligand complexes with cognate receptors.<sup>49–51</sup> Also, transforming growth factor  $\beta$  (TGF- $\beta$ ) exists in a latent form bound to the ECM and requires proteolytic processing within the myocardial interstitium to become a competent signaling molecule.<sup>52–54</sup> TGF signaling produces multiple cellular responses—most importantly, the stimulation of ECM protein synthesis.<sup>55–57</sup> Thus while this chapter will primarily focus upon the collagen fibrillar network, it is becoming recognized that the myocardial interstitium is a complex environment that contains structural and signaling molecules that directly affect overall myocardial form and function.

## MYOCARDIAL EXTRACELLULAR MATRIX REMODELING IN CHRONIC HEART FAILURE

The myocardium is a highly organized structure that contains a vascular network, nonmyocyte cells such as fibroblasts and macrophages, and cardiac myocytes. The ECM forms a continuum between these cell types within the myocardium and provides a structural supporting network to maintain myocardial geometry during the cardiac cycle. Significant changes in myocardial ECM structure and composition have been identified in cardiac disease states that give rise to the clinical manifestation of CHF.

### Myocardial Extracellular Matrix Remodeling in Myocardial Infarction

It is now recognized that a number of architectural events occur following acute MI that involve both the infarcted and noninfarcted regions.<sup>3–5,7,10–12</sup> The LV remodeling process, which occurs in the post-MI period, can be considered in two phases: the acute healing phase and the chronic adaptive phase. The acute phase of MI healing involves myocyte necrosis and replacement fibrosis (see Chapter 15). In the chronic adaptive phase, changes within the MI region and in the noninfarcted region occur. Within the MI region, fibroblasts proliferate and form an extracellular matrix that provides a support structure for infarct scar maturation. This extracellular matrix within the MI region also provides a means to tether viable myocyte fascicles and thereby forms a substrate to resist deformation from the intracavitary stresses generated during the cardiac cycle. Failure of this extracellular support has been associated with LV wall thinning and slippage of myocyte fascicles.<sup>3–5,8–12</sup> This adverse remodeling process has been termed “infarct expansion” and occurs in the absence of additional myocyte injury or alterations in LV loading conditions. Studies performed over the past decade have clearly demonstrated that alterations within the myocardial matrix contributes to the LV remodeling process post-MI.<sup>1–10,19,20,23,24</sup> A number of clinical studies have clearly demonstrated an increased risk for the development of heart failure and mortality in those patients with MI-expansion and regional dilation.<sup>1,3,7</sup> In fact, the extent of infarct expansion that occurs post-MI and the subsequent myocardial remodeling of the left ventricle are the strongest predictors for the development of CHF.<sup>6,7</sup> In addition to CHF, impaired ECM formation within the MI region has been associated with LV rupture.<sup>23</sup> In contrast to the MI region, it has been postulated that an acceleration of ECM degradation occurs within the myocardium surrounding the MI (border zone) and may facilitate the infarct expansion process. These events within the myocardial ECM occur in a time- and region-dependent manner following MI. Thus different patterns of ECM remodeling are taking place simultaneously in the post-MI period; enhanced ECM accumulation occurs within the MI region while increased degradation occurs within the border zone. Therapeutic strategies

that are targeted at minimizing the degree of infarct expansion must take into account the absolute requirement to maximize ECM stability within the MI region. Animal studies demonstrated that modulating ECM degradation in the early post-MI period reduced the relative degree of infarct expansion; however, it also impaired the wound healing response within the MI.<sup>23,24</sup> Past studies have also clearly demonstrated that therapeutic strategies targeted at the inflammatory response in the early post-MI period are not associated with favorable outcomes.<sup>3,4</sup> The mechanisms and stimuli that determine the balance between ECM synthesis and degradation are likely to be different within each region of the left ventricle following MI. Thus elucidating the molecular mechanisms that locally control ECM synthesis and degradation in the post-MI period will likely yield specific therapeutic strategies that will facilitate the wound healing response, while also attenuating the adverse myocardial remodeling that gives rise to infarct expansion and LV failure.

### Myocardial Extracellular Matrix Remodeling in Left Ventricular Hypertrophy

The hallmark of myocardial structural remodeling with pressure overload hypertrophy (POH), such as hypertension or aortic stenosis, is ECM accumulation.<sup>58-63</sup> Specifically, prolonged POH is associated with significantly increased collagen accumulation between individual myocytes and myocyte fascicles. The extent and degree of ECM remodeling with POH are clearly exemplified by the landmark studies of Weber and Janicki.<sup>47,48</sup> As shown in Figure 5-2, these studies demonstrated thickening of the collagen weave and overall increased relative content between myocytes in a nonhuman primate model of POH. While the accumulation of ECM with POH is not exclusive to collagen, these initial structural studies gave rise to the generic term myocardial fibrosis to describe this extracellular remodeling process. In POH, the accumulation of ECM and eventual myocardial fibrosis significantly contributes to LV function. With POH, the highly organized architecture of the ECM is replaced with a thickened, poorly organized ECM. Thus initial degradation of the

normal ECM is likely followed by decreased capacity for ECM degradation and turnover in the later stages of POH.<sup>43-45,60-71</sup> Increased plasma levels of PIP and PIIP occur in hypertension and imply that significant ECM synthesis and remodeling occur, which may be associated with the LV remodeling process.<sup>45-47</sup> In particular, enhanced synthesis and deposition of myocardial ECM is directly associated with increased properties of LV myocardial stiffness, which in turn causes poor filling characteristics during diastole.<sup>64-71</sup> Indeed, recent clinical evidence suggests that progressive ECM accumulation and diastolic dysfunction are important underlying pathophysiological mechanisms for heart failure in patients with POH.<sup>60,61,69-72</sup> Moreover, serial studies in patients with AS have shown that the significant changes in myocardial ECM structure and composition that occur during the progression of POH may not be readily reversible.<sup>73-75</sup> Thus an emerging concept supported by both basic and clinical studies is that dynamic changes in myocardial ECM structure and composition occur in POH, and can contribute to certain manifestations of diastolic dysfunction and ultimately CHF. A chapter contained within this text by Zile et al discusses in greater detail the factors that contribute to diastolic dysfunction and eventually CHF.<sup>76</sup>

### Myocardial Extracellular Matrix Remodeling in Cardiomyopathy

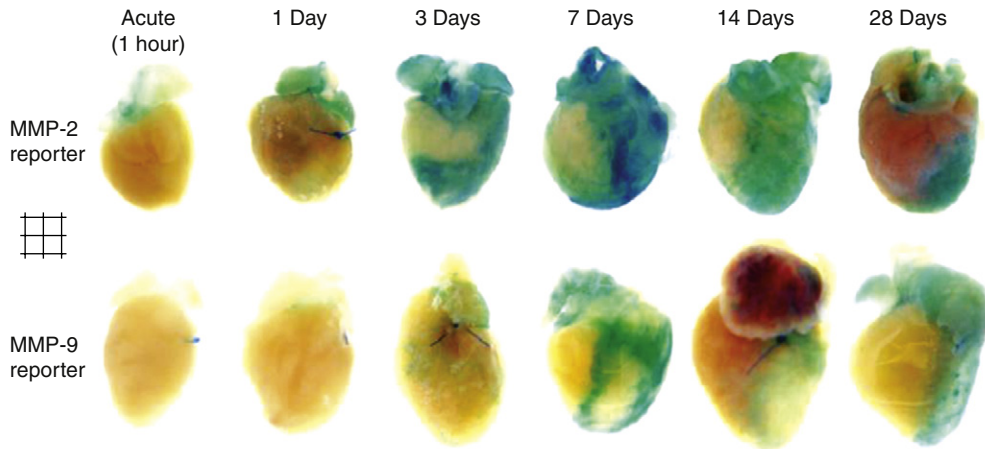

The dilated cardiomyopathies are a classification of primary myocardial disease states that constitute a significant proportion of patients with heart failure. While the causes for dilated cardiomyopathy are diverse, a general pathophysiological classification scheme has been developed and termed ischemic, idiopathic (nonischemic), or infectious. The pathophysiology of dilated cardiomyopathy involves an increase in LV ventricular chamber radius compared with wall thickness. This increased ratio is accompanied by increased myocardial wall stress, which can in turn promote further dilation. In patients with rapidly progressive LV remodeling and dilation, morbidity and mortality are increased.<sup>77,78</sup> At the myocardial level, significant changes in the myocardial ECM occur in patients with cardiomyopathic disease and likely facilitate this remodeling process.<sup>8,9,13-16</sup> For example, a loss of the normal fibrillar collagen weave surrounding myocytes and diminished fibrillar collagen cross-linking have been reported in patients with DCM.<sup>8,15</sup>

### EXTRACELLULAR MATRIX PROTEOLYTIC DEGRADATION: THE MATRIX METALLOPROTEINASES

The matrix metalloproteinases (MMPs) are a family of zinc-dependent proteases that play a role in a number of tissue remodeling processes.<sup>11,12,77-84</sup> Currently, more than 25 distinct human MMPs have been identified and characterized. MMPs have been shown to be responsible for matrix remodeling in a number of physiological processes, such as bone growth and wound healing along with pathological processes such as inflammation, tumor invasion, and metastasis.<sup>77-84</sup> While initially thought to only cause ECM proteolysis, the MMPs likely possess a large portfolio of biological functions.<sup>85-87</sup> Analysis of MMP protein structure has revealed four well-conserved modular regions. The signal peptide and propeptide sequences constitute the NH<sub>2</sub>-terminal domain. The catalytic domain contains the zinc (Zn<sup>2+</sup>) binding region and is responsible for proteolytic activity. The hemopexin/vitronectin domain is found in all MMPs except MMP-7, and confers substrate specificity. For MMP activation to occur, a sequence of proteolytic events must take place. In the latent state, the MMP catalytic domain is concealed by

**FIGURE 5-2** Scanning electron micrographs taken from normal nonhuman primate LV myocardium and following the induction of pressure overload hypertrophy (POH). These microscopic studies demonstrated thickening of the collagen weave and overall increased relative content between myocytes with POH. (Figures reproduced from Abrahams C, Janicki JS, Weber KT. Myocardial hypertrophy in *Macaca fascicularis*. Structural remodeling of the collagen matrix. *Lab Invest* 1987;56:676-683.)

**FIGURE 5-3** The full-length MMP-2 or MMP-9 promoter was ligated to the  $\beta$ -galactosidase reporter and fused into mice, thereby providing an in vivo index of selective MMP promoter activity. An MI was induced in these transgenic constructs and reporter levels visualized at 1 to 28 days post-MI. MMP-2 promoter activity could be readily observed by 3 days post-MI and MMP-9 promoter activity by 7 days post-MI. MMP-2 promoter activity was initially localized to the MI region but later extended to the border and remote regions as time passed post-MI. Similarly intense MMP-9 promoter activity could be observed within the area surrounding the MI (border region) that then extended into the remote regions with longer post-MI periods. Scale bar 2 mm  $\times$  2 mm square. (Figure reproduced from Mukherjee R, Mingoia JT, Bruce JA, et al. Selective spatiotemporal induction of matrix metalloproteinase-2 and matrix metalloproteinase-9 transcription after myocardial infarction. *Am J Physiol Heart Circ Physiol* 2006;291(5):H2216–H2228.)

the propeptide mediated by a cysteine-Zn<sup>2+</sup> interaction.<sup>83,88</sup> This biochemical interaction of concealing the catalytic site with subsequent activation is known as the cysteine switch. The MMPs were historically classified into subgroups based upon substrate specificity and/or structure, and an informal nomenclature for some of the individual MMPs arose from these initial substrate studies. However, there is significant overlap in MMP proteolytic substrates and a more rigid numerical classification is now used. Important MMPs in the context of this review include the collagenases such as MMP-1 and MMP-13, the stromelysins/matrilysins MMP-3/MMP-7, the gelatinases MMP-9 and MMP-2, and the membrane-type MMPs (MT-MMPs). Once activated, the MMPs can work synergistically to degrade the entire extracellular matrix component. For this reason it is important that their activity is kept under tight control.

### Transcriptional Regulation

The control of gene expression through changes in transcription is an important determinant of MMP tissue levels.<sup>85-93</sup> Characterization of MMP gene promoters has provided some insight into possible mechanisms that regulate MMP gene expression. Studies have identified several consensus sequences for nuclear binding proteins on MMP genes.<sup>85,86</sup> These elements include the tumor response element (TRE), activator protein-1 (AP-1) binding sites, and the polyoma virus enhancer A-binding protein-3 (PEA-3) sites. The AP-1 and TRE sites bind the dimers of Fos and Jun families, while the members of the Ets family of transcription factors bind to the PEA-3 sites. Although there are similarities among MMP promoters, the promoter of MMP-2 is notably distinct from other members of the MMP family.<sup>85,86,91</sup> Although most MMP genes contain similar promoter elements, the position of the elements relative to the transcription start site differs between different MMPs, which may partly account for different expression patterns. A clear example of differential MMP transcriptional regulation within the myocardium has been achieved using MMP promoter-reporter constructs.<sup>94,95</sup> Specifically, the full-length MMP promoter is fused to a reporter and placed into the mouse genome.<sup>94,95</sup> Through this approach, MMP-type specific promoter activity can be examined from a spatial and temporal aspect following a pathological stimulus such as MI. Representative whole heart mounts

for MMP-9 and MMP-2 promoter activity are shown in Figure 5-3. The promoter activity of MMP-9 and MMP-2 were readily appreciated following the induction of MI in the transgenic mice, but the spatial-temporal patterns were different. These studies clearly demonstrate that regulation of MMP promoter activity constitutes an important focus for selective MMP induction within the myocardium.

### Matrix Metalloproteinase Gene Polymorphisms

The potential importance of MMP gene/transcriptional regulation can also be shown from clinical studies identifying variant forms of DNA sequences and polymorphisms for several of the MMP subtypes.<sup>96-109</sup> The polymorphisms that have been identified thus far often affect the promoter region of the MMP gene, and thereby influence critical steps in the binding of transcription factors and the overall efficiency of transcription. An overview of some of the major polymorphisms reported with respect to MMP-9, -2, -3, and MMP-1 and the potential consequences of these alterations in DNA sequences are summarized in Table 5-1. The most intensely studied to date are polymorphisms that occur within the promoter region for MMP-9 and MMP-3.<sup>96-103,107,109</sup> With respect to MMP-9, a gene variant has been observed within the promoter region located at position -1562 relative to the transcription start site. This MMP-9 variant is a single base substitution where a transition between cytosine(C) and thymidine(T) occurs. The T allele results in a higher relative level of promoter activity when compared with the C allele.<sup>96-98</sup> In turn, presence of the MMP-9 1562(T) allele has been associated with increased plasma levels of MMP-9 protein.<sup>96</sup> A naturally occurring variant in the MMP-3 promoter region is the 5A and 6A alleles that signify a 5 or 6 adenine sequence, respectively. The 5A allele has been associated with increased MMP-3 promoter activity, and in turn increased relative MMP-3 protein levels.<sup>99-103</sup> In contrast, the 6A allele has been associated with reduced MMP-3 promoter activity. In a study performed in more than 2800 Japanese patients, the 5A polymorphism was associated with increased risk of MI in women.<sup>101</sup> Mizon-Gerard et al have also reported that homozygosity for the 5A allele in patients with nonischemic cardiomyopathy was associated with a reduced survival rate.<sup>98</sup> One preliminary clinical study showed that the addition of guanine within the MMP-1 promoter region (-1607 1G/2G) is associated with the

**TABLE 5-1 Polymorphisms in Matrix Metalloproteinase Promoter Sequences**

Polymorphism	Biological Effect	Clinical Association	Reference
<b>MMP-9</b>

<b>MMP-1</b>			
-1607 1G/2G	↑Transcription factor binding	↑Risk of post-MI remodeling	104, 105
-519-340 A/G-C/T	↓Promoter activity	↓Risk of post-MI remodeling	106

acceleration of adverse LV myocardial remodeling in patients post-MI.<sup>104,105</sup> In another study, certain single nucleotide polymorphisms within the MMP-1 promoter that are believed to reduce MMP-1 transcriptional activity were identified and associated with reduced risk of MI.<sup>106</sup> While it is likely that additional MMP polymorphisms will be identified, it must be recognized that these MMP genotyping approaches do not provide a clear cause-effect relationship between the MMP system and myocardial matrix remodeling. Another consideration is that these MMP polymorphisms may not occur as independent events but rather are associated with other polymorphisms in the genome. However, it is intriguing to speculate that these MMP polymorphisms may be able to identify those patients who are more vulnerable to adverse matrix myocardial remodeling and therefore are likely to experience a more rapid progression of CHF.

### Neurohormones, Cytokines, and Intracellular Activation

MMP mRNA expression can be influenced by a variety of biological signaling molecules, such as neurohormones, corticosteroids, and cytokines (see Chapter 11).<sup>\*</sup> For example, cytokines such as TNF have been demonstrated to influence MMP gene expression by activating and modulating response elements on MMP gene promoters in several cell systems.<sup>90,92,111-113</sup> While the mechanisms of MMP induction by these factors can be complex, one common pathway appears to involve the AP-1 site.<sup>89,90</sup> Other factors such as retinoids, TGF, and glucocorticoids are thought to inhibit MMP gene expression by several mechanisms, which include sequestering unbound AP-1 proteins.<sup>114</sup> Transcription of MMPs is not

only dependent upon a specific portfolio of transcription factors, but it may also be determined by a cell-specific response. For example, interleukin-1 induces expression of MMP-1 and MMP-3 in fibroblasts but not in keratinocytes, and transforming growth factor  $\beta$  suppresses MMP-9 production in fibroblasts but induces its production in keratinocytes.<sup>115</sup> Another potentially important promoter binding site located on MMPs, such as the one on MMP-9, is the nuclear factor  $\kappa$ B site.<sup>110,111</sup> Exposure of human fibroblasts to inflammatory cytokines, which induce nuclear factor  $\kappa$ B, have been shown to cause an upregulation of MMP-9.<sup>116,117</sup> In several cell systems, exposure to phorbol esters, which activates the protein kinase C (PKC) intracellular pathway, also increases MMP mRNA transcription.<sup>111</sup> Finally, past studies have identified a transmembrane protein that induces the expression of specific MMPs in vitro; the extracellular matrix metalloproteinase inducer protein (EMMPRIN).<sup>118-121</sup> The most active area of EMMPRIN investigation has been with respect to tumor invasion where increased EMMPRIN expression has been localized to areas with intense remodeling activity or highly invasive tumors.<sup>119</sup> In this pathological tissue remodeling process, it is likely that EMMPRIN is a contributory factor in the stimulation of MMPs required for tumor invasion and metastasis. A recent clinical study has clearly demonstrated an upregulation of EMMPRIN in platelets following MI.<sup>121</sup> Moreover, increased EMMPRIN levels have been identified in patients with DCM.<sup>14</sup> For these reasons EMMPRIN may also be an important contributory factor in the upregulation of various MMPs in the context of myocardial remodeling.

### Matrix Metalloproteinase Activation

While the level of MMP synthesis is an important determinant of matrix degradation, the true degradative capacity of the MMPs is dependent upon the activation of the MMP pro-enzyme. After being synthesized in a latent, pro-enzyme, or zymogen form, the MMPs are secreted into the extracellular space. For MMP zymogen activation to occur, a sequence of proteolytic events must take place. Thus an important control point of MMP activity is proteolytic cleavage by other enzymes (e.g., serine proteases and other MMP species), or exposure to certain physical and chemical effectors.<sup>83,84,88</sup> For MMP activation to occur, the NH<sub>2</sub> terminal sequence of the propeptide domain must be cleaved, resulting in the exposure of the zinc binding site of the catalytic domain. It has been demonstrated serine proteases such as plasmin can generate active MMPs. In addition, MMP activation can also occur at the cell surface involving the MT-MMPs.<sup>122-128</sup> At the cell membrane, MT-MMP is already in an active state such that it can then activate other MMP species at the cell surface. It has been clearly established that MT1-MMP activates MMP-2, and in fact may be the predominant pathway for MMP-2 activation.<sup>123-128</sup> Moreover, it appears that a very wide proteolytic portfolio for MT1-MMP exists, which would imply that this MMP type may participate in a number of enzymatic and signaling cascades within the myocardial ECM.<sup>85-87</sup> This is likely to hold particular relevance since robust levels of MT1-MMP have been identified within both experimental and clinical forms of CHF.<sup>14,25,30,129-131</sup>

### Endogenous Matrix Metalloproteinase Inhibition

Another important control point of MMP activity is in the inhibition of the activated enzyme by action of a group of specific MMP inhibitors termed tissue inhibitors of matrix metalloproteinases (TIMPs).<sup>11,12,81-84</sup> There are four known TIMP species of which TIMP-1 and TIMP-2 are the best characterized. The TIMPs are low molecular weight proteins that can complex noncovalently with high efficiency to MMPs in a 1:1 molar ratio. Therefore, these inhibitory proteins are an

\*References.11, 51, 82, 88, 89, 92, 110, 111.

important endogenous system for regulating MMP activity *in vivo*. While the TIMPs are expressed in a variety of cells, TIMP-4 shows a high level of expression in cardiovascular tissue.<sup>132,133</sup> While it is believed that the predominant role of TIMPs is the inhibition of active enzymes, this is likely to be an oversimplistic view of the function of these proteins. For example, studies have demonstrated TIMPs to be involved in the process of MMP activation, to exhibit growth factor-like properties, and to participate in apoptosis.<sup>134-137</sup> In one study the overexpression of TIMP-1, -2, -3, -4 was induced in murine myocardial fibroblasts by adenoviral-mediated transduction.<sup>135</sup> Many differential biological consequences were observed after the induction of TIMPs, including effects on collagen synthesis and apoptosis. These differences were not secondary to MMP inhibition since past studies involving pharmacological MMP inhibition did not recapitulate these effects, thus indicating a direct action of TIMPs on fibroblast function. Moreover, TIMP-specific effects were also observed; TIMP-2 caused a robust increase in collagen synthesis whereas TIMP-3 accelerated fibroblast apoptosis. These results underscore the highly diverse and complex nature of the proteins existing within the myocardial interstitium.

## Matrix Metalloproteinases and Myocardial Remodeling

### Matrix Metalloproteinases and Myocardial Infarction

While dependent upon the severity and duration of the ischemic insult, alterations in LV myocardial collagen structure can occur following MI that would implicate changes in MMP activity within the myocardial interstitium.<sup>8-12</sup> Several clinical studies have provided data to demonstrate that increased plasma levels of MMPs occur in patients in the early post-MI period.<sup>138-141</sup> As discussed in a subsequent section, a time-dependent change in plasma MMP and TIMP profiles occurs in patients post-MI. However, the specificity of this MMP release with respect to myocardial MMP activation and the relationship to clinical outcomes remains an area of active investigation.

Experimental studies have provided mechanistic evidence that increased expression and activation of MMPs contribute to the post-MI remodeling process.<sup>19,20,22-24,29,129-131</sup> For example, it has been demonstrated that manipulating MMP expression in transgenic mice can alter tissue remodeling within the MI region and influence the degree of post-MI remodeling.<sup>22-24,27</sup> These past studies have demonstrated that MMPs may play an operative role in several phases of the evolving MI. First, early activation of MMPs may be essential for degradation of the extracellular interface between the ischemic and nonischemic regions and thereby provide an egress for inflammatory cells into the MI region. Second, activation of MMPs within the MI region may facilitate the extracellular protein degradation necessary for proper scar formation and angiogenesis. Third, prolonged activation or an acceleration of MMP expression within the viable post-MI myocardium may contribute to the process of infarct expansion. A common event following myocardial ischemia and subsequent reperfusion is an influx of inflammatory cells into the ischemic region, which results in the release and activation of a number of proteolytic enzymes. Neutrophils have been demonstrated to release several species of MMPs, including MMP-8 and MMP-9.<sup>79-84</sup> Fibroblasts and smooth muscle cells also synthesize a complement of MMPs including MMP-9. Past studies have demonstrated that MMPs, particularly MMP-2 and MMP-9, can be synthesized by myocytes.<sup>11,12</sup> Thus the induction of MMP-9 following MI is likely the result of liberated MMP-9 from endogenous and exogenous cell types. The putative role for MMP-9 induction to contribute to the post-MI remodeling process has been exemplified in transgenic mouse studies.<sup>24</sup> However, it is unlikely that a single MMP type is responsible for the adverse post-MI remodeling

process. For example, gene deletion of MMP-2 has also been demonstrated to cause favorable effects on LV geometry and function in the early post-MI period.<sup>22</sup>

In addition to the induction of a large portfolio of MMPs in the post-MI period, a loss of MMP inhibitory control also appears to play an important role in the adverse LV remodeling process. First, pharmacological MMP inhibition deployed in various animal models of MI have invariably demonstrated a favorable effect on the early post-MI remodeling process.<sup>23,130,131</sup> Second, the induction of MMPs within the myocardium post-MI is not paralleled by an induction of TIMPs.<sup>129,130</sup> Finally, gene deletion of TIMPs, such as TIMP-1 or TIMP-3, have been shown to cause accelerated post-MI LV remodeling.<sup>20,142</sup> These findings suggest that increased MMP expression and activation coupled with a loss of endogenous MMP inhibitory control occurs early in the post-MI period and contributes to post-MI remodeling.

### Matrix Metalloproteinases in Hypertrophy

LV hypertrophy occurs in response to a persistent increase in either pressure or volume overload. These chronic overload states result in two very different patterns of LV remodeling and changes in the extracellular matrix.<sup>11,12,58-76</sup> In states of chronic pressure overload, a common observation is the accumulation of myocardial fibrillar collagen secondary to an increase in collagen synthesis and deposition combined with a decrease in collagen degradation.<sup>1,111</sup> For example, chronic hypertension is associated with a relative reduction in the plasma levels of collagen telopeptides, which may also suggest a reduction in the proteolytic activity of MMPs.<sup>43-45</sup> In pressure overload secondary to aortic stenosis, the significant myocardial collagen accumulation was associated with a concomitant increase in relative myocardial TIMP levels.<sup>60,63</sup> In addition, reduced plasma MMP levels and increased TIMP levels have been reported in patients with systemic hypertension and LV hypertrophy.<sup>64-70</sup> For example, as shown in Figure 5-4, increased plasma levels of TIMP-1 are directly associated with the presence of LV hypertrophy, and TIMP-1 levels continue to increase with the presence of heart failure.<sup>70</sup> Experimental studies support the concept that diminished myocardial MMP activity can facilitate collagen

**FIGURE 5-4** Plasma TIMP-1 levels were quantified in age-matched patients with no history of hypertension (control,  $n = 39$ ), patients with hypertension (HTN) but no LV hypertrophy ( $n = 14$ ), patients with LV hypertrophy (LVH) but without symptoms of heart failure ( $n = 23$ ), and in patients with LVH and congestive heart failure (CHF,  $n = 26$ ). TIMP-1 levels appeared to increase incrementally as a function of the natural history of hypertensive heart disease, with a significant increase in patients with LVH and CHF (\* $P < .05$  vs. control, # $P < .05$  vs. LVH with no CHF). (Figure reproduced from Ahmed SH, Clark LL, Pennington WR, et al. Matrix metalloproteinases/tissue inhibitors of metalloproteinases: relationship between changes in proteolytic determinants of matrix composition and structural, functional, and clinical manifestations of hypertensive heart disease. *Circulation* 2006;113(17):2089-2096.)

accumulation in developing hypertrophy.<sup>143-146</sup> In the spontaneously hypertensive rat, the development of compensated hypertrophy is associated with increased myocardial TIMP levels, which would imply reduced MMP activity.<sup>145,146</sup> The changes in myocardial MMP activation are likely to be time dependent and may not be constant throughout the development of pressure overload hypertrophy. In support of this postulate, studies completed by this laboratory demonstrate time-dependent changes in myocardial MMP levels following an acute and prolonged pressure overload stimulus.<sup>62</sup> Furthermore, using a microdialysis method to directly measure MMP interstitial activity, it was demonstrated that MMP activity was reduced as a function of LV afterload.<sup>28</sup>

In contrast to chronic pressure overload, a disruption of the normal myocardial fibrillar collagen weave has been reported in chronic volume overload states such as mitral regurgitation or aorto-caval fistula. This disruption is associated with increased myocardial MMP levels and zymographic activity.<sup>11,12,62,143,144</sup> For example, in a rat model of volume overload, increased myocardial MMP zymographic activity was associated with changes in LV volumes and mass.<sup>144</sup> These studies would suggest that the early induction of myocardial MMP activity occurs with an overload stimulus that in turn alters extracellular myocyte support. These changes in extracellular fibrillar support and architecture in turn facilitate alterations in myocyte size and geometry, which is the structural basis of hypertrophy.

#### Matrix Metalloproteinases and Dilated Cardiomyopathy

There are several animal models of dilated cardiomyopathy (DCM) that have identified increased MMPs within the myocardium.<sup>18,21,25</sup> A model of CHF reporting a relationship between LV remodeling and MMP activity is the pacing-induced heart failure model.<sup>17,18,21</sup> In this pacing protocol, MMP activity as measured by an *in vitro* assay was increased. This study demonstrated that increased abundance of several species of MMPs within the myocardium coincided with the onset of LV remodeling and dilation. Moreover, these changes in MMP myocardial levels and LV geometry preceded significant alterations in cardiomyocyte contractile function, suggesting that the induction of myocardial MMPs is an early event in the progression of the heart failure process. In several rodent models of a dilated LV phenotype, a correlation between increased MMP expression and the myocardial remodeling process has also been established.<sup>25,143,144</sup> More definitive cause-effect relationships between LV myocardial remodeling and MMP induction have been shown through the use of pharmacological MMP inhibitors.<sup>18,25</sup> For example, MMP inhibition in the pacing model of heart failure attenuated the degree of LV dilation and dysfunction.<sup>18</sup> In the canine model of ischemic DCM, pharmacological MMP inhibition attenuated the progression of LV dilation and systolic dysfunction.<sup>147</sup> Thus a contributory mechanism for LV remodeling in experimentally provoked DCM is MMP induction and heightened MMP activity within the LV myocardium.

A number of studies have examined relative MMP and TIMP expression in DCM and have uniformly demonstrated an increase in certain MMP species in end-stage human heart failure.<sup>13-17</sup> One of the first studies was by Gunja-Smith et al in which increased myocardial MMP gelatinolytic activity was reported in DCM.<sup>15</sup> Using immunoblotting procedures, subsequent studies identified several MMP species that were increased in LV myocardial extracts taken from patients with end-stage DCM.<sup>13,14</sup> Specifically, increased MMP-3 and MMP-9 levels were observed in the DCM myocardial extracts compared with normal myocardium. In addition, MMP-13 was barely detected in the normal myocardium, while a robust immunoreactive signal for MMP-13 was observed in DCM myocardium.<sup>14</sup> These past observations may hold relevance for several reasons. First, MMP-13 has been associated

with pathological remodeling states such as breast carcinomas.<sup>148,149</sup> Second, MMP-13 is activated by MT1-MMP whereas MMP-1 is not.<sup>85-88</sup> Therefore the emergence of this virulent form of interstitial collagenase as the predominant collagenase within the DCM myocardium may contribute to increased degradation of the myocardial fibrillar collagen network. In addition to increased MMP-13 levels with DCM, the most robust change in MMP types was the increased levels of MT1-MMP.<sup>14</sup> Moreover, the increased levels of MT1-MMP appeared to be due to an induction within LV myocytes and fibroblasts. Specifically, a robust signal for MT1-MMP has been localized to the LV myocyte sarcolemma.<sup>14</sup> Furthermore, recent studies have shown that a persistent induction and expression of MT1-MMP occurred in DCM fibroblasts when compared with myocardial fibroblasts harvested from nonfailing patients (Figure 5-5).<sup>150</sup> The increased levels of MT1-MMP along the myocyte and fibroblast interface form a localized site for MMP activation and a persistent induction of MMP proteolytic activity within the myocardial interstitium of DCM patients.

One potential mechanism for increased myocardial MMP activity associated with myocardial remodeling is a loss of endogenous TIMP inhibitory control.<sup>13,14,16</sup> Li et al provided evidence to suggest that changes in the MMP/TIMP stoichiometric ratio occurred with end-stage DCM disease.<sup>16</sup> Specifically, TIMP-1 and TIMP-3 levels were reduced in the DCM samples, whereas TIMP-2 levels were unchanged when compared with nonfailing samples. Additionally, in both ischemic and nonischemic DCM, an absolute reduction in MMP-1/TIMP-1 complex formation has been observed.<sup>14</sup> In a transgenic model of TIMP-3 deletion, a DCM phenotype was reported as a function of age.<sup>151</sup> Taken together, these results suggest that reduced MMP/TIMP complex formation may occur in cardiomyopathic disease states, which in turn contribute to increased myocardial MMP activity and ECM remodeling.

**FIGURE 5-5** Representative high-power confocal images of normal (left panels) and DCM (right panels) human myocardial fibroblasts that were stained for MT1-MMP, DNA, and cytoskeletal actin. A more robust cytoplasmic staining for MT1-MMP was observed in DCM fibroblasts that appeared to coalesce near the actin filaments. (Reproduced from Spruill LS, Lowry AS, Stroud RE, et al. Membrane-type-1 matrix metalloproteinase transcription and translation in myocardial fibroblasts from patients with normal left ventricular function and from patients with cardiomyopathy. *Am J Physiol Cell Physiol* 2007;293(4):C1362-C1373.)

The cellular and molecular events that likely trigger the induction of MMPs with DCM are likely to be multifactorial. Increased neurohormonal activation and increased levels of cytokines are biological hallmarks of the DCM process. Thus it would be a reasonable assumption that these signaling molecules produce transcription factors that lead to the induction of MMP. As discussed in an earlier section, MMP genes contain response elements that bind members of the AP-1 protein family. Bioactive peptides and cytokines, such as TNF, can induce transcription factors that bind to AP-1 promoter elements found on several MMP genes.<sup>50,89-92,111,112</sup> Clinical evidence to support a relationship between TNF receptor activation and MMP induction was demonstrated through simultaneous measurement of soluble TNF receptors and plasma MMP levels in patients with CHF.<sup>152,153</sup> Physical stimuli, such as stress and strain, also likely induce MMP expression within the failing myocardium.<sup>26,62</sup> In DCM patients, chronic unloading of the left ventricle through the use of ventricular assist devices was associated with a reduction in LV chamber dilation and myocardial MMP levels.<sup>26</sup> These clinical observations suggest that the persistently elevated LV myocardial wall stress common to DCM can augment MMP levels.

**MODULATION OF MYOCARDIAL EXTRACELLULAR MATRIX REMODELING: DIAGNOSTIC AND THERAPEUTIC TARGETS**

One diagnostic/prognostic potential is to monitor ECM remodeling through profiling determinants of myocardial interstitial synthesis and degradation. As detailed in a previous section, several studies have demonstrated that profiling collagen peptide and TIMP levels in patients with pressure overload hypertrophy provides insight into the rate of ECM synthesis and predictive value with respect to identifying patients with diastolic dysfunction and CHF.<sup>43,44,64-70</sup> In large survey studies, plasma levels of MMPs and TIMPs have provided clear prognostic information with respect to cardiovascular events and mortality.<sup>71,153-156</sup> Perhaps the most actively studied cardiovascular disease state with respect to plasma profiling MMPs/TIMPs is in coronary artery disease and subsequent MI.<sup>138-141</sup> For example, relative TIMP-1 levels do not match the increase in MMP-9 levels post-MI, resulting in an elevated MMP-9/TIMP-1 ratio.<sup>138,140</sup> The temporal pattern for TIMP-4, which is preferentially expressed within the cardiovascular system, was examined in patients up to 6 months following MI.<sup>140</sup> In this study, a large increase in plasma MMP-9 accompanied by a relative reduction in TIMP-4 was observed early in the post-MI period. One potential net effect of the relative reduction in MMP inhibition during the post-MI period would be an increase in overall matrix degradation. Indeed, unique profiles of plasma MMP levels during the post-MI period are emerging as an independent predictor of adverse LV remodeling and probability of progression to CHF.<sup>140,141,157</sup> For example, a study by Wagner et al showed that an early increase in MMP-9 concentration was associated with an increased risk of developing heart failure in the future (odds ratio of 6.5).<sup>157</sup> Taking these studies together, a specific MMP/TIMP profile is emerging with respect to patients with coronary artery disease at risk for an acute coronary syndrome, and in patients post-MI.<sup>158-168</sup> This profile is summarized in Table 5-2. However, the degree in which modifying the changes in plasma MMP/TIMP profiles during the post-MI period may beneficially alter the course of LV remodeling and progression to CHF remains to be established.

With respect to therapeutic interventions, modulating ECM biosynthesis may provide novel strategies. For example, the importance of posttranslational processing with respect to collagen cross-linking has been demonstrated.<sup>37-41,68,69</sup> Thus strategies that alter collagen fibril stability may provide a unique

Plasma profiling in patients with established coronary artery disease (left columns) and following an acute coronary syndrome/MI (right columns). A specific MMP/TIMP portfolio emerges when compared with baseline or referent control values. For example, MMP-8 and MMP-9 levels are increased in patients with stable coronary disease and continue to markedly increase during and following an MI. In contrast, TIMP levels do not parallel these changes in MMP levels, which would favor a heightened proteolytic state. Data extracted and summarized from the references shown (Key: arrows indicate changes from baseline/referent controls)

approach in modulating ECM myocardial structure and function. Due to the fact that MMPs play a prominent role in tissue remodeling processes, a large effort was made to develop pharmacological MMP inhibitors. These were initially constructed around a hydroxamate structure.<sup>169,172</sup> A significant and somewhat paradoxical systemic side effect was termed the musculoskeletal syndrome (MSS) or the “frozen joint” syndrome.<sup>169,173-175</sup> While the mechanisms and pathways responsible for this adverse effect remained unknown, the use of hydroxamate-based MMP inhibitors was for the most part abandoned. Accordingly, a number of nonhydroxamate MMP inhibitors were subsequently developed.\* These MMP inhibitors exhibited inhibitory effects across a wide range of MMP types, and therefore were generically termed “broad spectrum” MMP inhibitors. Preclinical studies of the broad spectrum MMP inhibitors were successfully performed in several animal models and beneficial effects were uniformly provided regarding LV remodeling and the slowing of CHF progression.† However, concern arose whether and to what degree these broad spectrum MMP inhibitors may affect closely related proteases. Moreover, it was postulated that the inhibition of certain MMPs, such as MMP-1, may significantly contribute to the development of MSS. Accordingly, more selective MMP inhibitors were developed that could be pharmacologically titrated to prevent inhibition of certain MMP types; particularly MMP-1. The most advanced of these “selective” MMP inhibitors in terms of cardiovascular disease was PG11680.<sup>131,147,176,177</sup> This MMP inhibitor was evaluated in several animal models of myocardial remodeling and eventually advanced to a clinical study. In this study (Prevention of Myocardial Infarction Early Remodeling, PREMIER), 253 post-MI patients primarily

\*References 18, 19, 22, 23, 25, 131, 147, 169, 170-176.  
†References 11, 12, 18, 19, 22, 23, 25, 130, 144.

from international study centers were enrolled. Initially the study design called for a 200-mg dose to be given orally twice daily for the entire study interval of 180 days. However, due to historical concerns regarding the risk of MSS, the dosing regimen was altered following initiation of the study.<sup>177</sup> Specifically, patients randomized to PG116800 were treated initially with 200 mg once per day for the study period. The major endpoint of this study was echocardiographic indices of LV size. As a composite, LV end-diastolic volumes increased slightly from baseline (~10%) at 90 days. The relative degree of LV dilation, as a function of baseline values, was 8.4% in the PG11680 group and 10.3% in the placebo group. This did not reach statistical significance by *t*-test. The reasons for the neutral result of this MMP inhibitor are likely to be multifactorial and include an inadequate dosing regimen, a minimal change in the primary response variable, and experimental design issues. With respect to the dosing regimen, it is unlikely that this study achieved significant therapeutic efficacy of PG11680 in a large number of patients. Specifically, using published and available pharmacokinetic data,<sup>147,176</sup> the predicted plasma levels for PG11680 given as a single oral 200-mg dose fell well below an effective inhibitory concentration of any MMP type for durations of approximately 12 hours each day. The initial outfall from this clinical study was the closure of a number of development programs for MMP inhibitors. The longer term consequences from this initial clinical study are yet to be fully realized, but the near future for developing pharmacological strategies for MMP inhibition in the clinical context of cardiovascular disease is certainly in question. However, there are some important lessons that can be learned from this initial clinical MMP inhibitor study. First, these results underscore the complexity of translating basic studies into clinical therapeutics in general. Second, this study emphasizes the complexity and diversity of the MMP system.

Clinical and experimental studies suggest that MMP upregulation in developing CHF is far from a nonselective, nonspecific process. Thus a specific cassette of MMPs may be responsible for the pathological progression of myocardial ECM remodeling in CHF. An important future direction would be to define the specific portfolio of MMPs that are expressed within the failing myocardium and develop selective targeting strategies to inhibit these MMP species. The biophysical stimuli that contribute to the local expression of myocardial MMPs is likely to be a complex and dynamic process determined by the summation of a number of extracellular signals. While a number of therapeutic interventions are likely to be developed that will directly modulate the myocardial extracellular environment, it is important to recognize that the temporal sequence and pattern of myocardial ECM remodeling are distinctly different post-MI, with overload-induced hypertrophy or in cardiomyopathic disease states. For example, inhibiting ECM degradation may be desirable in rapidly progressive cardiomyopathies, but may actually exacerbate LV function in hypertrophy. Early induction and activation of MMPs may be essential for the wound healing response post-MI and exogenous MMP pharmacological inhibition may actually worsen myocardial viability in the acute MI period. However, persistently increased myocardial MMP activation following an established MI may contribute to the maladaptive process of infarct expansion. Thus interventional strategies targeted at modulating the myocardial ECM must be time and disease specific. Further advancements in directly interrogating the myocardial ECM,<sup>28,30</sup> and directly imaging MMP activity within the myocardium,<sup>29</sup> are likely to provide the necessary tools to address this complex issue.

From the first report of the importance of collagenase by Gross et al<sup>178</sup> regarding the reabsorption of a tadpole tail, it is now clearly recognized that ECM remodeling plays a critical role in tissue structure and function. The myocardial ECM is not a passive entity, but rather a complex and dynamic

microenvironment that represents an important structural and signaling system within the myocardium. Future translational and clinical research focused upon the molecular and cellular mechanisms that regulate ECM structure and function will likely contribute to an improved understanding of the LV remodeling process in CHF and yield novel therapeutic targets.

## ACKNOWLEDGMENTS

The authors wish to recognize the significant contributions of past MUSC medical and graduate students who participated in the cardiothoracic research program that eventually made this chapter possible.

# Myocardial Basis for Heart Failure: Role of Cell Death

Saurabh Jha and Richard N. Kitsis

In advanced heart failure, the myocardium is unable to pump sufficient blood to meet the requirements of the body. Traditionally, the pathogenesis of this syndrome is thought to result from multiple structural and functional abnormalities in the myocardium including cardiac myocytes, nonmyocytes, and the interstitium.<sup>1</sup> Inciting triggers include increases in hemodynamic load, inflammatory cytokines, renin-angiotensin-aldosterone signaling, and catecholamines. The resulting abnormalities within cardiac myocytes include alterations in multiple intracellular signaling pathways, including adrenergic desensitization, abnormalities of intracellular Ca<sup>2+</sup> handling, dysregulation of excitation-contraction coupling, myofibrillar and cytoskeletal remodeling, and alterations in mitochondrial function and energetics. These mechanisms, which are discussed elsewhere in this volume, are indeed important in the pathogenesis of heart failure.

In contrast to the previously mentioned processes, which induce dysfunction in living cells, recent work has highlighted a critical role for cardiac myocyte death in the pathogenesis of heart failure.<sup>2</sup> In some cases, cardiac myocyte death is triggered by the same stimuli that elicit cardiac myocyte dysfunction, although it remains unclear in most situations as to whether cellular dysfunction and death are causally linked. Most commonly, however, the underlying precipitant of cardiac myocyte death is multifactorial. The absolute rate of cardiac myocyte death in failing hearts is quite low, but as discussed later, is 10-fold to 100-fold higher than that of control hearts. Moreover, as heart failure is a chronic condition, a modest increase in the rate of cell death can result in a substantial cumulative loss of cells over the course of the disease. While regeneration of cardiac myocytes from progenitor cells<sup>3</sup> and/or through self-replication<sup>4</sup> may mitigate some of these losses, the magnitude of this response, at least under basal conditions, appears inadequate to compensate. Loss of cardiac myocytes causes pathological remodeling and systolic dysfunction, although detailed mechanisms have not been delineated.

## CELL DEATH OVERVIEW

Cell death has classically been viewed as passive and unregulated, the one exception being some instances of cell death during development, where the highly reproducible temporo-spatial pattern of cell demise suggests that these events are somehow “programmed.” In the mid-1980s, H. Robert Horvitz et al proved this was the case by identifying a small network of genes that regulates cell death in the developing nematode (round worm) *Caenorhabditis elegans*<sup>5</sup> (Figure 6-1, A). This work was groundbreaking in that it provided the first definitive proof that cell death could be a regulated process that was carried out by the cell itself. The term “programmed cell death” was used to describe these developmental cell deaths, and later was applied more loosely to describe any type of regulated cell death. It is important to note, however, that “programmed” does not imply that the signals to die need to originate

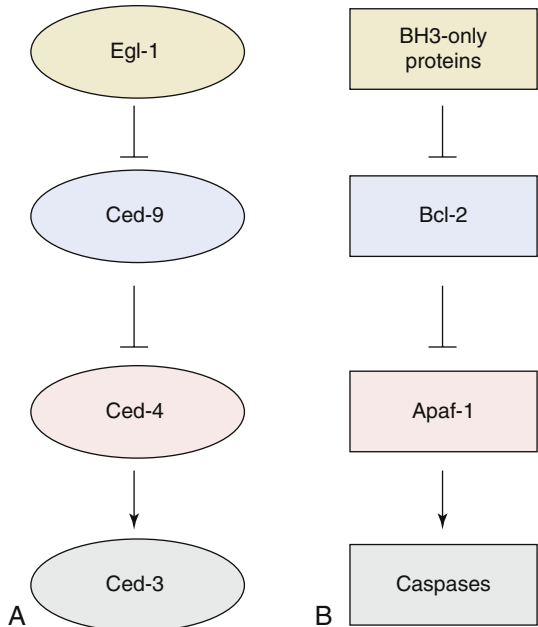

exclusively within the cell. In fact, the cellular death machinery may be triggered by cues both within and outside the cell.

A second big surprise came in the 1990s when orthologs of the genes identified by Horvitz were recognized to regulate a type of mammalian cell death termed “apoptosis” (see Figure 6-1, B, and discussed later). These observations demonstrate a basic commonality in the regulation of developmental cell death in the worm and apoptosis in mammals. Moreover, they demonstrate a high degree of conservation of this cell death mechanism over 600 million years of evolution.

Apoptosis is one of three major forms of cell death, the others being necrosis and autophagic cell death (Table 6-1). Pending a more complete understanding of molecular mechanisms, this classification is based upon morphological characteristics (Table 6-2). Apoptosis is a highly regulated process, and many of the underlying mechanisms and pathways have been delineated over the past 2 decades.

In contrast to apoptosis, necrosis has traditionally been seen as the major example of unregulated cell death. Recent data have mandated a shift in that view.<sup>6-9</sup> At least a portion, if not more, of necrotic deaths are regulated. Although our understanding of the molecular basis of necrosis remains primitive, this field is progressing quickly with two key pathways identified to date.

Autophagy is a normal intracellular process in which organelles, proteins, and lipids are catabolized in the lysosome to provide energy and substrates.<sup>10</sup> Autophagy serves as a means of quality control for proteins and organelles, and functions as a survival mechanism during cellular starvation and stress. Cell death has been described in association with autophagy in some contexts. This has raised several questions including: (1) Does autophagy cause cell death or is it merely associated with it? (2) If autophagy causes cell death, does it kill using its own death machinery or via that of necrosis or apoptosis? (3) If autophagy causes cell death, what converts its survival function to a death function? The amount of autophagy? Other factors? These questions notwithstanding, autophagy and autophagic cell death—and apoptosis and necrosis—are found in the failing heart.

**FIGURE 6-1** Evolutionary conservation of apoptosis pathways. **A**, Programmed cell death during *Caenorhabditis elegans* development. Precisely 131 cells (out of the 1090 somatic cells in the adult hermaphrodite) die at specific times during nematode development. Mutagenesis studies have revealed genes that regulate these deaths.<sup>170</sup> These genes are termed *cell death* abnormal, or *ced*, and include *ced-3* and *ced-4*, which promote death, and *ced-9*, which inhibits death. Loss-of-function mutations of *ced-9* result in widespread death, which can be rescued by loss-of-function mutations of either *ced-4* or *ced-3*. Thus *ced-9* is upstream of and inhibits *ced-4* and *ced-3*. The relationship between *ced-4* and *ced-3* was elucidated in studies in which *ced-4* killing was shown to require *ced-3*.<sup>171</sup> **B**, Mammalian apoptosis. Although apoptosis in worms and mammals differs in some respects, the genetic blueprint has been conserved over 600 million years of evolution from worms to mammals. The ortholog of *Ced-3* is the caspase family of cysteine proteases. *Ced-4* is represented by a single protein, *Apaf-1*, which functions as an adaptor in the apoptosome. Orthologs of *Ced-9* are the antiapoptotic branch of the *Bcl-2* family. The mammalian *Bcl-2* family also contains two subfamilies of proapoptotic proteins, one of which, the BH3-only branch, is present in *C. elegans*. The worm BH3-only protein *Egl-1* (Egg laying defective-1) inhibits *Bcl-2* to promote apoptosis. The equivalent step in mammals is the inhibition of *Bcl-2* by various BH3-only proteins. Mammalian BH3-only proteins may also induce apoptosis through additional mechanisms. (Reprinted with permission from the Annual Review of Physiology, Volume 72 (c) 2010 by Annual Reviews www.annualreviews.org.)

TABLE 6-1 Cell Death		
Process	Evolutionary Conservation	What Is It?
Apoptosis	Metazoans	Regulated cell suicide
Necrosis	Metazoans More ancient?	Traditionally considered unregulated, but regulated in at least some cases
Autophagic cell death	Unicellular eukaryotes and metazoans	Autophagy—normal survival process Death process caused by autophagy? Triggers not defined?

Cell death is essential for normal life in metazoan organisms. For example, apoptosis is needed for normal embryonic development and viability in the mouse.<sup>11</sup> Necrosis also occurs during development, but its role has not yet been defined. An important developmental role for autophagic “degeneration” has been clearly demonstrated in *Drosophila*.<sup>12</sup> Apoptosis also plays critical homeostatic functions in postnatal life. By regulating cell number, it maintains the

TABLE 6-2 Morphology of Apoptosis and Necrosis	
Apoptosis	Necrosis
Cell shrinkage	Cell swelling
Plasma membrane blebbing	Plasma membrane loss of integrity
Chromatin condensation (classically against nuclear membrane)	Sometimes chromatin condensation
Nuclear fragmentation	
Cytoplasmic organelles: grossly intact Sometimes mild mitochondrial changes	Mitochondria grossly swollen
Fragmentation of cell and nucleus into membrane-enclosed apoptotic bodies. These get phagocytosed by macrophages and/or neighboring cells.	Lysis of cell with release of intracellular contents into the extracellular space
Classically, single cells affected, but sometimes more diffuse	Groups of cells affected
No inflammation	Inflammation

composition of complex tissues. In addition, apoptosis is a major means of disposal for transformed and damaged cells. Given these fundamental functions, it is not surprising that dysregulation of cell death (too little, too much, or mislocalized) often results in disease. For example, defects in apoptosis characterize most, if not all, cancers. The burst of cell death during acute myocardial infarction and stroke occurs through both apoptosis and necrosis.<sup>2,7,8</sup> Similarly, both apoptosis and necrosis are causal factors in the pathogenesis of heart failure.<sup>2,13</sup> Again, the possible role of autophagic cell death in these processes is more controversial and will be discussed later.

The notion that cell death can be both regulated and a causal factor in the pathogenesis of human disease has raised hopes of pharmacologically manipulating cell death to therapeutic advantage. In fact, this has already been realized with ABT-737<sup>14</sup> (Abbott Pharmaceuticals), a small molecule “BH3-only-mimetic” (see later discussion) that induces apoptosis and which is currently in trials for human cancer. Conversely, it may be possible to devise new therapies for myocardial infarction, stroke, heart failure, diabetes, and certain neurodegenerative disorders based around the concept of inhibiting cell death.

This chapter will review the fundamental basis of cell death and its relationship to the pathogenesis of advanced heart failure. Interplay among the various forms of cell death will be considered. When possible, death mechanisms will be placed within the context of the traditional pathophysiology of heart failure. Finally, we will summarize challenges related to the development of novel therapies based on inhibiting cell death.

APOPTOSIS

The quintessential morphological features of apoptosis include cytoplasmic shrinkage, chromatin condensation, and margination against the inner aspect of the nuclear membrane; budding of the plasma membrane; and fragmentation of the cytoplasm and nucleus into membrane-enclosed apoptotic bodies<sup>15</sup> (see Table 6-2). The latter get phagocytosed by macrophages or neighboring cells. Plasma membrane integrity is maintained until late in the process, thereby not eliciting an inflammatory response. In contrast to apoptosis, necrosis involves early loss of plasma membrane integrity and loss of intracellular contents into interstitium, leading to inflammation.

**FIGURE 6-2** Apoptosis pathways. Apoptosis is mediated by an extrinsic pathway involving cell surface death receptors and by an intrinsic pathway that uses the mitochondria and endoplasmic reticulum. The extrinsic pathway is activated by binding of the death ligand to its receptor, which triggers formation of the DISC. Caspase 8 is activated by forced proximity within the DISC and then cleaves and activates downstream procaspases. Caspase 8 can also cleave the BH3-only protein Bid, the carboxyl portion of which translocates to the mitochondria to trigger apoptotic mitochondrial events. The intrinsic pathway is activated by diverse biological, chemical, and physical stimuli. These signals are transduced to the mitochondria and ER (not shown) by proapoptotic Bcl-2 proteins: Bax (a multidomain protein) and BH3-only proteins. These death signals trigger the release of apoptogens from the mitochondria into the cytosol, one of which, cytochrome *c*, is depicted here. Cytosolic cytochrome *c* triggers the formation of a second multiprotein complex, the apoptosome, in which procaspase 9 undergoes activation. Caspase 9 then cleaves and activates downstream procaspases. Downstream caspases cleave several hundred cellular proteins to bring about the apoptotic death of the cell. (Reprinted with permission from the Annual Review of Physiology, Volume 72 (c) 2010 by Annual Reviews www.annualreviews.org)

Although defined by the previously mentioned morphological criteria, the main functional characteristic of apoptosis is its regulated nature. The apoptotic machinery is part of the cell itself. In most cases, the relevant proteins are present constitutively and need only to be triggered to assemble into specific multiprotein complexes that bring about cell death (see later discussion). The death stimuli themselves can originate inside (e.g., oxidative stress, misfolded proteins) or outside (e.g., cytokines, nutrient deprivation) the cell. Apoptosis is mediated by two interconnected, evolutionarily conserved pathways: the extrinsic (or death receptor) pathway and the intrinsic (or mitochondrial/endoplasmic reticulum [ER]) pathway (Figure 6-2). The immediate objective of these pathways is to activate caspases.

## Caspases

Caspases are a family of cysteine proteases that cleave proteins following aspartic acid residues.<sup>16</sup> These proteases exist in a hierarchy with upstream caspases 2, 8, 9, and 10 and downstream caspases 3, 6, and 7. Caspases are synthesized as largely inactive procaspases. Upstream procaspases, which are normally monomeric, become activated when forced to dimerize<sup>17</sup> following recruitment into multiprotein complexes, such as the death-inducing signaling complex (DISC) or apoptosome. Once activated, upstream caspases undergo autocleavage, but dimerization rather than autocleavage is the primary activating event. Activated upstream caspases then

cleave downstream procaspases. In contrast to upstream procaspases, downstream procaspases already exist as dimers. Instead, the activating event for downstream procaspases is cleavage,<sup>18</sup> which separates the procaspase into three parts: prodomain, p20 subunit, and p10 subunit. The activated downstream caspase is formed by the noncovalent reassembly of two p20 and two p10 subunits. The major role of downstream caspases is to cleave up to several hundred cellular proteins, structural and regulatory, to bring about cell death. The precise mechanisms by which this proteolytic cascade deconstructs the cell are incompletely understood. Downstream caspases also accelerate cell killing by cleaving and activating other key proapoptotic proteins.<sup>19,20</sup>

## Extrinsic Pathway

The extrinsic (or death receptor) pathway relays signals from a variety of specialized death ligands.<sup>21</sup> Some of these are soluble (e.g., tumor necrosis factor  $\alpha$  [TNF- $\alpha$ ]), while others are located on the plasma membranes of other cells (Fas ligand). When death ligands bind their cognate death receptors (e.g., TNF receptor 1 or 2 [TNFR1 or TNFR2] or Fas), formation of the DISC is triggered.<sup>22</sup> This will be described for Fas signaling. The more complex events involved in TNF- $\alpha$  signaling will be considered in the discussion of necrosis.

The binding of the Fas ligand to Fas is thought to trigger a conformational change in the intracellular domain of Fas, which results in recruitment of FADD (Fas-associated

via death domain) through an interaction mediated by death domains (DD) in each of these proteins. FADD, in turn, recruits procaspase 8 or 10, the binding in this case mediated by death effector domains (DED) in each protein. DDs, DEDs, and Caspase Recruitment Domains (CARDs) are members of the death-fold superfamily.<sup>23</sup> These motifs, which consist of six antiparallel  $\alpha$ -helices, mediate many of the protein-protein interactions in the multiprotein complexes that carry out apoptosis. At a minimum, the Fas DISC consists of the Fas ligand, Fas, FADD, and procaspase 8 (or 10). The recruitment of procaspase 8 (or 10) into the DISC causes its forced dimerization, resulting in caspase activation. Caspase 8 goes on to cleave and activate downstream procaspases. While this alone could activate apoptosis (type I cells), it is insufficient in most cells (type II cells) to trigger large amounts of downstream caspase activation and cell death.<sup>24</sup> For extrinsic pathway activators to bring about efficient cell killing, signals from the extrinsic pathway must be amplified by activation of the intrinsic pathway. The key molecule connecting these two pathways is Bid (BH3 [Bcl-2 (B cell leukemia/lymphoma-2) homology domain 3]-interacting domain death agonist).<sup>20</sup> Bid is a direct substrate of caspase 8. Following cleavage, its C-terminal fragment (truncated Bid [*t*Bid]) translocates to the outer mitochondrial membrane and triggers events to be discussed that contribute to activation of the intrinsic pathway.

## Intrinsic Pathway

### Premitochondrial/Endoplasmic Reticulum Events

The intrinsic (or mitochondrial/ER) pathway transduces a wide spectrum of death signals that originate both inside and outside the cell. These include deficiency of survival factors, deficiency and/or excess of nutrients, hypoxia, oxidative/nitrosative stress, radiation, drugs, DNA damage, and misfolded proteins. These stimuli are transduced to the mitochondria and/or ER by a variety of proapoptotic Bcl-2 (B cell leukemia/lymphoma-2) proteins. These events stimulate the release of mitochondrial apoptogens (e.g., cytochrome *c*<sup>25,26</sup>) and ER  $\text{Ca}^{2+}$ <sup>27,28</sup> into the cytosol. Once cytosolic, cytochrome *c* triggers the formation of the apoptosome,<sup>29,30</sup> which leads to caspase activation. Other mitochondrial apoptogens relieve the inhibition of already activated caspases.<sup>31-34</sup>  $\text{Ca}^{2+}$  released by the ER is taken up by the mitochondria, resulting in cell death as will be discussed later.

The Bcl-2 proteins regulate the integrity of the outer mitochondrial membrane (OMM) and therefore the release of mitochondrial apoptogens.<sup>26,35</sup> Antiapoptotic Bcl-2 proteins inhibit OMM permeabilization and apoptogen release, while proapoptotic Bcl-2 proteins promote these events. Bcl-2 proteins possess one or more Bcl-2 homology (BH) domains.<sup>36</sup> Members of the antiapoptotic branch, typified by Bcl-2 and Bcl-x<sub>L</sub> (Bcl-x, long isoform), contain multiple domains. Proceeding from the amino to the carboxyl end of the protein, these include BH4 (found only in antiapoptotic family members), BH3, BH1, and BH2. The proapoptotic branch of the family is divided into two classes. The first includes the multidomain proapoptotics, such as Bax (Bcl-2-associated X protein) and Bak (Bcl-2 homologous antagonist/killer), each of which possesses BH3, BH1, and BH2 domains. The second proapoptotic class is composed of the BH3-only proteins.

Under normal conditions, Bax resides primarily in the cytosol in an inactive conformation. In response to intrinsic pathway stimuli, it undergoes conformational activation, which in part involves exposure of a C-terminal transmembrane domain.<sup>37</sup> Although several proteins that bind Bax and influence its conformational activation have been identified, the precise regulatory events and the pathways connecting them with death stimuli remain incompletely understood.<sup>38,39</sup> Bax conformational activation is linked to its translocation to the mitochondria and ER, although key mechanistic details are

lacking. Once at the mitochondria, Bax inserts into the OMM through its transmembrane domain. Bak, the other major multidomain proapoptotic Bcl-2 protein, resides constitutively at the OMM and ER membrane. Under normal conditions, Bak is maintained in an inactive conformation at the mitochondria through its interactions with several proteins.<sup>40,41</sup> In response to death signals, these proteins are displaced, resulting in Bak activation. Most importantly, Bax and Bak together constitute an obligate control point through which death signals must pass to activate apoptotic mitochondrial events. In many systems, there is redundancy in the actions of Bax and Bak such that the absence of both is required for a cell to be resistant to mitochondrial-mediated apoptosis.<sup>42</sup> In other systems, including cardiac myocytes, redundancy between Bax and Bak appears significantly less complete, and loss of either diminishes the full apoptotic response.<sup>43</sup>

The BH3-only proteins play a critical role in facilitating the apoptotic mitochondrial events mediated by the multidomain proapoptotic proteins. In contrast to the multidomain proapoptotics, which provide a universal gateway to mitochondrial apoptotic events, each BH3-only protein transduces signals from only a subset of apoptotic stimuli.<sup>36</sup> In addition, these signals activate BH3-only proteins through a diversity of molecular mechanisms. For example, the BH3-only protein Bad is important in sensing deficiencies of growth/survival factors. Inadequate IGF-1 results in dephosphorylation of Bad, leading to its release from the 14-3-3 protein. Bad subsequently translocates to the mitochondria and contributes to apoptogen release. BH3-only proteins Noxa and PUMA (p53-upregulated modulator of apoptosis), on the other hand, undergo transcriptional activation by p53, which itself is activated by a variety of noxious insults. Bid, which we have already discussed as a link between extrinsic and intrinsic apoptotic pathways, is a BH3-only protein that is activated by caspase 8 cleavage.

How the BH3-only proteins work to promote apoptosis is a matter of debate and reflects larger questions as to the biochemical relationships among the antiapoptotic, multidomain proapoptotic, and BH3-only Bcl-2 proteins. One model holds that some BH3-only proteins (*t*Bid, PUMA, and Bim [Bcl-2-interacting mediator of cell death]) directly interact with and activate Bax and Bak.<sup>44</sup> Conversely, antiapoptotic Bcl-2 proteins inhibit apoptosis by binding *t*Bid, PUMA, and Bim, rather than by directly inhibiting Bax and Bak. Other BH3-only proteins promote apoptosis by displacing *t*Bid, Bim, and PUMA from antiapoptotic Bcl-2 proteins, thereby making *t*Bid, Bim, and PUMA available to activate Bax and Bak. Thus, in this model, certain BH3-only proteins activate the multidomain proapoptotics. According to a competing model, Bax and Bak are constitutively inhibited by antiapoptotic Bcl-2 proteins. BH3-only proteins do not interact with Bax or Bak, but instead bind antiapoptotic Bcl-2 proteins and, thereby, disinhibit Bax and Bak.<sup>45</sup>

### Mitochondrial Events

Although it is clear that Bax and Bak promote OMM permeabilization, the molecular/physical basis for this event is unclear. It is known that activation of the intrinsic pathway stimulates a complex pattern of Bax/Bak homo-oligomerization and hetero-oligomerization,<sup>46,47</sup> which may be facilitated by BH3-only proteins such as Bid.<sup>48</sup> Although these higher ordered complexes correlate with OMM permeabilization, a mechanism remains obscure. Bax and Bak are known to form channels in artificial lipid bilayers, but the existence of such channels in cells is debatable. Other theories focus on the possibility that Bax and Bak regulate a yet to be identified protein or lipid, modulate OMM topology, or induce mitochondrial fission.<sup>49</sup> It is important to emphasize, however, that OMM permeabilization during apoptosis is distinct from OMM rupture that sometimes occurs in necrosis (see later discussion).

Bax/Bak-dependent OMM permeabilization is critical for the release of mitochondrial apoptogens, which reside in the intermembrane space (between the OMM and inner mitochondrial membrane [IMM]) and/or are loosely attached to the IMM itself. The efficient release of some mitochondrial apoptogens, however, also involves additional events.<sup>50</sup> For example, remodeling of mitochondrial cristae junctions is required to mobilize a large portion of cytochrome *c* from within cristae to the intermembrane space for subsequent release. Interestingly, remodeling of cristae may involve cyclophilin D,<sup>50</sup> a matrix protein that is a critical regulator of necrosis (discussed later), suggesting one potential point of convergence between apoptosis and necrosis signaling.

Mitochondrial apoptogens are proteins that are released into the cytosol and directly or indirectly promote apoptosis. These proteins include cytochrome *c*,<sup>25,26</sup> Smac/DIABLO (second mitochondria-derived activator of caspase/direct IAP-binding protein with low PI),<sup>31,32</sup> Omi/HtrA2 (Omi/high temperature requirement protein A2),<sup>33,34</sup> AIF (apoptosis inducing factor),<sup>51</sup> and EndoG (Endonuclease G).<sup>52</sup> In contrast to their death-promoting properties in the cytosol, mitochondrial apoptogens are thought to carry out important physiological functions within the mitochondria of normal cells. This is best exemplified by cytochrome *c*, which is essential for electron transport during respiration.

### Postmitochondrial Events

The release of apoptogens into the cytosol brings about a series of events that are critical for the induction of apoptosis via the intrinsic pathway. Cytochrome *c* in the cytosol is the trigger for apoptosome formation.<sup>29</sup> The apoptosome is a multiprotein complex, which provides a dimerization interface for the activation of upstream procaspase 9. The binding of cytochrome *c* and dATP (which is already present in the cytosol) to Apaf-1 (apoptotic protease activating factor-1) stimulates Apaf-1 oligomerization and its subsequent recruitment of procaspase 9 (through CARD-CARD interactions). The resulting apoptosome consists of a heptad of Apaf-1, cytochrome *c*, dATP, and procaspase 9 in a wheel-and-spoke arrangement.<sup>30</sup> Procaspase 9 is activated by forced dimerization, following which it cleaves and activates downstream procaspases.

Other mitochondrial apoptogens have different roles. Smac/DIABLO and Omi/HtrA2 counteract apoptosis inhibitors, and discussion of their functions will be deferred to the section on apoptosis inhibitors. Following its release from mitochondria, AIF translocates to the nucleus where it may contribute to the large-scale (200 kb to 50 kb) DNA cleavage during apoptosis, presumably through a yet to be identified endonuclease.<sup>51</sup> These actions of AIF do not require caspases, and AIF-induced cell death is often described as caspase-independent. This term may not be completely accurate, however, as in some contexts, caspases appear necessary for AIF release and/or translocation.<sup>53,54</sup> Subsequent cleavage of DNA into oligonucleosomal fragments is carried out by EndoG<sup>52</sup> and CAD (caspase-activated deoxyribonuclease), whose functions appear to be redundant.

### ER Stress-induced Apoptosis

In addition to its physiological roles in protein folding and posttranslational modifications, lipid biosynthesis, and Ca<sup>2+</sup> homeostasis, the ER is a critical mediator of cell death. Important death signals include misfolded proteins, oxidative stress, and certain lipids.<sup>28</sup> Although a unifying mechanism for ER stress-induced apoptosis remains elusive, some critical components have been delineated.

Improperly folded proteins can cause severe cellular stress, dysfunction, or even death. The unfolded protein response (UPR) is a normal cellular mechanism in which the recognition of unfolded proteins is transduced into a

transcriptional response, the goal of which is to temporarily halt further translation and refold denatured proteins.<sup>55</sup> The UPR is initiated when unfolded proteins in the ER lumen recruit BiP/GRP78 (immunoglobulin heavy chain binding protein/glucose-regulated protein 78) away from PERK (double-stranded RNA-dependent protein kinase R [PKR]-like ER kinase), IRE1 $\alpha$  (inositol-requiring enzyme 1 $\alpha$ ), and ATF6 (activating transcription factor 6), which are integral ER membrane proteins that control the three arms of the UPR. Dissociation of BiP/GRP78 leads to activation of PERK, IRE1 $\alpha$ , and ATF6, which initiates a complex network of transcriptional events to correct misfolding and restore cellular homeostasis. When the UPR is severe and prolonged, however, apoptosis can result. Although the factors that convert this compensatory response to a death response are not understood, some of the proteins that mediate apoptosis have been identified. One key molecule is the transcription factor CHOP (C/EBP [CCAAT/enhancer-binding protein]-homologous protein), which is downstream of PERK, IRE1 $\alpha$ , and ATF6. CHOP activates genes that mediate not only the UPR, but also apoptosis including DR5 (death receptor 5), TRB3 (tribbles-related protein 3), Bim, and GADD34 (growth arrest and DNA damage-inducible protein 34).

A second mechanism of ER stress-induced apoptosis involves the release of Ca<sup>2+</sup> from the ER lumen into the cytosol.<sup>28</sup> This mechanism appears particularly relevant to ER stress-induced apoptosis triggered by oxidative stimuli and certain lipids (e.g., arachidonic acid). The basic schema is that a death stimulus triggers the release of a Ca<sup>2+</sup> bolus into the cytosol followed by its subsequent uptake into the mitochondria. It is not clear how mitochondrial Ca<sup>2+</sup> overload stimulates cell death in this context. Possibilities include triggering of mitochondrial permeability transition pore (MPTP) opening, a seminal event in necrosis (see later discussion), and classic apoptosis with apoptogen release, although the mechanism is unclear.

The magnitude of the Ca<sup>2+</sup> bolus elicited by an apoptotic stimulus is determined by the resting ER luminal Ca<sup>2+</sup> concentration. Resting ER luminal Ca<sup>2+</sup> concentration is determined by an interplay between Bax/Bak and Bcl-2 proteins.<sup>28</sup> As with the mitochondria, Bak and Bcl-2 reside at the ER membrane. Moreover, Bax can translocate from cytosol to ER in response to an apoptotic signal. Bcl-2 interacts with IP3R-1 (inositol 1,4,5-triphosphate receptor-1) to induce a baseline Ca<sup>2+</sup> “leak” into the cytosol. This leak is cytoprotective because by decreasing basal ER luminal Ca<sup>2+</sup> concentrations, it diminishes the magnitude of the Ca<sup>2+</sup> bolus that can be induced by a subsequent death stimulus. In contrast, the presence of Bax and Bak decreases the interaction of Bcl-2 with IP3R-1, thereby opposing the Bcl-2-induced IP3R-1 Ca<sup>2+</sup> leak. Bax and Bak therefore increase the resting ER luminal Ca<sup>2+</sup> concentration, ensuring that a subsequent death stimulus will result in a larger bolus of Ca<sup>2+</sup> release. Thus, by regulating the baseline ER luminal Ca<sup>2+</sup> concentration, Bcl-2 proteins influence the magnitude of Ca<sup>2+</sup> released by an ER death stimulus.

ER death pathways may also interface with the extrinsic pathway. Bap31 (B-cell receptor-associated protein 31), an integral ER membrane protein, can be cleaved by caspase 8 activated at the DISC or by the procaspase 8L isoform, which is recruited and activated in complex with Bap31.<sup>27,56</sup> Bap31 cleavage triggers the release of ER Ca<sup>2+</sup> and mitochondrial cytochrome *c* (through unclear mechanisms), and cell death. This pathway appears to represent an amplification mechanism for the extrinsic pathway using the ER, similar to the Bid-mediated mechanism by which the extrinsic pathway is amplified using the mitochondria. This amplification mechanism may be self-reinforcing as recent work shows that procaspase 8 is activated by ER stress and critical for ER stress-induced cell death.<sup>57</sup>

Although procaspase 12 has been considered to be a mediator of ER stress-induced apoptosis, critical examination of the data raises serious doubts about its role. While the initial knockout mouse provided strong evidence that procaspase 12 is critical for ER stress-induced apoptosis,<sup>58</sup> an independent knockout indicates that it is dispensable.<sup>59</sup> Moreover, full-length, functional procaspase 12 protein is absent from most humans due to genetic variation.<sup>60</sup> While there is some evidence that procaspase 12 may modulate activation of procaspase 1 and inflammation/sepsis, the role of procaspase 12 in ER stress-induced cell death is questionable.

### Inhibitors of Apoptosis

Because of the potentially profound and irreversible consequences of initiating apoptosis, key activating molecules are opposed by a variety of endogenous inhibitors. c-FLIP (FLICE [FADD-like interleukin-1 $\beta$  converting enzyme]-inhibitory protein), an important inhibitor of the extrinsic pathway, inhibits formation of the DISC.<sup>61</sup> c-FLIP exists as two isoforms that arise from alternative splicing. The long isoform (FLIP<sub>L</sub>) is homologous to procaspase 8, but enzymatically inactive due to mutation of the catalytic cysteine. The short isoform (FLIP<sub>S</sub>) contains only two DEDs. FLIP<sub>S</sub> blocks DISC assembly probably by binding the DEDs on FADD and procaspase 8, thereby preventing FADD from recruiting procaspase 8. In contrast, low concentrations of FLIP<sub>L</sub> can promote the recruitment and activation of procaspase 8, while high concentrations are inhibitory.

Bcl-2 and Bcl-x<sub>L</sub>, which oppose OMM permeabilization and the release of mitochondrial apoptogens into the cytosol, are key inhibitors of the intrinsic pathway. Models for their mechanisms of action have been discussed previously.<sup>44,45</sup>

The IAP (inhibitor of apoptosis) family of proteins (e.g., XIAP [X-linked inhibitor of apoptosis protein] and cIAP 1 and 2 [cellular inhibitor of apoptosis 1 and 2]) antagonize the postmitochondrial intrinsic pathway. IAPs bind to and inhibit already activated downstream caspases 3 and 7 by blocking the access of substrate to the caspase active site.<sup>18,62,63</sup> In addition, IAPs bind to and inhibit the activation of procaspase 9 in the apoptosome.<sup>64</sup> IAPs also contain E3-ubiquitin ligase activity. Consistent with their role as apoptosis inhibitors, the E3 ligase activity promotes the degradation of downstream caspases.<sup>65</sup> However, IAPs can also promote their own degradation,<sup>66</sup> perhaps to limit their window of activity. As will be discussed later in the necrosis section, the E3-ubiquitin ligase activities of cIAP 1 and 2 also promote survival through K63 polyubiquitination of RIP1 and TRAF2.<sup>67-69</sup>

Having introduced the IAP family of apoptosis inhibitors, we can now consider the two remaining mitochondrial apoptogens, Smac/DIABLO<sup>31,32</sup> and Omi/HtrA2,<sup>33,34</sup> which promote apoptosis by neutralizing IAPs. Smac/DIABLO and Omi/HtrA2 bind directly to IAPs, thereby displacing the active caspases bound by IAPs. Thus, Smac/DIABLO and Omi/HtrA2 relieve IAP-mediated inhibition of caspases. Furthermore, Omi/HtrA2 possesses a serine protease activity that inactivates IAPs irreversibly through cleavage.<sup>70</sup> These mechanisms underscore that efficient cell killing requires not only activation of proapoptotic molecules but also inactivation of inhibitors.

Most endogenous inhibitors of apoptosis target circumscribed steps in either the extrinsic or intrinsic pathway. By contrast, ARC (apoptosis repressor with CARD [caspase recruitment domain]) antagonizes both the extrinsic and intrinsic pathways through a variety of mechanisms.<sup>71</sup> The extrinsic pathway is inhibited by the direct interaction of ARC with Fas, FADD, and procaspase 8, which prevents DISC assembly as required for extrinsic pathway activation.<sup>71</sup> ARC inhibits the intrinsic pathway through several mechanisms. It binds directly to Bax, which inhibits Bax conformational activation and translocation to the mitochondria.<sup>71,72</sup> In addition,

ARC neutralizes p53, a transcription factor that activates multiple proapoptotic genes.<sup>73</sup> The mechanism involves direct binding between ARC and p53 in the nucleus. This inhibits p53 tetramerization, which both cripples p53 function as a transcription factor and reveals a nuclear export signal in the p53 molecule that relocates p53 to the cytoplasm. These events markedly decrease p53-dependent transcription.

## NECROSIS

Necrosis is characterized by severe cellular ATP depletion and the early loss of plasma membrane integrity. Decreases in ATP levels reflect severe mitochondrial dysfunction, while the cause of plasma membrane dysfunction is not yet understood. Moreover, it is unclear whether ATP depletion or plasma membrane dysfunction or neither is the primary insult. The most characteristic morphological feature of necrosis is cellular swelling, reflecting loss of plasma membrane integrity (see Table 6-2). In contrast, apoptotic cells are shrunken. Loss of plasma membrane integrity in necrosis results in the release of the intracellular contents into the extracellular space, which often engenders a marked inflammatory response. In contrast, apoptotic cells maintain plasma membrane integrity, even after fragmenting into apoptotic bodies, so long as phagocytosis is carried out in a timely manner. Thus apoptosis takes place without inflammation, resulting in the silent deletion of cells.

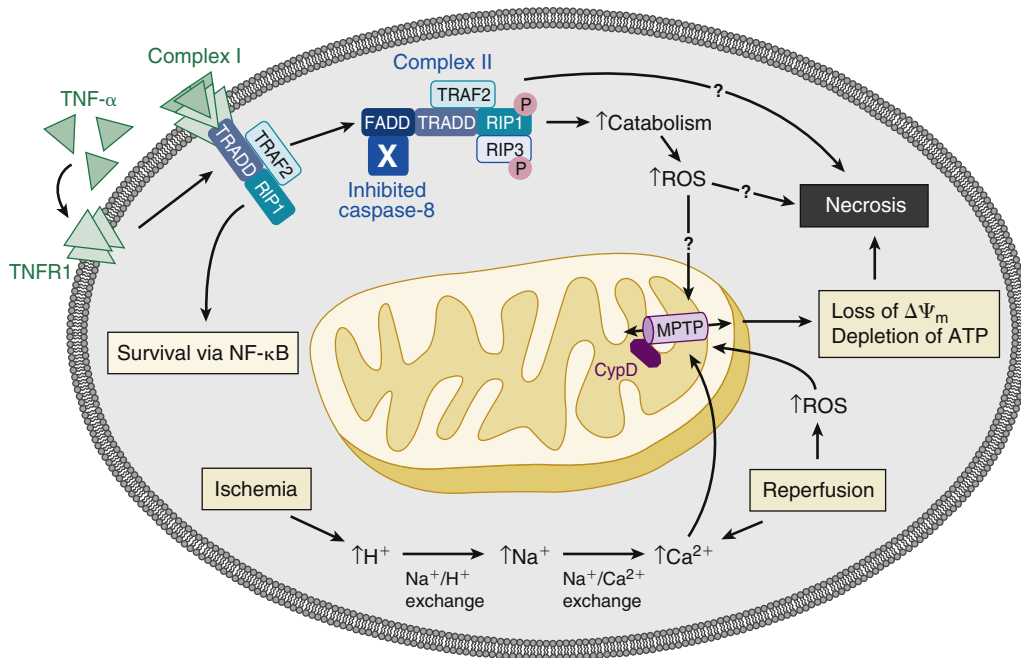

Although necrosis has long been considered an unregulated death process, a body of work over the past decade indicates that at least a portion of necrotic cell deaths is actively mediated and highly regulated. While the precise proportions of necrotic cell deaths that are regulated versus unregulated is not known, regulated necrosis has been shown to be a significant component of the cell death in myocardial infarction,<sup>7,8</sup> heart failure,<sup>13</sup> and stroke.<sup>9</sup> Current understanding of the mechanisms that mediate necrosis is incomplete—especially in comparison to the detailed apoptotic pathways that have been delineated over the past 20 years. Nevertheless, two necrosis pathways have been identified to date (Figure 6-3). As in apoptosis, one involves cell surface receptors (death receptor/RIP pathway) and the other the mitochondria (cyclophilin D/MPTP pathway). Beyond these superficial similarities, however, these necrosis pathways are different biochemically and functionally from those that mediate apoptosis.

### Death Receptor/RIP Pathway

In addition to their role in apoptosis described previously, death receptors also signal cellular survival, proliferation, and necrosis.<sup>6</sup> This has been most extensively studied in the case of TNFR1. TNF kills most cells inefficiently because it activates death and survival pathways simultaneously. The ability of TNF to kill is unmasked when survival mechanisms are inhibited. TNF can induce apoptosis. But when apoptosis is inhibited, TNF killing occurs by necrosis.

These pleiotropic effects are mediated by two multiprotein complexes.<sup>74</sup> Complex 1 signals survival. Its assembly at the plasma membrane is triggered by the binding of TNF to TNFR1, which stimulates the recruitment of TRADD (TNFRSF1A [TNF receptor superfamily 1A]-associated via death domain), RIP1 (receptor interacting protein 1, a serine/threonine kinase), TRAF2 (TNF receptor-associated factor 2), and cellular inhibitor of apoptosis proteins cIAP1 and 2 (which, as noted previously, possess E3-ubiquitin ligase activity). cIAP1 and 2, along with TRAF2, promote the K63-polyubiquitination of RIP1 and TRAF2.<sup>67-69</sup> Once polyubiquitinated, RIP1 and TRAF2 recruit TAB 2/3 (TAK1 [TGF- $\beta$ -activated kinase 1]-binding protein 2/30), leading to the activation of TAK1, a MAPKKK (mitogen-activated protein

**FIGURE 6-3** Necrosis pathways. Information about necrosis signaling is currently limited to two pathways. The first involves death receptors, as exemplified by TNFR1 (tumor necrosis factor  $\alpha$  receptor 1). Depending on context, activation of TNFR1 can promote cell survival or either apoptotic or necrotic cell death. These choices are mediated by multiprotein complexes I and II. The binding of TNF- $\alpha$  to TNFR1 stimulates formation of complex I, which contains TNFR1, TRADD, RIP1, TRAF2, and cIAP1/2. The exact relationships among these proteins have not yet been defined, but one model postulates that TNFR1-TRADD-RIP1 proteins are linked through their respective death domains (DDs). RIP1 and TRAF2 undergo K63 polyubiquitination by cIAP1/2 in conjunction with TRAF2 (not shown). Polyubiquitinated RIP1 and TRAF2 recruit TAK1, which activates NF  $\kappa$ B, thereby stimulating transcription of survival genes (see text for details). Death effects of TNFR1 signaling are mediated via complex II, which forms following endocytosis of complex I, the dissociation of TNFR1, and the deubiquitination of RIP1 by CYLD and A20 (not shown). TRADD recruits FADD (DD-DD interactions), and FADD recruits procaspase 8 (DED-DED interactions). Unless inhibited, procaspase 8 undergoes activation and cleaves RIP1, rendering RIP1 unable to signal either survival or necrosis. Caspase 8 also activates downstream caspases inducing apoptosis. In contrast, if procaspase 8 is inhibited (genetically or pharmacologically), RIP1 is not cleaved and instead recruits RIP3. RIP1 and RIP3 undergo a complex set of phosphorylation events, and necrosis ensues through unclear mechanisms. One potential mechanism may involve the activation of catabolic pathways and ROS production as shown. A second necrosis pathway involves the mitochondrial permeability transition pore (MPTP) in the inner mitochondrial membrane and its regulation by cyclophilin D (CypD). This pore may be opened by increased  $\text{Ca}^{2+}$ , oxidative stress, decreased ATP, and other stimuli that operate during ischemia/reperfusion and heart failure. Ischemia/reperfusion can lead to increased  $\text{Ca}^{2+}$  and ROS as depicted. MPTP opening results in profound alterations in mitochondrial structure and function as described in text, which results in decreased ATP. No definitive connections have been delineated between death receptor and mitochondrial necrosis pathways. A possible connection is RIP3-induced ROS generation. (Reprinted with permission from the Annual Review of Physiology, Volume 72 (c) 2010 by Annual Reviews www.annualreviews.org)

kinase kinase kinase).<sup>67,68</sup> Activated TAK1 phosphorylates the IKK (I $\kappa$ B [inhibitor of  $\kappa$ B] kinase) complex, leading to activation of NF  $\kappa$ B (nuclear factor  $\kappa$  light-chain enhancer of activated B cells).<sup>67</sup> NF  $\kappa$ B transcriptionally activates multiple genes encoding survival proteins including c-FLIP. The net result is TNF-induced survival.

In contrast to complex 1, complex 2 mediates the killing functions (apoptosis and necrosis) of TNF. Complex 2 is thought to form from complex 1. This involves endocytosis of complex 1, dissociation of TNFR1, deubiquitination of RIP1 by CYLD (cylindromatosis) and A20, and recruitment of FADD and procaspase 8.<sup>74-76</sup> Recruitment to complex 2 activates procaspase 8 and initiates apoptosis. One important caspase 8 substrate in complex 2 is RIP1, which as described later is critical for necrosis. The cleavage of RIP1 by caspase 8 abrogates the ability of RIP1 to promote necrosis<sup>77</sup> and its previously described survival functions.<sup>78</sup> Furthermore, the C-terminal RIP1 fragment resulting from caspase 8 cleavage enforces further caspase 8 activation and apoptosis.<sup>78</sup>

Under conditions in which procaspase 8 activation/caspase 8 activity is inhibited, however, RIP1 remains intact and recruits RIP3 into complex 2.<sup>79,80</sup> RIP1 and RIP3 undergo a complex series of phosphorylation events that trigger necrosis. While the kinase activity of RIP1 is not required for its survival functions in complex 1, the kinase activities of both RIP1 and RIP3 are critical for necrosis.<sup>6,79</sup> In one mechanism, RIP3 binds and activates several metabolic enzymes, resulting in the generation of reactive oxygen species that presumably

contribute to necrosis.<sup>81</sup> It is likely that other yet to be identified RIP1/RIP3 targets are also involved in necrosis signaling.

The physiological significance of the death receptor/RIP pathway has not been fully delineated. The fact that necrosis was revealed only when caspase 8 was inhibited has suggested that necrosis serves as a default pathway when apoptosis is unavailable. This scenario may be relevant to certain cancer cells that induce molecules such as c-FLIP, which inhibit procaspase 8 activation, or infection with certain viruses that encode caspase inhibitors.<sup>82</sup> Further work will be needed to determine the general applicability of the notion that necrosis is a default to apoptosis. As will be discussed later, suppression of apoptosis does not appear to be a prerequisite for induction of necrosis via the cyclophilin D/MPTP pathway.

### Cyclophilin D/MPTP Pathway

Mitochondrial dysfunction is a hallmark of both apoptosis and necrosis. For example, during apoptosis, the release to the cytosol of cytochrome *c* and perhaps other mitochondrial apoptogens can lead to defects in mitochondrial function. However, gross alterations in mitochondrial morphology are uncommon in apoptosis until late in the process. In contrast, necrosis is characterized by marked swelling of mitochondria, decreases in ATP formation, and increases in the generation of reactive oxygen species.

A major event underlying these mitochondrial abnormalities is mitochondrial permeability transition (MPT) caused by

opening of the MPTP in the IMM.<sup>83</sup> The MPTP is a nonselective channel that can accommodate molecules less than 1.5 kDa. A variety of proteins have been hypothesized to be components of the pore including adenine nucleotide translocase (IMM), cyclophilin D (matrix), voltage-dependent anion channel (OMM), peripheral benzodiazepine receptor (OMM), mitochondrial phosphate carrier (IMM), and others. Current opinion, however, is that the composition of the channel is not known with any certainty. Moreover, while cyclophilin D may or may not be part of the structural pore, it plays an important regulatory role, as will be discussed later.

MPTP opening is stimulated by elevated mitochondrial matrix  $\text{Ca}^{2+}$  concentration, oxidative stress, elevated phosphate concentration, and decreased adenine nucleotide concentration. The consequences of MPTP opening are (1) Redistribution of water and solutes across the IMM. In particular, there is a massive entry of water from the mitochondrial intermembrane space (IMS) to the matrix. This occurs because the osmolality of the matrix is significantly higher than that of the IMS. This redistribution of water causes the matrix to swell and expands the IMM. Since the IMM has considerably more surface area than the OMM, this swelling outstrips the ability of the OMM to contain the IMM. Rupture of the OMM can ensue. (2) Loss of the electrical potential difference across the IMM ( $\Delta\psi_m$ ). Electron transport generates an electrical potential difference ( $\Delta\psi_m$ ) across the IMM, in which the matrix is markedly negative in relation to the IMS. Opening of MPTP causes loss of  $\Delta\psi_m$ , which is the electromotive force coupled to the phosphorylation of ADP to ATP. Thus, ATP production plummets. (3) Increased ROS production due to electron transport chain dysfunction and electron leakage.

Cyclophilin D is a peptidyl-prolyl *cis-trans* isomerase encoded by the *ppif* gene. The endogenous substrates of its enzymatic activity are not known with certainty, although it is clear that this enzymatic activity is needed for MPTP opening. Overexpression of cyclophilin D in transgenic mice causes mitochondrial swelling and cell death. Conversely, mitochondria derived from cyclophilin D knockout mice are resistant to swelling induced by  $\text{Ca}^{2+}$  (an MPTP opener), but remain sensitive to cytochrome *c* release in response to Bax and *tBid* (classic apoptotic stimuli). Similarly, primary cells isolated from cyclophilin D knockout mice are resistant to killing by  $\text{Ca}^{2+}$  and oxidative stress while remaining sensitive to Bax-induced death. Taken together, cyclophilin D does not appear to mediate apoptosis, but rather regulates a death process with several key features of necrosis.<sup>7-9</sup>

It is instructive to consider differences between mitochondrial events in apoptosis and necrosis. The major mitochondrial event in apoptosis is permeabilization of the OMM resulting in apoptogen release. In contrast, the most important mitochondrial event in necrosis is opening of the MPTP in the IMM. As noted, mitochondrial swelling resulting from MPTP opening, however, can lead to OMM rupture. This, in turn, can permit the release of apoptogens, although their importance in cell killing, as compared with the catastrophic IMM events during necrosis, is not clear. At one time, it was thought that OMM permeabilization during apoptosis was caused by OMM rupture resulting from IMM events (e.g., MPTP opening and loss of  $\Delta\psi_m$ ). It is now known, however, that OMM permeabilization during apoptosis is distinct from OMM rupture during necrosis. In fact, IMM events, such as loss of  $\Delta\psi_m$ , which sometimes occur during apoptosis, are not required for OMM permeabilization and usually occur after OMM permeabilization.<sup>50,84</sup> To summarize, OMM permeabilization during apoptosis is a Bax/Bak-dependent process, while OMM rupture during necrosis results from cyclophilin D-dependent MPTP opening in the IMM. There may be areas of functional overlap, however. For example, as previously noted, remodeling of the IMM to “open” cristae and free

cytochrome *c* stores for release during apoptosis may involve cyclophilin D.<sup>50</sup>

## Ca<sup>2+</sup>/Proteases

A proteolytic cascade mediated by caspases is a critical feature of apoptotic cell death. Indeed, a major goal of both the extrinsic and intrinsic apoptosis pathways is to bring about the activation of caspases. These observations have raised questions as to whether necrosis is also mediated by a hierarchy of executioner proteases.

There is evidence that orthologs of calpains and cathepsins mediate necrosis in *C. elegans*. Gain-of-function mutations in *mec-4* (*mechanosensory 4*), encoding a  $\text{Ca}^{2+}$  and  $\text{Na}^{+}$  channel, induce necrotic death in neurons.<sup>85,86</sup> *mec-4*-induced necrosis is decreased by mutation or knockdown of *unc-68* (encoding an ortholog of the ryanodine receptor, a  $\text{Ca}^{2+}$  release channel), *itr-1* (encoding an ortholog of IP3R, a  $\text{Ca}^{2+}$  release channel), *crt-1* (encoding an ortholog of calreticulin), or *cnx-1* (encoding an ortholog of calnexin). Thapsigargin (an inhibitor of SERCA [sarcoplasmic/endoplasmic reticulum  $\text{Ca}^{2+}$ -ATPase], which pumps  $\text{Ca}^{2+}$  from the cytoplasm into the ER lumen) antagonizes the rescue of *mec-4*-induced necrosis by *crt-1* mutation. Taken together, these data suggest that increases in cytoplasmic  $\text{Ca}^{2+}$  may mediate necrosis, perhaps related to the role of  $\text{Ca}^{2+}$  in MPTP opening.

As shown previously, gain-of-function mutations in  $\text{Ca}^{2+}$  and  $\text{Na}^{+}$  channels that induce necrosis in worms are associated with high cytoplasmic  $\text{Ca}^{2+}$  levels. Calpains are  $\text{Ca}^{2+}$ -activated noncaspase cysteine proteases. Loss-of-function mutations in *clp-1* or *tra-3* (encoding calpain orthologs) ameliorate necrosis induced by gain-of-function mutations in  $\text{Ca}^{2+}$  or  $\text{Na}^{+}$  channels.<sup>87</sup> Taken together, these data suggest that calpain orthologs mediate necrosis in the worm. Cathepsins, another family of proteases that reside in lysosomes, may be released during cellular stress. Loss-of-function mutations in *asp-3* and *asp-4* (encoding cathepsin orthologs) also suppress necrosis due to  $\text{Ca}^{2+}$  or  $\text{Na}^{+}$  channels,<sup>87</sup> suggesting that cathepsin orthologs are also involved in necrosis in the worm.

The involvement of calpains, cathepsins, and other proteases in mammalian necrosis is less clear. There is evidence that calpains play important signaling roles in apoptosis. Calpain-cleavage can promote apoptosis by activating Bid and Bax, inactivating Bcl-2 and Bcl- $x_L$ , and generating a fragment of Atg5 (autophagy-related 5 homolog, discussed later) that translocates to mitochondria where it binds Bcl- $x_L$ .<sup>88</sup> In contrast, calpain-mediated cleavage of caspases can inhibit apoptosis. Its role in signaling aside, there is currently no compelling evidence that calpains or other proteases play a central proteolytic role in necrosis.

## Some Unresolved Questions

We have discussed two emerging pathways that mediate necrosis: the death receptor/RIP pathway and cyclophilin D/MPTP pathway. These pathways affirm that necrosis, at least in some situations, is an actively mediated and regulated process. While these pathways are almost certainly interconnected, there has been little work thus far to define their genetic or mechanistic relationships. Preliminary evidence that the two pathways are connected in the myocardium is suggested by ischemia-reperfusion experiments showing that necrostatin-1 (which inhibits RIP1 kinase activity<sup>89</sup>) does not augment cardioprotection resulting from cyclophilin D ablation.<sup>90</sup> One likely molecular connection between the pathways is RIP3-generated ROS, which may play a role in MPTP opening.<sup>81</sup> Finally, there are likely to be additional necrosis pathways based on genomewide siRNA screens<sup>76</sup> that have revealed unexpected mediators of necrosis such as Bmf (Bcl-2

modifying factor), a BH3-only protein with a well-established proapoptotic role.

The most essential necrosis phenotypes are ATP depletion and plasma membrane disruption. ATP depletion is due, in large part, to MPTP opening. However, additional mechanisms may operate. For example, PARP (poly [ADP-ribose] polymerase), which is activated in certain instances of necrosis (e.g., DNA damage from alkylating agents), adds ADP-ribose to histones and, in so doing, consumes NAD<sup>+</sup> and depletes ATP.<sup>91</sup> In contrast, the basis for loss of plasma membrane integrity in necrosis is poorly understood.

## AUTOPHAGIC CELL DEATH

### Autophagy

Before considering autophagic cell death, we will discuss autophagy,<sup>92</sup> which is a normal cellular survival process. There are three types of autophagy, but this discussion will be restricted to macroautophagy, referred to hereafter as autophagy. Autophagy (meaning “self-eating”) is a process in which organelles, proteins, and lipids are transported in double membrane vesicles, called autophagosomes, for catabolism in lysosomes to provide the cell with amino acids, free fatty acids, and energy during times of starvation or stress. In addition, autophagy is one of the major pathways in the cell for regulating protein degradation. Finally, autophagy provides a critical quality control mechanism for proteins and organelles and regulates organelle abundance.

The macromolecules and organelles destined for degradation are first surrounded by a double membrane vesicle termed the *autophagosome*. This process, which is regulated by evolutionarily conserved *atg* (*autophagy-related*) genes, begins with vesicle nucleation involving Beclin-1, UVRAG (UV radiation resistance-associated gene), Vps34 (vacuolar protein sorting 34), IP3R, and others.<sup>92</sup> Next, vesicle elongation is directed by Atg12 and Atg8 conjugation pathways. Finally, the autophagosome fuses with the lysosome to create the autophagolysosome, and lysosomal enzymes degrade its contents.

Autophagy is regulated by mTOR (mammalian target of rapamycin), which under normal nutrient conditions, phosphorylates and inactivates Atg proteins to inhibit autophagy. In contrast, deficiency of nutrients decreases the activity of the class I PI3K (phosphatidylinositol 3-kinase)-Akt axis, decreasing mTOR activity, and inducing autophagy. A second pathway involves Beclin-1, which binds Vps34, a class III PI3K, to promote autophagosome formation. Interestingly, Beclin-1 possesses a BH3 domain,<sup>93</sup> a motif discussed previously in connection with Bcl-2 proteins. Antiapoptotic Bcl-2 proteins, such as Bcl-2 and Bcl-x<sub>L</sub>, interact with Beclin-1 through the Beclin-1 BH3 domain. Moreover, the binding of Bcl-2 and Bcl-x<sub>L</sub> to Beclin-1 inhibits starvation-induced autophagy in the myocardium.<sup>94</sup> On the other hand, the binding of Beclin-1 does not abrogate the antiapoptotic effects of Bcl-2 and Bcl-x<sub>L</sub>.<sup>95</sup>

### Autophagic Cell Death

Because autophagic morphology (e.g., autophagosomes) can be observed in association with damaged/dying cells, the possibility has been raised that autophagic cell death may be an independent form of cell demise. The most pressing question is whether autophagy causes the resulting cell death versus merely being associated with it. The strongest evidence to date in support of a causal connection between autophagy and cell death comes from studies of salivary gland degradation during development in *Drosophila* showing that both apoptosis and autophagy play important roles.<sup>12</sup> A second critical question is whether specific death machinery carries out autophagic cell death and, if so, whether it is that used in apoptosis, necrosis, or novel. A third important question is

what converts autophagy as a survival mechanism to autophagic cell death. One hypothesis is that too much autophagy begets autophagic cell death, while another is that the switch is unrelated to the intensity of autophagy. Clearly, further work is needed to resolve this question.

A general problem in the field of autophagic cell death research is that, in contrast to apoptosis, there are no markers for autophagic cell death. The only way to diagnose autophagic cell death is by electron microscopy showing autophagosomes or autophagolysosomes in a degenerating cell. Although this is the gold standard, it presents several problems including not knowing for sure whether the cell is dead, and more importantly, not knowing whether autophagy is contributing to or ameliorating cell death. In many studies, electron microscopy is not carried out. Rather, autophagy is manipulated genetically, and changes in autophagy (not autophagic cell death) are correlated with a downstream functional readout.

## PUTTING CELL DEATH TOGETHER

It is possible that different regulated death processes coexist in the same cell. We already know that, despite their distinct morphological features, the various forms of cell death share important mechanistic and functional connections. Mechanistic connections may take the form of common mediators such as Ca<sup>2+</sup> (necrosis<sup>83</sup> and apoptosis<sup>88</sup>), Bcl-2 (apoptosis<sup>26,35</sup> and autophagy<sup>94</sup>), and others. Other potential connections between death processes may result from common or closely situated sites of action. For example, the IMM is central to MPTP opening in necrosis,<sup>83</sup> but is also involved in remodeling of cristae during apoptosis.<sup>50</sup> There are likely to be additional, more direct connections. For example, caspase 3 activated during apoptosis can cleave NDUFS1 (NADH dehydrogenase [ubiquinone] Fe-S protein 1), a component of respiratory complex 1 in the IMM to trigger a necrotic phenotype.<sup>96</sup> Presumably, caspase 3 gains access to this protein through the previously permeabilized OMM. Conversely, as described previously, rupture of the OMM during necrosis can allow the release of mitochondrial apoptogens,<sup>7</sup> although their contribution to the demise of the necrotic cell is unclear. Although not yet tested, these situations may place different death programs in series with one another, in addition to their conventional parallel relationships. These concepts raise the possibility of new relationships among death programs (see Whelan<sup>97</sup> for a more in-depth consideration).

## LESSONS FROM MYOCARDIAL INFARCTION

Although the focus of this chapter is the role of cell death in heart failure, we will review the larger body of information pertaining to the regulation of cardiac myocyte death in models of myocardial infarction (for a more detailed discussion, see Foo<sup>2</sup> and Whelan,<sup>97</sup> and references therein). These models have been studied extensively both for their clinical relevance and because the large magnitude and limited time frame of cell death provides a more robust readout than the heart failure models. Rodent myocardial infarction models include (1) permanent surgical occlusion of the left coronary artery and (2) prolonged, but transient, surgical occlusion of the left coronary artery followed by reperfusion (I/R). Ischemia in either model subjects the myocardium to severe deficits of oxygen, nutrients, and survival factors and the buildup of H<sup>+</sup> and waste products. Reperfusion is the standard therapy for ST-segment elevation myocardial infarction because it results in net salvage of myocardium.<sup>98</sup> Despite this, reperfusion is accompanied by potentially toxic effects including oxidative stress from the sudden reintroduction of oxygenated blood; increased cytosolic and mitochondrial

Ca<sup>2+</sup>; too rapid normalization of intracellular acidosis, which can trigger MPTP opening; and inflammation.<sup>99</sup> Although the timing and proportions of apoptosis and necrosis vary with the model, both permanent coronary occlusion and I/R result in both forms of cell death in the infarct zone itself.<sup>100-102</sup> Autophagy also occurs during permanent coronary occlusion and I/R,<sup>103,104</sup> but data are lacking on autophagic cell death.

Myocardial I/R activates both the intrinsic and extrinsic apoptosis pathways. Mutations causing decreased abundance or function of multiple mediators in these pathways (e.g., Fas,<sup>105</sup> PUMA,<sup>106</sup> and Bax<sup>107</sup>) decrease cardiac myocyte apoptosis and infarct size and, when measured, lessen cardiac dysfunction in vivo. Similar results are obtained with overexpression of apoptosis inhibitors (Bcl-2,<sup>108,109</sup> ARC,<sup>110</sup> and c-IAP2<sup>111</sup>) and pharmacological inhibitors of caspases<sup>112-115</sup> or the serine protease of Omi/HtrA2.<sup>116,117</sup> These data indicate that the intrinsic and extrinsic apoptosis pathways mediate the death of cardiac myocytes during I/R.

In addition to apoptosis, I/R also elicits substantial amounts of cardiac myocyte necrosis. Deletion of cyclophilin D decreases necrotic death and lessens infarct size following I/R.<sup>7,8</sup> As previously discussed, similar results are obtained with necrostatin-1, an RIP1 kinase inhibitor.<sup>90</sup> These studies show that both the death receptor/RIP and cyclophilin D/MPTP pathways are important in myocardial infarction.

Autophagy is induced during permanent occlusion and I/R.<sup>103,104</sup> During permanent occlusion, increases in autophagy are mediated by AMPK (5'-adenosine monophosphate-activated protein kinase), a negative regulator of mTOR. Overexpression of dominant negative AMPK inhibits induction of autophagy, and this is accompanied by increased infarct size.<sup>104</sup> These data suggest that autophagy plays a protective role during permanent occlusion, although pleiotropic effects of AMPK on metabolism and apoptosis must also be considered. Induction of autophagy during I/R is mediated by increases in Beclin-1 levels. Heterozygous deletion of Beclin-1 decreases infarct size during I/R, suggesting that autophagy is pathogenic in this setting,<sup>103</sup> although other data suggest a beneficial role for autophagy in this setting.<sup>118</sup> Thus the role of autophagy in I/R is currently unresolved. Note that the variable under study in these experiments is autophagy, not autophagic cell death.

Taken together, these data demonstrate that regulated cardiac myocyte death plays a critical causal role in the genesis of myocardial infarction during I/R. An important issue relates to the possible connections among death programs that were discussed previously. If the programs are connected in a substantial way, the interpretation of studies that perturb a given death program will need to be reinterpreted in light of their effects on other programs (i.e., while each of the genetic or pharmacological manipulations discussed previously clearly modulates infarct size, the question is through which death programs). Future experiments to assess connections among death programs will be critical in understanding the effect of mutations in one program on the others and on overall cell loss.

## CELL DEATH AND HEART FAILURE

Various underlying diseases (e.g., prior myocardial infarction[s], hypertension, etc.) set into motion a complex series of molecular, cellular, and mechanical events that lead to heart failure.<sup>1</sup> The initial response is usually compensated cardiac hypertrophy, characterized by increased myocyte volume (primarily increases in cell width), addition of sarcomeres in parallel, increased wall thickness with normalization of wall stress, normal or reduced chamber volume, normal systolic function, and reversion to a "fetal program" of gene expression. Eventually, however, there is a transition to overt heart failure, characterized by chamber dilation, wall thinning, and deterioration of systolic function. Myocytes exhibit increased length with sarcomeres

arranged in a series. Moreover, there is evidence of myocyte loss, which may occur by apoptosis, necrosis, and autophagic cell death.<sup>119,120</sup> The molecular and cellular basis of the transition from compensated hypertrophy to heart failure is not understood. As previously noted, multiple processes have been implicated including derangements in signaling, Ca<sup>2+</sup>/excitation-contraction coupling, energetics, contractile proteins, and cytoskeleton, inflammation, and cell death.

In this section, we will focus on cardiac myocyte death as a causal component for both myocardial remodeling and failure. While the central events of cell death described previously are common to most death signals, the upstream pathways are usually stimulus-specific. Accordingly, we will first discuss connections between stimuli of clinical relevance to heart failure and cell death. Second, we will consider genetic and pharmacological models that attempt to isolate the critical issue of whether cell death is playing a causal role in the pathogenesis of heart failure.

## Stimuli and Pathways That Mediate Cardiac Myocyte Death in Heart Failure

### Stretch

As shown in rats, chronic pressure overload induces cardiac hypertrophy accompanied by myocyte apoptosis.<sup>121</sup> Pressure overload is mediated by a complex interplay of mechanical and humoral factors. While the exact signaling events are unclear, some data link mechanical stretch with cell death. First, stretch can induce myocyte apoptosis in isolated rat papillary muscles accompanied by increased ROS.<sup>122</sup> Second, cardiac myocyte in vivo can lead to anoikis, disruption of cellular anchorage seen in apoptotic death.<sup>123</sup> Third, stretch of isolated rat cardiac myocytes elicits the release of angiotensin II, resulting in both cardiac hypertrophy<sup>124</sup> and apoptosis.<sup>125</sup> As will be discussed later, survival signals appear important in suppressing mouse cardiac myocyte apoptosis in response to hemodynamic overload.<sup>126</sup> In summary, stretch induces cardiac myocyte apoptosis through incompletely defined signaling pathways in association with the transition to heart failure.

### Adrenergic Signaling

Levels of plasma norepinephrine correlate directly with the severity of heart failure<sup>127</sup> and mortality in humans.<sup>128</sup> Cardiac-specific overexpression of the  $\beta_1$ -adrenergic receptor ( $\beta_1$ AR) leads to hypertrophy with enhanced function in younger mice, but chamber dilation and dysfunction accompanied by increased cardiac myocyte apoptosis in older mice.<sup>129,130</sup> Most of the harmful effects of  $\beta$ -adrenergic receptor activation, including cardiac myocyte apoptosis, are mediated by the  $\beta_1$ -isoform.<sup>131</sup> In contrast, the  $\beta_2$ -isoform inhibits apoptosis.<sup>132</sup> For example, inhibition of the  $\beta_1$ -isoform and activation of the  $\beta_2$ -isoform attenuate myocyte apoptosis in a rodent model of postinfarct remodeling.<sup>133</sup> As the  $\beta_1$ -isoform is most abundant in the myocardium, the net effect of catecholamines is induction of apoptosis.

Although the mechanism by which  $\beta_1$ AR activation causes cardiac myocyte apoptosis is not well understood, calcium/calmodulin-dependent protein kinase II (CaMKII) has been shown in mouse cells to play an important role.<sup>134</sup> Interestingly, the classic cAMP-protein kinase A pathway does not appear to be critical.  $\beta_1$ AR activation increases CaMKII activity.<sup>134</sup> Moreover, transgenic cardiac-specific overexpression of CaMKII- $\delta$ , the predominant isoform, exacerbates isoproterenol-induced cardiac myocyte apoptosis<sup>134</sup> and precipitates lethal heart failure.<sup>135</sup> Conversely, general inhibition or CaMKII or deletion of CaMKII- $\delta$  ameliorates cardiac myocyte apoptosis induced by isoproterenol or prior myocardial infarction<sup>134,136</sup> and blunts the

development of hypertrophy or failure in response to hemodynamic overload in mice.<sup>137,138</sup> Thus CaMKII- $\delta$  mediates  $\beta_1$ AR-induced cardiac myocyte death. Identification of relevant CaMKII- $\delta$  substrates will likely extend our understanding of this pathway.

### Renin-Angiotensin-Aldosterone System

The renin-angiotensin-aldosterone system is one of the major neurohumoral pathways in heart failure. Interruption of this axis ameliorates cardiac remodeling and dysfunction, and improves morbidity and mortality in a variety of pathological contexts in humans.<sup>139</sup> Renin-angiotensin-aldosterone signaling can affect cardiac myocytes directly or indirectly through alteration of systemic hemodynamics. In addition, cardiac myocytes possess an intrinsic “local” renin-angiotensin system that acts in an autocrine/paracrine manner. This complexity makes it difficult to identify precise mechanisms responsible for the striking clinical benefits noted previously. These caveats notwithstanding, angiotensin II and aldosterone each induce apoptosis in isolated rat cardiac myocytes through activation of the angiotensin II type 1 (AT<sub>1</sub>) and mineralocorticoid receptors, respectively.<sup>140,141</sup> Knockout or pharmacological blockade of AT<sub>1</sub> lessens cardiac myocyte apoptosis induced by doxorubicin or diabetes in rodents in vivo.<sup>142,143</sup> Similarly, blockade of the mineralocorticoid receptor attenuates postinfarct remodeling and periinfarct apoptosis in rats.<sup>144</sup> The mechanism by which AT<sub>1</sub> activation brings about apoptosis is incompletely understood. AT<sub>1</sub> can signal through G $\alpha_q$  to transcriptionally activate Nix, a BH3-only-like protein that stimulates cardiac myocyte apoptosis in mice.<sup>145</sup> AT<sub>1</sub> may also induce myocyte apoptosis through NADPH oxidase (nicotinamide adenine dinucleotide phosphate-oxidase) and ASK1 (apoptosis signal-regulating kinase 1).<sup>146,147</sup> Additional evidence suggests a positive feedback loop in which AT<sub>1</sub> activates p53, whose target genes may include angiotensinogen and AT<sub>1</sub>.<sup>146</sup>

### Proinflammatory Cytokines

Proinflammatory cytokines play an important role in heart failure via their effects on myocyte contractility, inflammation, and cell death and endothelial function. The cytokines most relevant to heart failure are TNF, interleukin (IL)-1, and IL-6. In the Framingham Heart Study, elevated levels of TNF and IL-6 were associated with increased risk of heart failure in asymptomatic patients without prior myocardial infarction.<sup>148</sup> Among other effects, IL-1 and TNF can induce apoptosis in isolated rat cardiac myocytes.<sup>149,150</sup> As discussed previously, however, TNF activates survival and death pathways simultaneously under many conditions and, therefore, does not kill efficiently.<sup>74,75</sup> IL-6 is believed to be antiapoptotic.

Cardiac-specific overexpression of TNF in mice causes cardiac hypertrophy, dilation, and dysfunction accompanied by induction of cardiac myocyte apoptosis via the extrinsic and intrinsic pathways.<sup>151,152</sup> Deletion of TNFR1 blunts heart failure and improves survival in TNF overexpressors, while deletion of TNFR2 does the opposite.<sup>152</sup> Moreover, TNFR1 promotes, and TNFR2 inhibits, cardiac myocyte apoptosis during postinfarction remodeling.<sup>153</sup> Thus, it appears that TNFR1 mediates the deleterious effects of excess TNF on postinfarct remodeling, while TNFR2 is protective. In contrast, infarct size following permanent occlusion is unaffected by deletion of either TNFR1 or TNFR2, but rather is increased significantly by deletion of both, and this is accompanied by increased apoptosis but not necrosis.<sup>154</sup> Thus, both TNFR1 and TNFR2 seem to exert a protective role during acute infarction. These data underscore divergent roles played by TNF receptor subtypes in different contexts.

The ability of TNF antagonism to improve heart failure in humans has been assessed in three clinical trials. RENAISSANCE (Randomized Etanercept North American Strategy to

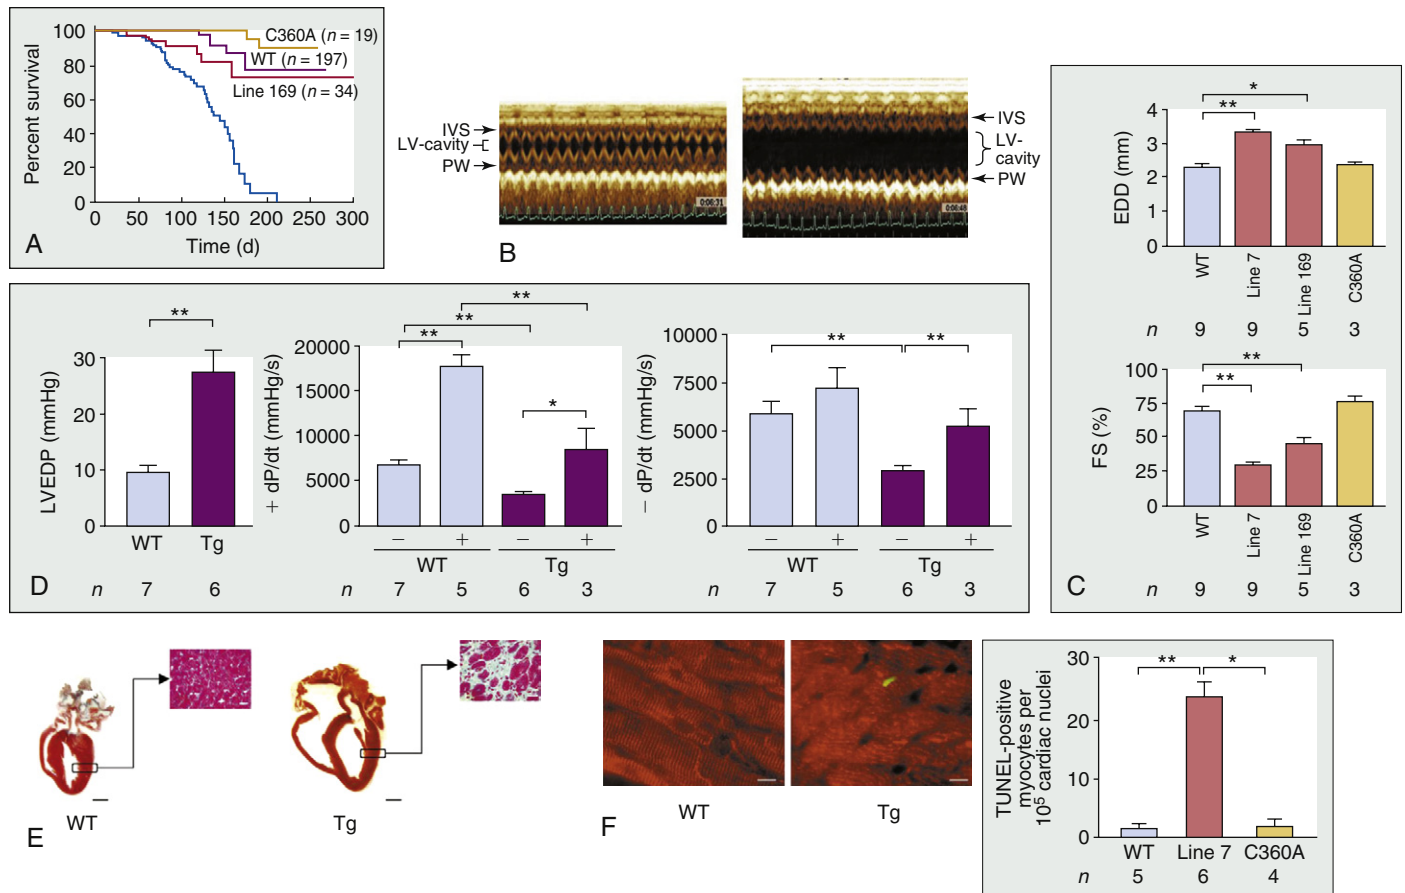

Study Antagonism of Cytokines)<sup>155</sup> and RECOVER (Research into Etanercept Cytokine antagonism in Ventricle dysfunction)<sup>155</sup> used etanercept, a soluble TNFR2 fusion protein, while ATTACH (Anti-TNF $\alpha$  Therapy Against Congestive Heart failure)<sup>156</sup> used infliximab, a mouse-human chimeric monoclonal antibody that specifically and potently binds to and neutralizes soluble TNF homotrimer. These clinical trials failed to demonstrate any beneficial role of TNF inhibition in heart failure. Possible explanations include inadequate dosing or duration of treatment, upregulation of endogenous TNF (not measured), redundancy of other proinflammatory cytokines in heart failure pathogenesis, and complexities of TNF signaling including possibly opposing effects of the receptor subtypes. Regarding the latter, the treatment strategy in these trials may have abrogated beneficial, as well as deleterious, effects.

### Heart Failure and Apoptosis

In contrast to the large but brief burst of apoptosis during myocardial infarction, heart failure is characterized by a modest—but clearly elevated—level of cardiac myocyte apoptosis that can persist for months. This is illustrated by patients with end-stage dilated cardiomyopathy who exhibit rates of cardiac myocyte apoptosis of 0.08% to 0.25% compared with 0.001% to 0.002% in controls.<sup>157-159</sup> Many studies have assessed the role of cardiac myocyte apoptosis in the pathogenesis of heart failure. We will review several that have been particularly illustrative of key points.

Although clearly higher than controls, the modest rates of apoptosis in failing hearts call into question a role for cell death in heart failure. On the other hand, heart failure is a protracted syndrome, opening up the possibility that even moderately elevated levels of cell death could result in substantial cell loss over time. To resolve this question, transgenic mice were created with cardiac-specific expression of a caspase 8 allele that exhibits low levels of activation at baseline (Figure 6-4).<sup>160</sup> These mice develop a lethal dilated cardiomyopathy over 2 to 6 months. In contrast, nontransgenic mice and mice expressing an enzymatically-dead caspase 8 at similar levels are normal. Control mice exhibit apoptotic rates of 0.001% to 0.002%. In contrast, rates of cardiac myocyte apoptosis in mice expressing the activated caspase 8 allele were 0.023%, or tenfold higher. Notably, these rates of apoptosis are threefold to tenfold lower than the rates in patients with dilated cardiomyopathy as specified previously. Thus this transgenic model illustrates that a modest, although elevated, rate of cardiac myocyte apoptosis is sufficient to cause a lethal dilated cardiomyopathy over time. To test whether cardiac myocyte apoptosis in this model is causally linked with heart failure, a caspase inhibitor was administered chronically before the development of cardiomyopathy. The caspase inhibitor decreased cardiac myocyte apoptosis (as expected) and markedly attenuated development of left ventricular dilation and dysfunction over time. These data demonstrate a causal connection between modest levels of cardiac myocyte apoptosis and heart failure.

While the caspase 8 transgenic mice are informative with respect to one of the most critical questions, this gain-of-function model is ultimately artificial. Accordingly, the goal of the next level of inquiry was to assess the effect of inhibiting cardiac myocyte apoptosis in models of heart failure. G $\alpha_q$  transduces hypertrophic signals from the AT<sub>1</sub>, endothelin, and  $\alpha_1$ -adrenergic receptors. Accordingly, transgenic cardiac-specific overexpression of G $\alpha_q$  results in hypertrophy. This transitions to heart failure accompanied by cardiac myocyte apoptosis.<sup>161</sup> In addition, a high proportion of pregnant G $\alpha_q$  transgenic females die from fulminant cardiomyopathy accompanied by high rates of cardiac myocyte apoptosis.<sup>162</sup> Transcriptional profiling of the hearts of G $\alpha_q$  transgenic mice

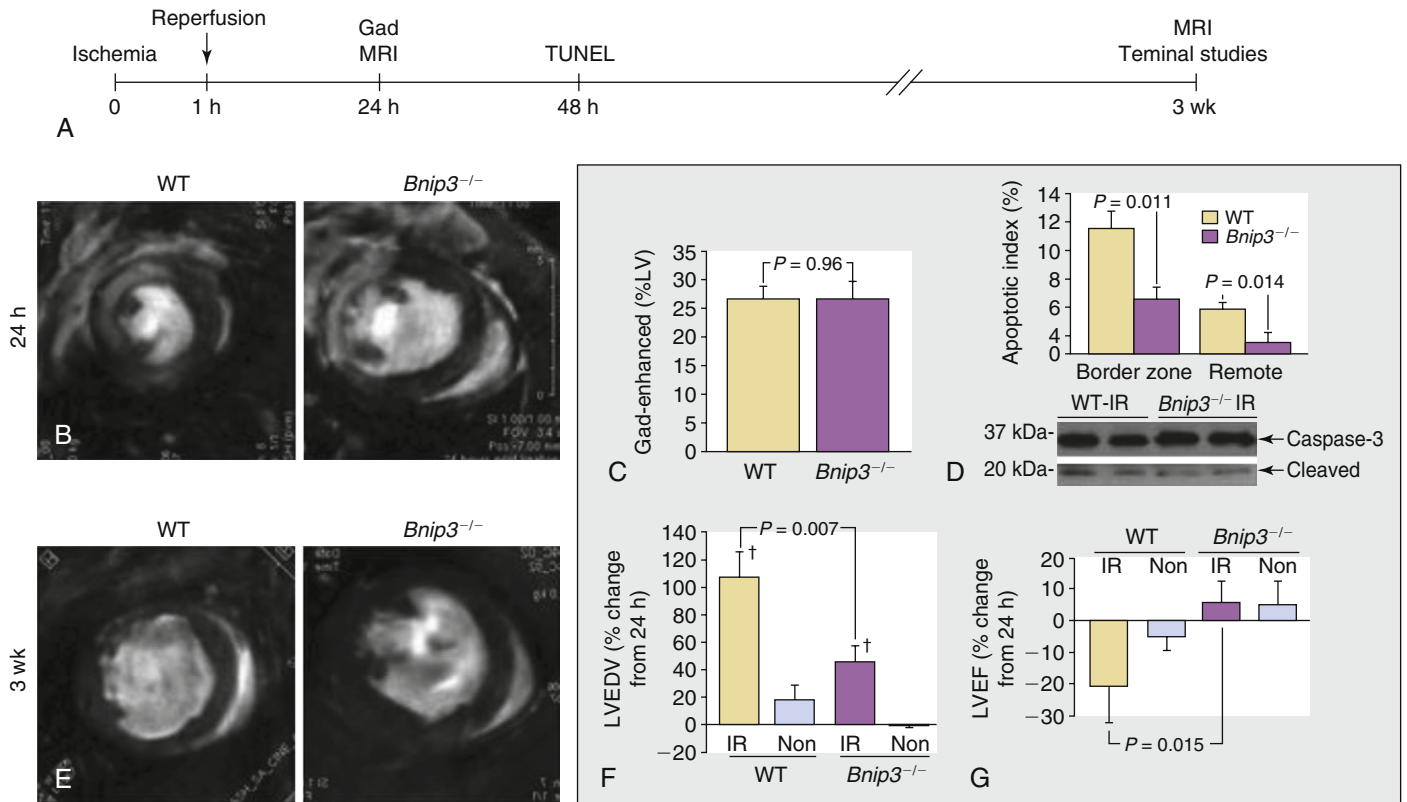

**FIGURE 6-4** Very low levels of cardiac myocyte apoptosis are sufficient to induce a lethal, dilated cardiomyopathy.<sup>160</sup> Mice with cardiac-specific transgenic overexpression of a modified caspase 8 allele exhibited chronic low, but abnormal, levels of cardiac myocyte apoptosis, cardiomyopathy, and premature death. The transgene protein consisted of the p20 and p10 catalytic subunits of human procaspase 8 fused to a trimer of the FK binding protein (FKBP) and a myristoylation signal to target the protein to the plasma membrane. Not shown here: Administration of the dimeric FKBP ligand, FK1012H2, triggers forced dimerization and activation of the caspase 8 transgene protein leading to rapid destruction of the heart and death of the mouse (see Figure 1 in Wencker<sup>160</sup>). However, even in the absence of FK1012H2, chronic, low-level activation of the caspase 8 transgene protein results in modest, but abnormal, levels of cardiac myocyte apoptosis, cardiomyopathy, and organismal death over 6 months. **A**, Kaplan-Meier survival curve showing increased mortality in line 7 mice that express the caspase 8 transgene at higher levels. In contrast, mortality is normal in line 169 mice that express the caspase 8 transgene at lower levels and in line C360A, which expresses high levels of a catalytically inactive caspase 8 mutant.  $P < .0001$  for line 7 vs. wild type (WT), line C360A, or line 169. **B** and **C**, Representative echocardiograms and quantification demonstrating left ventricular dilation and markedly decreased fractional shortening in lines 7 and 169. EDD, left ventricular end-diastolic dimension; FS, fractional shortening.  $*P < .01$ ,  $**P < .001$ . **D**, Left ventricular hemodynamics showing that line 7 transgenics exhibit increased left ventricular end-diastolic pressure (LVEDP) and decreased  $+dP/dt$  and  $-dP/dt$  at baseline (–) and in response to isoproterenol (+).  $*P < .02$ ,  $**P < .002$ . **E**, Hematoxylin and eosin staining of coronal heart sections (bar 1 mm) and Masson trichrome staining in boxed insets (bar 25  $\mu$ m) illustrate cardiomegaly and fibrosis, respectively, in transgenic hearts. **F**, Increased cardiac myocyte apoptosis in caspase 8 transgenic mice. Left panels: Double staining for TUNEL (green) and desmin (red, to identify myocytes) in hearts of WT and transgenic line 7 (bar 10  $\mu$ m). Right panel: Quantification of TUNEL-positive cardiac myocytes per  $10^5$  nuclei in WT, transgenic line 7, and C360A mice.  $*P < .002$ ,  $**P < .0003$ . Note that rates of cardiac myocyte apoptosis as low as 23 per  $10^5$  (compared with 1 to 2 per  $10^5$  in WT) were sufficient to beget a lethal, dilated cardiomyopathy. (Reproduced with permission from Wencker D, Chandra M, Nguyen K, et al. A mechanistic role for cardiac myocyte apoptosis in heart failure. *J Clin Invest* 2003;111(10):1497-1504.)

revealed induction in the expression of Nix/Bnip3L (Nip3 [19 kDa interacting protein-3]-like protein X/Bcl-2/adenovirus E1B), a BH3-only-like protein.<sup>145</sup> Transgenic expression of Nix/Bnip3L in mice is accompanied by dramatic cardiac myocyte apoptosis and increased mortality.<sup>145</sup> In contrast, transgenic expression of sNix, a dominant negative splice variant of Nix/Bnip3L, attenuates cardiac myocyte apoptosis, cardiac dysfunction, and mortality in the peripartum cardiomyopathy of Gαq transgenic mice.<sup>145</sup> Similarly, caspase inhibition rescues the Gαq peripartum cardiomyopathy.<sup>163</sup> Thus, overexpression of Gαq leads to transcriptional activation of Nix/Bnip3L expression, which triggers apoptosis. From the perspective of the pathogenesis of heart failure, the most important conclusion from these experiments is that cardiac myocyte apoptosis is a critical component of heart failure.

The next set of experiments examines the role of cardiac myocyte apoptosis in postinfarct remodeling (Figure 6-5). Bnip3 (Bcl-2/adenovirus E1B 19 kDa interacting protein 3) is

a BH3-only-like protein that is induced in cardiac myocytes by hypoxia and heart failure. Generalized knockout of Bnip3 in the mouse does not affect infarct size in response to I/R, perhaps because the time window for hypoxic induction is too narrow. In contrast, Bnip3 deletion attenuates cardiac myocyte apoptosis in the periinfarct and remote myocardium, and lessens postinfarct remodeling and cardiac dysfunction.<sup>164</sup> Viral transduction of the antiapoptotic Bcl-2 into rabbit myocardium results in similar findings.<sup>165</sup> These data indicate an important role for cardiac myocyte apoptosis in postinfarct remodeling.

Endogenous survival mechanisms often function to help cells withstand stressful stimuli. If stimuli are too noxious or prolonged, the endogenous survival mechanism is often inactivated, allowing the cell to die. Cardiac myocytes are subjected to ongoing biomechanical stress. The next set of experiments suggests that the gp130 pathway may provide a survival mechanism that allows cardiac myocytes to withstand not only basal stress but also increased biomechanical

**FIGURE 6-5** Effects of *Bnip3* ablation on postinfarct remodeling.<sup>164</sup> **A**, Schematic depiction of experimental design for in vivo I/R studies. *Gad*, gadolinium. **B** and **C**, Representative gadolinium-enhanced (white) MRI midventricle end-diastolic images 24 hours after I/R showing no significant difference in infarct size in WT and *Bnip3*<sup>-/-</sup> mice. **D**, TUNEL and caspase 3 activation 48 hours after I/R. The number of TUNEL-positive cells is decreased significantly in the border zone and remote myocardium of *Bnip3*<sup>-/-</sup> mice 48 hours postinfarct. **E-G**, Representative midventricle end-diastolic MRI images 3 weeks after I/R and quantitative analysis of MRI-derived LV end-diastolic volume (LVEDV) and LV ejection fraction (LVEF) as compared with these parameters at 24 hours. Deletion of *Bnip3* attenuates post-I/R abnormalities in both LVEDV and LVEF. This study shows that the proapoptotic BH3-only-like protein *Bnip3* plays a role in postinfarct remodeling following I/R. The absence of an effect of *Bnip3* on infarct size may be due to inadequate time for its induction by hypoxia following I/R. (Reproduced with permission from Diwan A, Krenz M, Syed FM, et al. Inhibition of ischemic cardiomyocyte apoptosis through targeted ablation of *Bnip3* restrains postinfarction remodeling in mice. *J Clin Invest* 2007;117(10):2825-2833.)

stress during hemodynamic overload. gp130 is a subunit of the receptors that bind several prosurvival cytokines of the IL-6 family, including cardiotrophin-1 (which mediates cardiac hypertrophy), LIF (leukemia inhibitory factor), IL-6, and oncostatin M. Cardiac-specific deletion of gp130 in the mouse results in no baseline cardiac abnormalities. The imposition of hemodynamic overload from transverse aortic constriction, however, precipitates massive cardiac myocyte apoptosis and fulminant cardiomyopathy.<sup>126</sup> Absence of gp130 abrogates hemodynamic overload-induced phosphorylation of STAT3 (signal transducer and activator of transcription 3), which in turn prevents activation of the transcription of antiapoptotic Bcl-x<sub>L</sub>. These results suggest that the gp130 pathway provides an endogenous survival mechanism that suppresses hemodynamic overload-induced cardiac myocyte apoptosis and heart failure.

### Heart Failure and Necrosis

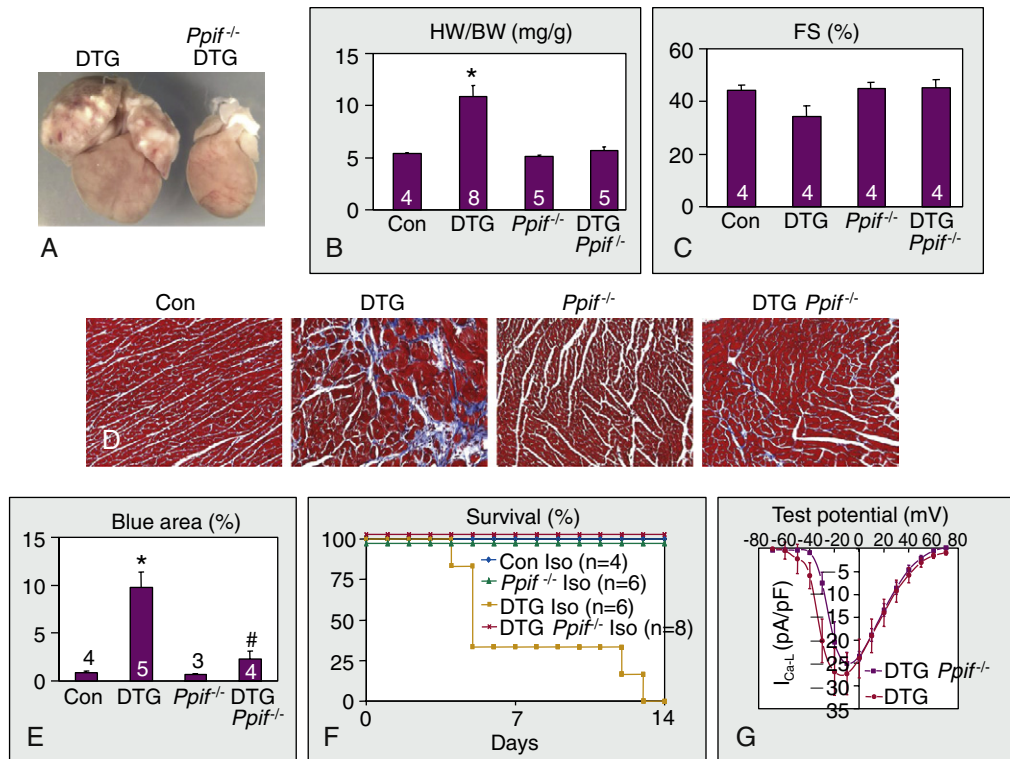

Rates of necrosis are increased in human heart failure.<sup>119,120</sup> The recent recognition that necrosis can be regulated and that regulated necrosis is critical to myocardial damage during I/R has suggested the possibility that necrosis is also important for the pathogenesis of heart failure.<sup>6-9,74</sup> Of note, this idea has been previously suggested.<sup>119,120,157</sup> To assess the role of necrosis in heart failure, this death process was inhibited genetically (Figure 6-6). For these experiments, a new model was created in which Ca<sup>2+</sup> overload from transgenic overexpression of the  $\beta_2$  subunit of the L-type Ca<sup>2+</sup> channel

triggers progressive cardiac myocyte necrosis, heart failure, and mortality.<sup>13</sup> These abnormalities were attenuated by deletion of cyclophilin D, which abrogates necrosis. Interestingly, overexpression of the antiapoptotic Bcl-2 had no effect on this phenotype. Cyclophilin D deletion also lessened heart failure in a model of doxorubicin-induced cardiomyopathy. These data provide the initial proof of concept that cardiac myocyte necrosis plays a crucial role in the pathogenesis of heart failure. It will be important to retest this hypothesis in additional clinically relevant models of heart failure, such as those resulting from hemodynamic overload and myocardial infarction.

### Heart Failure and Autophagy

Rates of cardiac myocyte autophagic cell death, determined by electron microscopy, have been reported to be increased in human heart failure.<sup>119,120,166</sup> Experiments have assessed the role of autophagy, but not autophagic cell death per se, in heart failure. In the first set of studies, autophagy was inhibited in the hearts of adult mice by cardiac-specific deletion of Atg5.<sup>167</sup> Loss of autophagy in the baseline state precipitated severe heart failure accompanied by increased abundance of ubiquitinated proteins and cardiac myocyte apoptosis, the latter possibly due to proteotoxic ER stress. In contrast, when Atg5 was deleted at embryonic day 8.0, no abnormalities were evident at birth, probably due to compensation. When these animals were stressed with transverse aortic constriction, however, mice lacking Atg5 went into heart failure, while

**FIGURE 6-6** Loss of cyclophilin D rescues cardiomyopathy in transgenic mice with  $\text{Ca}^{2+}$  overload.<sup>13</sup> Transgenic mice with cardiac-specific, inducible overexpression of the  $\beta_2\alpha$  subunit of the L-type  $\text{Ca}^{2+}$  channel (LTCC) were generated, resulting in enhanced  $\text{Ca}^{2+}$  currents in cardiac myocytes, cardiac myocyte necrosis, and cardiomyopathy. This figure shows that simultaneous deletion of cyclophilin D, which regulates MPTP opening, significantly rescues this cardiomyopathy. Necrosis is normally thought of as a mechanism of ischemic death. The importance of this work is that it implicates necrosis as a mechanism of heart failure. Although the model employed is artificial, the paper also suggests that necrosis may play a role in doxorubicin-induced cardiomyopathy. In this figure, DTG (double transgenic) denotes mice that overexpress the  $\beta_2\alpha$  subunit of the LTCC in cardiac myocytes in the absence of doxycycline. (Note: doxycycline is absent in the experiments depicted here.) The gene encoding cyclophilin D is called *ppif*, and *ppif*<sup>-/-</sup> denotes a knockout of both alleles of this gene. **A**, Gross morphology of hearts from a DTG mouse and a DTG mouse lacking *ppif*. Note the decrease in size of the DTG, *ppif*<sup>-/-</sup> heart. **B**, Heart weight normalized to body weight measurements showing that deletion of *ppif* decreases the hypertrophy of DTG hearts. **C**, Echocardiographic measurements of fractional shortening showing that deletion of *ppif* in DTG mice trends toward preservation of function (not significant). **D** and **E**, Masson trichrome staining of cardiac sections showing increased fibrosis in DTG and rescued by deletion of *ppif*. **F**, The drug isoproterenol synergizes with transgenic  $\beta_2\alpha$  overexpression to cause  $\text{Ca}^{2+}$  overload. Accordingly, mortality was scored during a 14-day infusion of isoproterenol. Mortality of DTG mice was markedly increased. In contrast, deletion of *ppif* in the context of DTG resulted in zero mortality. **G**, This is a control panel showing that deletion of *ppif* does not affect  $\text{Ca}^{2+}$  currents at different test potentials. \* $P < 0.05$  versus control; # $P < 0.05$  versus DTG. (Reproduced with permission from Nakayama H, Chen X, Baines CP, et al.  $\text{Ca}^{2+}$  and mitochondrial-dependent cardiomyocyte necrosis as a primary mediator of heart failure. *J Clin Invest* 2007;117(9):2431-2444).

wild-type mice did not.<sup>167</sup> Of note, both genotypes exhibited similar degrees of cardiac hypertrophy. These data suggest that (1) basal levels of autophagy are critical for maintaining normal cardiac myocyte structure, function, and survival and (2) autophagy is required during hemodynamic overload to avoid transitioning into heart failure. Taken together, this set of experiments suggests that autophagy is a compensatory mechanism in heart failure.

The role of autophagy in hemodynamic overload-induced heart failure was also assessed by using *Beclin-1*<sup>+/-</sup> mice to inhibit autophagy.<sup>168</sup> When subjected to transverse aortic constriction, *Beclin-1*<sup>+/-</sup> mice exhibit reduced autophagy, pathological cardiac remodeling, and cardiac dysfunction as compared with wild-type mice. The degree of hypertrophy was similar to wild-type mice, however. Conversely, transgenic overexpression of *Beclin-1* augmented autophagy and pathological remodeling in response to transverse aortic constriction. These data suggest that autophagy plays a pathological role in heart failure due to hemodynamic overload.

The *Atg5*<sup>-/-</sup> and *Beclin-1*<sup>+/-</sup> studies yielded opposite conclusions regarding the role of autophagy in hemodynamic overload-induced heart failure. Although an explanation is not evident, there are differences between the studies. First, the genetic manipulations differ. Second, the degree of inhibition of autophagy differs in that both alleles were inactivated

in the case of *Atg5*, while only a single *Beclin-1* allele was inactivated. Third, the transverse aortic constriction model was probably more severe in the *Beclin-1*<sup>+/-</sup> study. Although it is difficult to know how these differences may account for the opposing conclusions, one possibility is that autophagy is protective early in the disease process and pathological later. If the mice in the *Beclin-1*<sup>+/-</sup> study were at a later stage of the disease, perhaps inhibition of autophagy at this stage would reveal a pathological role. Further work is needed to explore these and other possibilities.

The role of autophagy was also examined in a model of desmin-related cardiomyopathy (transgenic mice expressing R120G mutation of  $\alpha\text{B}$  crystallin).<sup>169</sup> Inhibition of autophagy by deleting one allele of *beclin-1* increased polyubiquitinated proteins and aggregates, fibrosis, cardiac dysfunction, heart failure, and mortality. Thus autophagy plays an adaptive/protective function in this model of desmin-related cardiomyopathy.

The previous two studies, both using *Beclin-1*<sup>+/-</sup> mice, conclude that autophagy plays opposite roles in heart failure induced by hemodynamic overload versus desmin-related cardiomyopathy. While the manipulated gene and gene dosage are identical, the studies differ markedly with respect to the stimulus for heart failure. The key stimulus in desmin-related cardiomyopathy is proteotoxicity, which will induce

ER stress and possibly cell death. Autophagy would be expected to mitigate proteotoxic stress, consistent with the adaptive role reported previously. Hemodynamic overload, on the other hand, involves a number of mechanical and humoral stimuli, oxidative stress, and abnormalities in myocardial energetics. Many of these stimuli potentially interface with autophagy pathways, although it is difficult to predict which would dominate. Future efforts to delineate how various component stimuli impact differentially on autophagy will provide insights into the roles of autophagy in heart failure of various causes.

As previously mentioned, an important caveat regarding the previously noted studies is that autophagy, not autophagic cell death, was perturbed, measured, and correlated with a downstream readout. Thus, the only conclusion that can be drawn at this time pertains to the effects of changes in autophagy itself—not autophagic cell death—on heart failure.

## CELL DEATH IN HEART DISEASE: THE BIG PICTURE

Apoptosis, necrosis, and autophagic cell death take place during myocardial infarction and heart failure and impact on pathogenesis in the ways discussed previously. Despite this, little is known about the *relative* contributions of each type of cell death to either syndrome. A temporal and spatial map of the number of cell deaths attributable to each death program is needed for each syndrome. This information has not been easy to acquire, however, due to technical and conceptual issues.

The technical issues have to do with molecular markers used to identify the various forms of cell death. While reasonable markers exist for apoptosis, there are far fewer for necrosis, especially when assessing intact tissues. Moreover, as discussed previously, markers for autophagic cell death (as opposed to autophagy) are lacking. In addition, the utility of any marker is limited by its temporal window of sensitivity, the complexity of which is magnified when attempting to use markers to quantify several forms of cell death. While labor intensive, electron microscopy can simultaneously detect apoptosis, necrosis, and perhaps autophagic cell death and, thereby, address some of these concerns.

The conceptual issue has to do with the aforementioned possibility that different forms of cell death are linked. It should be emphasized that this is only a theoretical consideration at present. Cross talk between parallel death pathways has already been demonstrated. If death programs are also linked (e.g., in series), dying cells may exhibit hybrid morphologies and markers. These issues will require reexamination pending a better understanding of the relationships among the death programs (see Whelan<sup>97</sup> for a more detailed discussion).

These holes in knowledge aside, we will consider the current best assessment as to the types of cell death that occur during myocardial infarction and heart failure. Myocytes in the infarct zone appear to die by both necrosis and apoptosis during myocardial infarction (whether infarction is induced by I/R or permanent coronary occlusion).<sup>100,101</sup> In the case of I/R, manipulations that decrease either necrosis or apoptosis reduce infarct size, consistent with the notion that both necrosis and apoptosis causally contribute to generation of the infarct. Autophagy also occurs during myocardial infarction,<sup>103,104</sup> but as discussed previously, its role in myocardial damage appears to vary. It may be protective in permanent coronary occlusion, and perhaps detrimental in I/R, although this result remains controversial.

Cardiac myocytes die by apoptosis and necrosis during heart failure, and genetic manipulation of each of these death programs can limit pathological remodeling and deterioration of cardiac function. At this point, apoptosis has been studied

in a wider variety of models than has necrosis. Thus, the importance of necrosis in heart failure remains to be determined. Results are presently inconclusive concerning a role for autophagy in heart failure.

## TRANSLATION INTO THERAPEUTICS

Work in rodent models has provided strong evidence that cardiac myocyte death is a critical mechanism in the pathogenesis of heart failure. Whether these conclusions translate to humans remains to be assessed. In addition, it is crucial to note that cardiac myocyte death is not the only important factor in heart failure. Indeed, dysfunction of individual cardiac myocytes, resulting from mechanisms that will be discussed elsewhere in this volume, are also important factors. Nevertheless, there has been intense interest in devising ways to inhibit cardiac myocyte death because cell death is irreversible once completed. Given the existence of a substantial body of information concerning apoptosis and a promising start to understanding necrosis, it is tempting to consider the possibility of novel heart failure therapies directed at inhibiting cardiac myocyte death. In fact, some current therapies ( $\beta_1$ AR blockers, angiotensin II converting enzyme inhibitors, and angiotensin II type 1 receptor blockers) inhibit myocyte apoptosis, although the importance of this antiapoptotic effect in their overall actions is not clear.

Multiple antiapoptotic and antinecrotic agents have been tested for their abilities to inhibit cardiac myocyte death in rodent models of I/R. Promising small molecules include polycaspase inhibitors, UCF-101 (inhibits the serine protease activity of Omi/HtrA2), cyclosporine A (inhibits MPTP opening), and necrostatin-1 (inhibits kinase activity of RIP1). We have recently reviewed these<sup>97</sup> and other<sup>2</sup> potential therapies. In contrast to I/R, there has been minimal evaluation of cell death inhibitors in heart failure models. One exception is that caspase inhibition has been shown to improve cardiac function and/or mortality in the caspase 8 transgenic heart failure model<sup>160</sup> and the Gαq transgenic peripartum cardiomyopathy model,<sup>163</sup> discussed previously.

Beyond the question of which specific anti-cell death therapy may work is the larger question of safety. In contrast to ischemia-reperfusion where one can envision inhibiting cell death for 8 to 24 hours, inhibition of cell death as a treatment for heart failure would potentially be chronic. If administered systemically, cancer would be a likely complication, which some patients might find unacceptable. On the other hand, advanced heart failure is a lethal disease with limited treatment options for most. If an effective anti-cell death therapy existed for heart failure, an informed patient with advanced heart failure may deem the risk of cancer to be acceptable, just as a patient treated with certain chemotherapeutic agents accepts the risk of cardiomyopathy.

This discussion leads to a consideration of whether anti-cell death therapy could be administered locally to the heart, where it would hopefully eliminate or minimize the risk of cancer. There are at least two obvious approaches. The first is cardiac gene therapy. Given the chronic nature of heart failure, this may be one of the few instances in which there is adequate time to contemplate this approach. While a discussion of technical details is beyond the scope of this chapter, presumably the gene of interest would be driven by a cardiac myocyte-specific promoter and enhancer sequences (e.g.,  $\alpha$ -cardiac myosin heavy chain promoter). With gene therapy, the repertoire of anti-cell death approaches would be expanded to large molecules. For example, one could employ Bcl-2 (or a stable mutant of Bcl-2). Of course, this approach may still entail various issues that have beset gene therapy to date, including delivery of the vector, efficiency of transduction, duration of expression, safety of the vector,

and expressed gene. A second local approach could be based on materials science/nanotechnology. This would involve the long-term deployment of small molecules or viral vectors in the myocardium. Further thought is needed if anti-cell death therapy is to become a reality for heart failure.

## SUMMARY

Heart failure is accompanied by chronic low levels of cardiac myocyte death, which are 10-fold to 100-fold higher than those seen in nonfailing hearts. Cardiac myocytes die by apoptosis, necrosis, and perhaps autophagic cell death. Inhibition of apoptosis or necrosis in rodent models diminishes pathological cardiac remodeling, cardiac dysfunction, and in some cases, mortality. The recognition that much of cardiac myocyte death (apoptosis and necrosis) is actively mediated begs the question as to whether anti-cell death therapies for human heart failure could be developed.

## ACKNOWLEDGMENTS

We thank Gerald Dorn and Jeffery Molkentin for use of published figures. We thank Vladimir Kaplinskiy for critical reading of the manuscript. RNK was supported by NIH grants R01HL60665, P01HL078825, and P60DK020541, a New York State Stem Cell Initiative grant, The Dr. Gerald and Myra Dorros Chair in Cardiovascular Disease, and the David Himelberg Foundation. We are very grateful for the generous support of the Wilf Family Cardiovascular Research Institute.

## Interventions Designed to Alter Energetics in the Failing Heart: New Strategies for Therapy, 115

Shown by investigators using many different tools studying human myocardium and a wide variety of animal models of heart failure, it is now known that one characteristic of the failing heart is a progressive loss of ATP. Given that the requirement for ATP for all metabolic processes and for cell viability is absolute, the biochemistry of ATP is now a major focus of research in cardiac metabolism. Questions now being asked are: what mechanisms explain the fall in [ATP], what are the consequences of decreased [ATP], can metabolism be manipulated to restore a normal ATP supply, and does increasing energy supply have physiological consequences (i.e., does it lead to improved contractile performance in the failing heart)? Here, we address each of these questions from two points of view: using what we know about the basic biochemistry of ATP and what we are learning from new analyses of the human heart and of animal models of heart failure. Demonstrating renewed interest in this subject, there have been many reviews published over the past few years relevant to the energetics of the heart.<sup>1-23</sup>

## ENERGETICS OF THE NORMAL HEART

The normal mammalian cardiomyocyte maintains the average cytosolic [ATP] at a constant level of approximately 10 mM, enough ATP to support only a few beats. To supply enough ATP to meet beat-to-beat variations in ATP demand, the terminal phosphoryl group of ATP turns over as much as 10,000 times a day. Thus the rates of ATP synthesis and use in the heart are extraordinarily large. Energy metabolism is designed so that the rate of ATP synthesis via rephosphorylation of ADP closely matches the varying rate of ATP use by myosin, ion pumps, synthesis, and degradation of large and small molecules, etc. (Figure 7-1). The primary driver is ATP demand, and the myosin ATPase reaction is the main ATP consumer. The primary source of ATP resynthesis from ADP is via fatty acid oxidation (FAO) in the mitochondria; the contribution from glycolysis is quantitatively small. In addition to glucose and FA, other metabolites can be used for ATP synthesis as well, including glycogen, lactate, and certain amino acids. Phosphoryl transfer between sites of ATP production and use occurs by means of metabolic relays via creatine kinase (CK), adenylate kinase (AK), and glycolysis.

The relative contribution of the different metabolic pathways to overall ATP synthesis constantly changes even in the normal myocardium. The different pathways for ATP supply have different rates of ATP synthesis: phosphoryl transfer via CK is approximately 10- times faster than ATP synthesis in mitochondria, which is approximately 20- times faster than glycolysis. By summing reactions with varying rates of ATP synthesis, [ATP] is maintained high and constant on a beat-to-beat basis. Fluxes through existing pathways for ATP synthesis change rapidly in response to changes in fuel supply, hormonal and neural signals, and

the availability of substrates and inhibitors of specific enzyme reactions, and also by chemical modification of regulating proteins. Thus during acute increases in work in the normal myocardium, the *sum* of increased rates of ATP synthesis by the mitochondria, by glycolysis and glycogenolysis, and by the phosphotransferase reactions matches the increase in the total rate of ATP use. The increases in glycolysis and phosphotransferase rates are not due to a limitation in either O<sub>2</sub> supply or due to inadequate capacity of the mitochondria to support substrate oxidation. Rather, these biochemical pathways are designed to rapidly mobilize substrates such as glycogen to influx more glucose, to use phosphocreatine (PCr) to support acute demands for high ATP, and to salvage ADP via CK and AK to replenish ATP. Metabolism is designed so that during increased demand for ATP, inhibition of glycolysis by metabolic sensors coupling high FA use with low glucose use is partially relieved.

ATP synthesis pathways not only function to supply large amounts of ATP needed for beat-to-beat variations in cardiac work, but they also function to maintain a high ratio of [ATP] to the products of ATP hydrolysis [ADP] and [Pi] on the same time scale. The ratio, [ATP]/[ADP][Pi], known as the phosphorylation potential, determines the free energy available from ATP hydrolysis,  $|\Delta G_{-ATP}|$  that is used to drive ATP-requiring reactions. Without the energy supplied from the hydrolysis of ATP, myosin heads would not move, ions could not move against their concentration gradients, and most biological reactions simply would not proceed. ATP hydrolysis provides the chemical driving force for the unfavorable reactions required for excitation, contraction, and the basic workings of the myocyte. Maintaining a high chemical driving force to support the ATPase reactions during variations in work output is so important that the heart has several energy reserve systems, namely, CK and AK, that function to minimize large fluctuations in the chemical driving force.

## ATP Synthesis in Mitochondria

The heart derives as much as 90% of its energy from the oxidation of carbon-based fuels in the mitochondria. The capacity for oxidative phosphorylation (OXPHOS) in the heart is very large; the fraction of the

**FIGURE 7-1** Cartoon summarizing the integration of the ATP synthesizing and using pathways.<sup>117</sup> The primary ATP using reactions (shown on the right) are actomyosin ATPase in the myofibril, the  $\text{Ca}^{2+}$ -ATPase in the sarcoplasmic reticulum and the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase in the sarcolemma. Also shown is a polypeptide chain representing the requirement of ATP for macromolecular synthesis (in the form of GTP for protein synthesis). The primary ATP synthesizing pathways (left) are oxidative phosphorylation in the mitochondria and the glycolytic pathway. Also shown (bottom) is the creatine kinase (CK) reaction, representing the kinases that supply ATP via rapid phosphoryl transfer. (Redrawn with permission from Ingwall JS. (2002). *ATP and the heart*. Boston: Kluwer Academic, Norwell, MA.)<sup>28</sup>

adult mammalian cardiomyocyte occupied by mitochondria is approximately 0.35. High capacity and high turnover rates are illustrated in experiments simultaneously measuring indices of work and  $\text{O}_2$  consumed ( $\text{MVO}_2$ ). For example, in a small animal heart, the relationship between work and  $\text{MVO}_2$  is linear over a fivefold range.<sup>24</sup> [ATP] remained constant, showing that ATP synthesis rates by  $\text{O}_2$ -dependent reactions matched ATP use rates.

Figure 7-2 shows the major steps for oxidizing FA and pyruvate (made by glycolysis) in the mitochondria (see Chapter 20). OXPHOS is the process whereby ATP is formed as electrons are transferred from NADH or  $\text{FADH}_2$  made in the tricarboxylic acid (TCA) cycle to molecular  $\text{O}_2$  by a series of electron carriers. This is why  $\text{MVO}_2$  is a good measure of the ATP synthesis rate. The amount of ATP produced from FAO is much greater than the yield from oxidation of glucose because FAs supply many acetyl-CoA molecules (1 acetyl-CoA for each 2-carbon unit in the FA chain) while the same number of glucose molecules yields only two acetyl-CoA molecules. Although the efficiency of ATP production from the oxidation per mole of  $\text{O}_2$  reduced is slightly greater for glucose (P:O ~3.05 for glucose vs. <2.9 for fatty acids), on a molar basis, the amount of ATP produced from FAO is many-fold higher than for glucose oxidation. For example, for the equivalent number of moles, 129 ATPs are made from oxidation of palmitate versus 38 ATPs from oxidation of glucose. FAs are the predominant fuel for energy production in adult hearts whereas glucose and lactate are the major carbon sources for fetal and neonatal hearts and when  $\text{O}_2$  is limiting as in the ischemic myocardium.

Mitochondrial respiration is controlled by availability of ADP, Pi, NADH,  $\text{H}^+$ ,  $\text{Ca}^{2+}$ , and  $\text{O}_2$ . Relatively new information supporting the role of  $\text{Ca}^{2+}$  in regulating rates of respiration suggests that  $\text{Ca}^{2+}$  is the most likely candidate for rapid control of respiration.<sup>14</sup> Which metabolite or signaling ion is the

primary regulator supplying ATP to meet demand at any given time is likely to depend on the workload on the heart, the type and amount of carbon-based fuels available, and the extent of any molecular reprogramming that may have occurred. The existence of multiple regulators minimizes fluctuations in [ATP] and maintains a high phosphorylation potential in the cytosol. The importance of efficiently coupling ATP synthesis and use reactions by the same metabolic and ionic regulators for normal contraction cannot be overemphasized.

### ATP Synthesis by Glycolysis

In the normal heart, the amount of ATP produced via glycolysis is a small fraction of the amount made as a result of the oxidation of glucose: 2 versus 38 ATPs. Nonetheless, glucose and glycogen are important sources of ATP during rapid transitions to increased work or in other acute ATP supply/demand mismatches. Figure 7-3 shows the major steps in glucose metabolism.

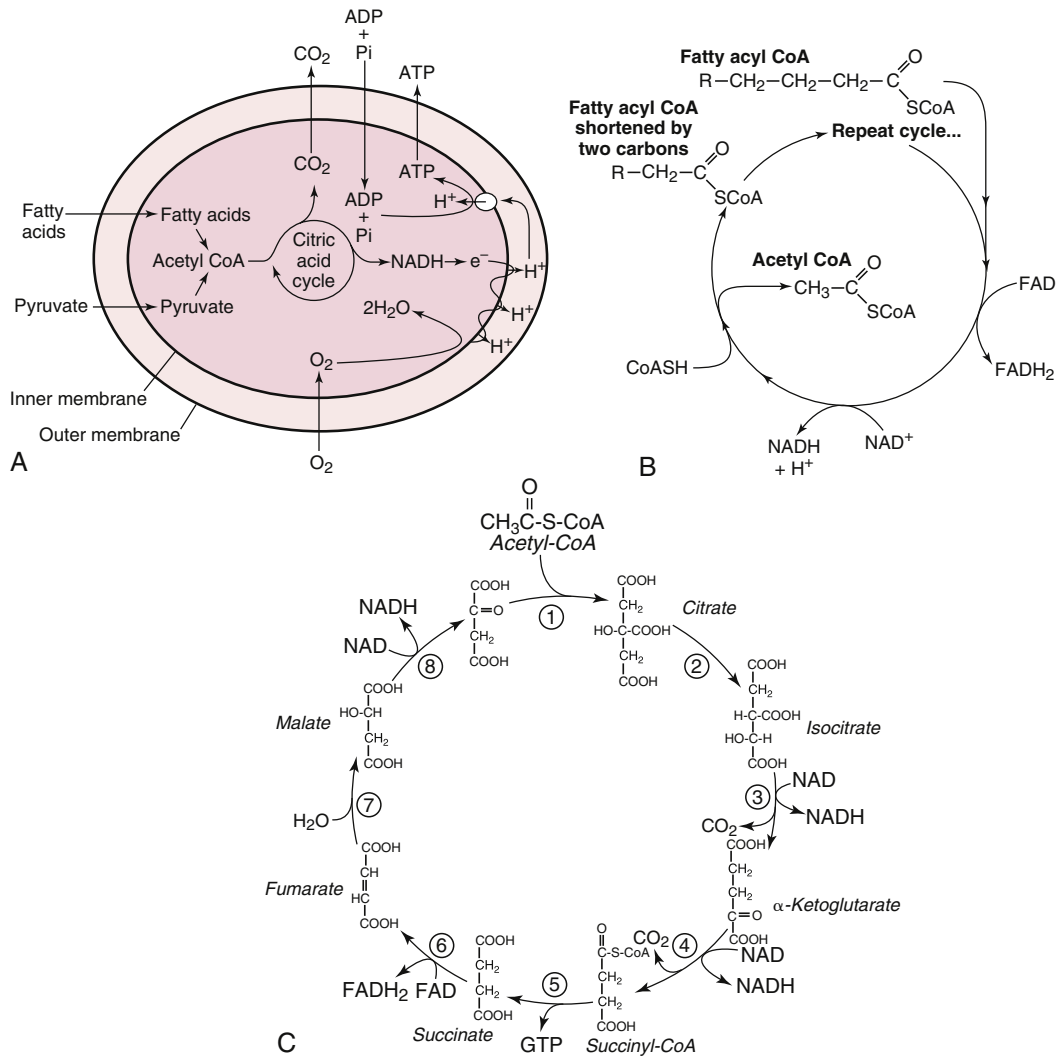

### ATP Synthesis by Phosphotransfer Reactions

The primary phosphoryl transferase reactions in muscle are catalyzed by CK and AK. Both enzymes are highly abundant in muscle cells and exist as families of isozymes that change in development and in disease states. The physical association of CK and AK with energy-producing and energy-using proteins provides the basis for the energy-transfer or relay properties attributed to these enzymes. These physical complexes also create microenvironments whereby phosphoryl groups can be supplied to ATPases without exchange with bulk cytosolic pools, improving the efficiency of ATP supply.<sup>3,9,25</sup>

Under conditions when ATP demand exceeds ATP supply, as in acute pump failure in ischemia and in acute and chronic conditions of high wall stress, use of PCr via the CK reaction ( $\text{PCr} + \text{ADP} + \text{H}^+ \rightarrow \text{Cr} + \text{ATP}$ ) is one way that the heart maintains high [ATP] and low [ADP]. Thus the CK reaction has two main functions: to supply ATP rapidly (~10 times faster than ATP resynthesis by mitochondria) and to maximize the chemical driving force for ATPase reactions. Most (but not all) reports of high work states in both cardiac and skeletal muscles of large and small animals report decreases in [PCr] and concomitant increases in [ADP] and [Pi].<sup>24,26,27</sup> AK also functions to maintain high levels of ATP by transferring phosphoryl groups among the adenine nucleotides:  $2\text{ADP} \leftrightarrow \text{ATP} + \text{AMP}$ . To know whether ATP-requiring reactions may be limited because of an insufficient chemical driving force, we need to know [ADP] and [Pi] along with [ATP]. The cytosolic concentrations of [ATP], [ADP], and [Pi] in normal ventricular tissue are approximately 10 mM, less than 50  $\mu\text{M}$ , and less than 1 mM, respectively. Figure 7-4 illustrates the coupling of the CK reaction to myosin ATPase to supply ATP and, using metabolite concentrations calculated from  $^{31}\text{P}$  NMR spectroscopy experiments, shows how variations in [ATP], [ADP], and [Pi] caused by acute inotropic challenge change the value of  $\Delta G_{\text{-ATP}}$ . In this example, the value of  $\Delta G_{\text{-ATP}}$  changed by approximately 4 kJ/mol. This is a large fraction, 4/7, of the range of  $\Delta G_{\text{-ATP}}$  observed for the well-oxygenated beating heart: -54 to -61 kJ/mol. See Ingwall<sup>28</sup> for more discussion.

### ATP AND THE FAILING HEART

The ability of the metabolic machinery to use a variety of fuels for ATP synthesis ensures that ATP supply matches ATP demand and that the chemical driving force for ATP-requiring reactions remains high on a beat-to-beat basis. We now know that the integration of ATP synthesizing and using reactions changes in the hypertrophied and failing myocardium. The cellular machinery designed to make and use ATP remodels

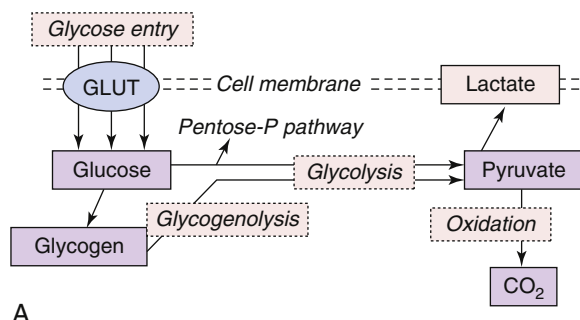

**FIGURE 7-2** **A**, Overall strategy for making ATP in mitochondria. **B**, Processing of fatty acids via  $\beta$ -oxidation to form acetyl-CoA; **C**, TCA cycle using acetyl-CoA to make molecules needed in the electron transport chain.

There are six basic steps in the pathway whereby fuels are converted into molecules that efficiently couple ATP synthesis to the reduction of O<sub>2</sub>. Known changes in the failing myocardium are in *italics*.

1. The first step is to **transport** fatty acids (FA) of different lengths or pyruvate into the mitochondrial matrix (**A**). *Long-chain FA carrier carnitine palmitoyl transferase-1 is decreased.*
2. Once in the matrix, these substrates are **converted into acetyl-CoA** to fuel the citric acid cycle. Pyruvate is converted to acetyl-CoA by pyruvate dehydrogenase; fatty acids are converted to acetyl-CoA by  $\beta$ -oxidation (**B**). *A smaller fraction of PDH exists in the active form.*
3. **The citric acid (TCA) cycle:** Each acetyl-CoA that enters the citric acid cycle yields 1 GTP, 1 FADH<sub>2</sub>, and 3 NADH; each GTP, FADH<sub>2</sub>, and 3 NADH ultimately yields 1, 2, or 3 ATPs, respectively. TCA cycle flux matches work output of the heart. *Citrate synthase activity is close to normal, suggesting that flux, not amount, is lower in the failing heart.*
4. FADH<sub>2</sub> and NADH are used in the electron transport chain. NADH and FADH<sub>2</sub> are the obligatory intermediary molecules that transfer electrons to O<sub>2</sub>. The transfer of electrons is energetically driven by the dissipation of a proton gradient across the inner mitochondrial membrane. *The number of mitochondrial-encoded and nuclear-encoded gene transcripts for respiratory chain proteins decrease.*
5. The flow of electrons provides the energy needed to phosphorylate ADP to form ATP via the **F<sub>1</sub>F<sub>0</sub>-ATPase**. *Both activity and mRNA levels decrease.*
6. Mitochondrial ATP is then exchanged for cytosolic ADP via the **adenine nucleotide transporter (ANT)**. *ANT1 isozyme falls in failing hearts. Pattern of ANT isozyme shifts is cardiomyopathy-specific. (Redrawn with permission from Ingwall JS. (2002). ATP and the heart. Boston: Kluwer Academic, Norwell, MA.)<sup>28</sup>*

(Figure 7-5). The remodeling is not random, but is controlled by energy sensors that produce changes in phosphorylation state (and many other chemical modifications) of many proteins leading to short-term preservation of ATP and by activation of transcription factors that coordinately control long-term remodeling of ATP synthesis and using pathways. There is consensus that in compensated hypertrophy, in addition to a long-recognized decreased capacity for phosphotransferase reactions,<sup>29-31</sup> glucose use increases while FAO either remains the same<sup>32,33</sup> or decreases.<sup>34</sup> In uncompensated hypertrophy, FAO is decreased; the increases in glucose uptake and use are not sufficient to compensate for overall decreases in ATP supply.<sup>17,35,36</sup>

Here we begin by describing the change in [ATP] and, the proximal mechanisms for the loss of [ATP] and then describe how and why the ATP synthesis pathways change in the failing heart. We will then do the same for Cr. For both ATP and Cr, we will discuss the physiological consequences of these changes and attempts to manipulate metabolism to rescue the failing myocardium. We conclude with a brief comment on clinical implications and future directions for research in this emerging area. Space does not allow discussion of either the energetics of the ATP-using reactions in the failing heart or the energetics of the diabetic heart; some of this was presented in the first edition of this monograph.

A

B

**FIGURE 7-3** A, Overall pathway for glycolysis. B, Details of glycolytic pathway.

The overall strategy of glycolysis is:

Step 1: transport glucose into the cell. *Increase in LVH/failure.*

Step 2: add phosphoryl groups to glucose.

Step 3: convert phosphorylated metabolites to compounds with high phosphoryl-transfer capacity.

Step 4: couple the metabolism of these compounds to the formation of ATP. *Increase in LVH/failure.*

The overall reaction of the breakdown of glucose to pyruvate is:

$\text{glucose} + 2 \text{ NAD}^+ + 2 \text{ Pi} + 2 \text{ ADP} \rightarrow 2 \text{ pyruvate} + 2 \text{ NADH} + 2 \text{ H}^+ + 2 \text{ ATP} + 2 \text{ H}_2\text{O}$ . Two ATPs are made via glycolysis for every glucose transported into the cell that directly enters glycolysis. If the glucose is transiently stored as glycogen, the yield is 3 ATPs. If the pyruvate made from glucose enters the mitochondrion and is oxidized, the total yield is 38 ATPs per mole glucose. (Redrawn with permission from Ingwall JS. (2002). *ATP and the heart*. Boston: Kluwer Academic, Norwell, MA.)<sup>28</sup>

## ATP Progressively Falls in the Failing Heart

In the severely failing human myocardium and in hearts of animal models of severe failure, [ATP] is approximately 30% lower than in normal myocardium (Table 7-1). Importantly the fall in [ATP] occurs in both left and right ventricular myocardium, in widely different species, and due to a variety of causes. Emphasizing the universality of this endpoint for the severely failing myocardium caused by widely different demands for ATP, a fall in [ATP] has even been shown in hearts of birds selected for ultrarapid growth. The energy requirements for exceptionally rapid macromolecular synthesis needed to support ultrarapid growth led to heart failure and a fall in myocardial [ATP].<sup>37</sup>

The rate of ATP loss is progressive.<sup>38</sup> In a longitudinal study of heart failure using the pacing-induced canine heart failure model, the rate of fall was approximately 0.12 nmol/mg protein per day or 0.35% of the total ATP pool per day. Thus making a quantitatively reliable measurement for the fall in ATP is possible only in severe failure, explaining the apparently conflicting results in the literature on this point.

## The Proximal Mechanism

The proximal mechanism explaining the loss of ATP is the loss of the adenine nucleotide pool. The primary pathway for ATP degradation is  $\text{ATP} \rightarrow \text{ADP} \rightarrow \text{AMP} \rightarrow \text{adenosine} \rightarrow \text{inosine} \rightarrow \text{hypoxanthine}$ . Phosphorylated metabolites do not readily

cross the cell wall, but nucleosides and bases readily diffuse to the extracellular space down their concentration gradients. Nucleosides and bases do not accumulate in the hypertrophied or failing myocardium (blood flow is not limiting), and the fall in the sum of [ATP+ADP+AMP] parallels the fall in [ATP].<sup>38</sup> Activation of cytosolic AMP-dependent 5'-nucleotidase (5'-NT), which converts [AMP] to adenosine, is sufficient to explain the decrease in the [ATP] in the failing heart. In the normal myocardium, the small loss of purine that constantly occurs is matched by *de novo* purine synthesis from glycine, glutamine, aspartate, and formate at a rate of approximately 1.5 nM/sec.<sup>39</sup> To put this into perspective, *de novo* purine synthesis is approximately 10<sup>6</sup> times slower than ATP synthesis from OXPHOS. Experiments determining whether the rate of *de novo* purine synthesis changes in the failing myocardium remain to be made.

It is not known what prevents [ATP] and the total adenine nucleotide pool (TAN) from falling to values less than approximately 70% of normal. A recent report describing a mathematical model of cardiac energetics that successfully recapitulated the quantitative fall in [ATP] and [TAN] in the failing heart suggests that this is an emergent or intrinsic property of cardiac metabolism and referred to this value as a critical tipping point beyond which the heart would be severely compromised.<sup>40</sup> This is reminiscent of the comparison of [ATP] and [TAN] in trivial, moderate, and severe ischemia in the canine myocardium showing sustained [ATP] and [TAN] for moderate ischemia (TAN ~73%

ATP utilization

ATP resupply

Sum

**FIGURE 7-4** Crash course in energetics. Coupling of the CK and ATPase reactions provide chemical driving force,  $\Delta G_{\sim\text{ATP}}$ , needed to drive the ATPase reactions. The chemical driving force changes in response to work.  $|\Delta G_{\sim\text{ATP}}|$  is calculated from the constant value for ATP hydrolysis under standard conditions,  $\Delta G^{\circ}_{\sim\text{ATP}}$ , corrected for the actual concentrations of ATP, ADP, and  $\text{P}_i$  in the cytosol. The only terms in this equation that can change are the concentrations of the reactants in the  $\ln$  term. To change  $\Delta G_{\sim\text{ATP}}$  even by 4 kJ/mol as shown here, there must be large changes in the concentrations of ATP, ADP, and/or  $\text{P}_i$ . Classical biochemical tools used to analyze extracts of even carefully freeze-clamped tissue cannot provide accurate measures of  $[\text{ADP}]$  and  $[\text{P}_i]$ . For example, estimates for  $[\text{ADP}]$  in tissue extracts are in the 1 to 2 mM range, whereas the size of the metabolically active pool of ADP is 10 to 50  $\mu\text{M}$  (i.e., about two orders of magnitude lower.  $[\text{P}_i]$  is also overestimated, by as much as tenfold. It is now possible to measure  $[\text{ATP}]$  and  $[\text{P}_i]$  and to obtain good estimates for  $[\text{ADP}]$  (using the CK equilibrium expression as shown) using  $^{31}\text{P}$  NMR spectroscopy for human hearts and hearts of animal models of heart failure.

$$\frac{[\text{ATP}]}{[\text{ATP}][\text{P}_i]} = \text{phosphorylation potential where } [\text{ADP}] = \frac{[\text{PCr}][\text{ATP}]}{K_{\text{eq}}[\text{H}^+][\text{Cr}_f]}$$

$$\Delta G_{\sim\text{ATP}} = \Delta G^{\circ}_{\sim\text{ATP}} - \frac{Rt}{\ln} \frac{[\text{ATP}]}{[\text{ADP}][\text{P}_i]}$$

**FIGURE 7-5** Summary of the major changes in metabolic regulation in the failing heart. The normal heart (*left*) uses primarily fatty acids for adenosine triphosphate (ATP) synthesis and, by the integration of ATP-synthesis and ATP-use pathways, maintains  $[\text{ATP}]$  and phosphocreatine ( $[\text{PCr}]$ ) concentrations at approximately 10 and 20 mM, respectively. In the severely failing heart (*right*), fatty oxidation decreases while glucose use (and probably lactate as well) increases. The capacity of the phosphotransferase reaction catalyzed by creatine kinase decreases. The net result is lower  $[\text{ATP}]$  and  $[\text{PCr}]$ . ADP, adenosine diphosphate; Cr, creatine;  $\text{P}_i$ , inorganic phosphate.

of normal at 30 minutes and 59% at 5 hours) but not severe ischemia (TAN ~66% of normal at 30 minutes falling to 14% at 5 hours).<sup>41</sup> The similarity in the tipping points for both severe ischemia and severe heart supports the notion that this is an emergent or intrinsic property of cardiac metabolism.

## The Long-Term Mechanisms

Metabolism remodels in hypertrophied and failing myocardium: the mix of oxidizable substrates transported across the sarcolemma changes, proteins are modified leading to their short-term (in)activation, and new mRNA transcripts made in response to activation of certain transcription factors are translated. Identifying the mechanisms underlying the coordinate control of proteins comprising entire metabolic pathways in normal and failing myocardium is a major focus of research in this field today. Importantly, individual proteins that exist as families of isozymes are also subject to remodeling. Some of these *isozyme switches* (which are rarely if ever complete) make major contributions to the new phenotype. For example, the change in lactate dehydrogenase isozymes in the hypertrophied myocardium makes the heart more likely to metabolize lactate.<sup>42</sup> The decreases in MM-CK and sarcomeric mitochondrial CK (sMtCK) isozymes decrease phosphoryl transfer at specific sites where CK isozymes colocalize with ATP-using and ATP-synthesizing reactions.<sup>3,43</sup> The species-specific “switch” in myosin heavy chain (MyHC) isozymes alters the intrinsic myosin ATPase activity, which determines the maximal force and speed of contraction of the heart.<sup>44</sup> Changes in titin isozymes contribute to the greater stiffness of the failing heart.<sup>45</sup>

## Changes in Glucose Uptake and Use

There appears to be universal agreement studying animal models and patients with cardiac hypertrophy and failure that glucose uptake rate and glycolysis increase (see chapter 20).<sup>46-52</sup> Increased glucose supply and use in the setting of chronic ATP demand is important because increased glycolysis could at least partially compensate for decreased ATP synthesis by other pathways. As several experimental studies of compensated hypertrophy have observed increased glycolysis with no change in FA use,<sup>32,53</sup> it seems likely that decreased FAO occurs later in the evolution of uncompensated hypertrophy (see later discussion).

The increase in glucose uptake is explained by increased expression of the basal insulin-independent glucose transporter GLUT1; expression of the dominant insulin-regulated glucose transporter GLUT4 is decreased or remains the same.

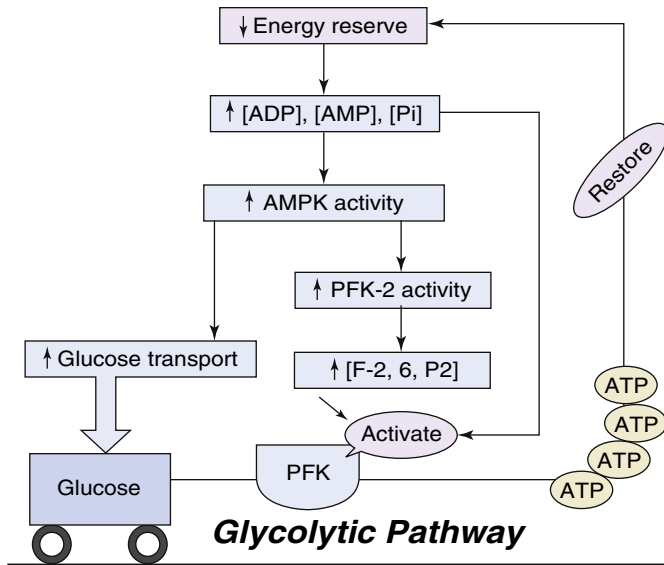

One mechanism explaining increased glucose uptake and use in the hypertrophied myocardium is triggered, at least in part, by the demand for more ATP (Figure 7-6). In chronic pressure-overload hypertrophy in the rat, decreases in [PCr] without a concomitant fall in total [Cr] lead to increases in [ADP], [AMP], and [Pi]. The increase in [AMP] activates the “low-on-fuel” sensor AMP-activated protein kinase (AMPK).<sup>46,54</sup> The consequences of activating AMPK are to activate proteins in ATP-synthesis pathways (increasing ATP) and to decrease the activity of proteins in ATP-consuming pathways (conserving ATP). Key among these are GLUT1 and phosphofructokinase-2 (PFK-2), leading to production of fructose-2,6-Pi<sub>2</sub>, a potent allosteric activator of the rate-limiting protein for glycolysis, PFK (see Figures 7-4 and 7-6). In this model of compensated cardiac hypertrophy, both cytosolic [AMP] and fructose-2,6-Pi<sub>2</sub> increased by approximately tenfold, sufficient to explain the approximately threefold increase in the rate of glucose uptake, and approximately twofold increase in the rate of glycolysis for the same amount of O<sub>2</sub> consumed.<sup>48</sup> These results suggest that increased ATP demand (manifest as decreased PCr) in the hypertrophied heart signals an increase in glycolytic flux by several coordinate mechanisms: increasing glucose transport (thereby increasing substrate supply) and activating PFK (thereby increasing use) both via AMPK-dependent processes and via classic substrate control.

Unless AMPK can be activated by AMP-independent mechanisms,<sup>46</sup> however, it seems unlikely that AMPK remains activated in the failing myocardium for two reasons. First, cytosolic [AMP] decreases in severely failing myocardium (see Table 7-1). Second, activating AMPK is known to stimulate translocation of FA transporters to the sarcolemma and promote FA use for ATP synthesis; however, FA uptake and oxidation have been shown to be decreased, not increased, in a variety of experimental models of failing myocardium and in heart failure patients (see later discussion). It seems likely that an AMPK-dependent mechanism could function only as long as there is increased [AMP].

Long-term regulation of glycolysis in hypertrophied and failing myocardium is under transcriptional control (see later discussion).

### Decreased Metabolic Reserve via Glycolysis

Unlike for control hearts, glucose uptake and glycolytic rates measured in the hypertrophied myocardium of animal models do not increase substantially further during work challenge<sup>47,50</sup> (but see later discussion for an analysis of contributions to oxidative metabolism).<sup>36</sup> Importantly, the limitation in metabolic reserve for glycolysis has also been observed in a group of Class I/II patients with dilated cardiomyopathy (DCM).<sup>49</sup> The approximately twofold increase in glucose uptake observed for DCM myocardium at baseline did not increase further when the heart rate increased, whereas it doubled in normal subjects. In terms of absolute values, glucose uptake was as high at baseline for DCM

**FIGURE 7-6** In chronic pressure-overload cardiac hypertrophy in the rat, increased ATP demand (signaled as decreased PCr) leads to an increase in glycolytic flux by two coordinate mechanisms: increasing glucose transport (increasing substrate supply) and activating PFK in the glycolytic pathway (increasing use), both mediated by AMPK. See text for more explanation. (Reprinted with permission from Nascimben, L., Ingwall, J., Lorell, B., et al. (2004) Mechanism for increased glycolysis in the hypertrophied rat heart. *Hypertension*. 44, 662-667.)<sup>48</sup>

myocardium as it was for normal myocardium with pacing, suggesting that there is an upper limit for glucose uptake in the DCM myocardium. FA uptake and oxidation, lower in DCM hearts, remained low. The authors described the inability of the DCM myocardium to meet increased ATP demand by increasing glucose uptake as “metabolic rigidity.” These results are important because they support that hypothesis that any increase in glycolysis in developing and compensated hypertrophy (presumably adaptive) is not sufficient to meet the ATP demand in uncompensated hypertrophy. In this scenario, ATP use would exceed supply, contributing the inexorable loss of ATP in the failing heart.

#### Rescuing the failing heart by manipulating glucose metabolism

Genetic strategies testing whether the glycolytic reserve of the hypertrophied heart is sufficient to support increased contractile demand and if it can be manipulated to improve survival rates merit highlighting here.

One example used mouse hearts deficient (see Chapter 50) in the transcriptional activator peroxisome proliferator activated receptor  $\alpha$  (PPAR $\alpha$ ), which have a threefold decrease in FAO and threefold increase in carbohydrate use, properties characteristic of the failing heart.<sup>55</sup> Isolated perfused PPAR $\alpha$  null mouse hearts are able to sustain baseline function, but not high workloads. PPAR $\alpha$  null mouse hearts had higher than normal MVO<sub>2</sub>, yet produced less ATP, and [ATP] fell with inotropic challenge. Importantly, increasing glucose uptake and use further by crossing the PPAR $\alpha$  null mouse with a transgenic mouse with cardiac-specific overexpression of GLUT1 rescued the PPAR $\alpha$  phenotype. Hearts with augmented glucose uptake via GLUT1 were able to sustain increased work without losing [ATP], and MVO<sub>2</sub> and ATP synthesis rates returned to near normal. Another experiment found that increasing glucose availability in this way rendered hypertrophied hearts more tolerant to chronic hemodynamic overload and improved survival.<sup>56</sup> These genetic studies suggest that increasing ATP synthesis in the failing heart, in this case by substantially increasing glucose availability, can alter the natural history of heart failure. Achieving this in the failing human heart remains to be accomplished.

## Changes in Mitochondrial ATP Synthesis

Genomic and proteomic studies,<sup>57</sup> and measures of specific enzyme activities, have shown that many proteins involved in FA transport and use are downregulated in failing hearts, contributing to the overall decrease in mitochondrial ATP synthesis rate.

### Decreased Oxidative Capacity

Based on NMR experiments measuring desaturation of myoglobin in large animal hearts as an index of O<sub>2</sub> supply relative to O<sub>2</sub> use, it was shown that O<sub>2</sub> is not limiting in the failing heart.<sup>58</sup> The failing myocardium is not ischemic.<sup>27</sup>

Although O<sub>2</sub> is not limiting and does not prevent increases in cardiac performance in response to inotropic stimulation, it is likely that the failing myocardium operates near its maximum in oxidative capacity. In a study comparing compensated hypertrophy and failure caused by pressure overload in swine,<sup>27</sup> both hypertrophied and failing myocardium increased MVO<sub>2</sub> with catecholamine stimulation. PCr/ATP fell in the normal and hypertrophied myocardium but did not fall further in the failing hearts. However, when mitochondria were chemically uncoupled during inotropic stimulation to provide a measure of maximal oxidative capacity, the failing but not the compensated hypertrophied hearts were found to be functioning at their limit. Experiments using isolated mitochondria, skinned fibers, and isolated hearts<sup>59,60</sup> all support the conclusions that oxidative capacity of mitochondria is reduced in the failing myocardium and that mitochondria in a failing heart are at least partially uncoupled, leading to decreased cardiac efficiency.<sup>38</sup> Increased uncoupling proteins (UCPs)<sup>59</sup> and increases in reactive O<sub>2</sub> species and NO likely contribute.<sup>20,60,61</sup>

### Changes in Substrate Selection for Oxidation Characteristic of the Heart Failure Phenotype Can Be Manipulated

Consistent with animal studies, patients with DCM have lower FA uptake (see Chapter 20).<sup>49</sup> Transplanted hearts from heart failure patients due to a variety of causes have lower total carnitine and total CPT (carnitine palmitoyltransferase) activities required for transport of long chain FA across the inner mitochondrial membrane for subsequent oxidation.<sup>62</sup> Analogous to increasing glucose supply to promote ATP synthesis, one approach to overcoming decreases in FA uptake is to increase FA supply. It has long been thought that supplying FA to hearts leads to lipotoxic effects, making this an unlikely strategy for rescuing the failing heart. This has recently been revisited, however, using a regimen that did not produce dysfunction on the heart.<sup>63</sup>

The kind of FA being oxidized is important.<sup>46</sup> Rates of FAO, glucose oxidation and glycolysis were compared in hypertrophied rat hearts supplied with either medium chain FA (octanoate) plus long chain FA (palmitate) or only longchain FA. With the mixture, FAO increased and, glycolysis fell to normal rates while glucose oxidation was unaltered in the hypertrophied hearts. Importantly, decreased cardiac performance of the hypertrophied heart revealed that perfusion with only long chain FA was normalized with the supply of both medium and long chain FAs. These results suggest differences in the capacity to use different classes of FAs in the hypertrophied myocardium.

<sup>13</sup>C NMR spectroscopy studies of the aortic banded rat model of early heart failure have been used to define the relative contributions of endogenous triacylglycerides, exogenous FAs, glucose, and glycogen to mitochondrial ATP synthesis at baseline and when challenged to increase work.<sup>36</sup> At baseline levels of work, the relative contributions from glycogen, glucose, and palmitate to mitochondrial ATP production were essentially the same ( $\pm 10\%$ ) as for sham hearts; the reason for this unexpected result was an absence of any contribution from endogenous triacylglycerides in the failing heart.

At high work for the failing heart, the contribution from glycogen and glucose increased by approximately 30% while that from palmitate decreased only slightly. Despite the increase in oxidation of glucose and glycogen, FAO was still the dominant source for ATP synthesis (60% for failing vs. 70% for sham hearts).

TCA cycle flux is closely matched to the amount of O<sub>2</sub> consumed to make ATP (see Figure 7-2), and thus plays a key role in setting the efficiency of the heart. A recent report<sup>34</sup> has shown that, at least in the hypertrophied myocardium, an unexpected mechanism contributes to maintaining a high TCA cycle flux needed to meet ATP demand. In response to pressure overload hypertrophy in the rat, PCr/ATP fell by 30% as expected, glycolysis was increased without an apparent increase in glucose oxidation, carnitine palmitoyltransferase (CPT-1) activity and FAO were reduced, yet MVO<sub>2</sub> and rate-pressure product were about the same. How were normal TCA cycle flux and MVO<sub>2</sub> sustained? The normal fate of pyruvate made by glycolysis in the cytosol is to be converted to acetyl-CoA for use by the TCA cycle by the pyruvate dehydrogenase complex (see Figure 7-3, A). That did not happen here. Instead, TCA cycle flux was sustained by use of glycolytically derived pyruvate through anaplerosis, a pathway that uses pyruvate to supply oxaloacetate downstream from acetyl-CoA in the TCA cycle (at 11 o'clock in Figure 7-4, C). The increase in anaplerosis is due to increased cytosolic malic enzyme in the hypertrophied myocardium, thereby increasing substrate competition for pyruvate between malic enzyme and PDH in favor of malic enzyme.<sup>64</sup> Activating PDH pharmacologically led to a decrease in malate, decreasing anaplerosis; importantly, triacylglyceride levels were restored and cardiac dysfunction was partially restored (improved dP/dt).<sup>64</sup>

There are at least three important implications of these observations. The first is that the apparent mismatch between glycolytic rate and glucose oxidation in hypertrophied myocardium is only apparent: pyruvate was used, just not to produce acetyl-CoA. Second, because conversion of pyruvate to oxaloacetate via anaplerosis consumes an ATP, this is a less efficient use of pyruvate. The increased in energy cost is unlikely to be sustainable; what appeared to be adaptive (maintaining TCA cycle flux via increased anaplerosis) is more likely maladaptive. This could be one step in the transition from compensatory hypertrophy to failure. Third, taken together, the results presented in this section show that the substrate supply for mitochondrial ATP production in the remodeled hypertrophied/early failing myocardium can be manipulated and that this can improve contractile performance.

## Transcriptional Control of ATP Metabolism

The past decade has witnessed an explosion of information identifying the molecular links between physiological and metabolic stimuli and the regulation of gene expression in the heart. Not only have the metabolic targets of specific nuclear receptors and DNA-binding transcriptional activators been identified, but we are also beginning to learn how their signals are amplified and sustained (see Chapter 20).

Transcription is activated when transcriptional activators including PPARs, estrogen receptors (ERRs), retinoid receptors (RXRs), nuclear respiratory factors (NRFs), and MEF2 complex with proteins called PPAR $\gamma$  co-activators, PGC-1 $\alpha$  and  $\beta$ , tethering it to DNA (Figure 7-7). When complexed with transcriptional activators, PGC-1s activate genes encoding proteins comprising entire metabolic pathways that control both ATP synthesis in mitochondria, phosphoryl transfer, and glucose uptake, and also ATP use. The different families of transcriptional factors bound to PGC-1 confer specificity for targets, although substantial overlap exists. PGC-1s in turn are regulated. Of particular interest here are Cdk 9 and 7, cyclin-dependent kinases that function to phosphorylate RNA polymerase II so that

**FIGURE 7-7** Schema showing transcriptional activators and coactivators important for long-term molecular remodeling of glycolysis and fatty acid metabolism in the hypertrophied and failing myocardium. Normal growth, cold and fasting all activate PGC-1 $\alpha$ ; but PGC-1 $\alpha$  is lower in the failing heart, leading to impaired mitochondrial ATP synthesis. (Redrawn from Ingwall JS. Energetics of the failing heart: new insights using genetic modification in the mouse. 2006; *Arch des Maladies du Cœur et des Vaisseaux* 99(9):839-847.)

transcriptional elongation and mRNA capping can occur. Cdks had been thought to function to support all transcription, but recent work suggests that Cdk 7 and 9 may well target PGC-1s, thereby conferring specificity for the transcriptional control of ATP synthesizing and using reactions. Other known regulators of PGC-1s in striated muscle include p38 MAPK, calcineurin A/CaMKII, possibly AMPK,<sup>65</sup> and the circulating factors endothelin-1 and aldosterone.<sup>66</sup> The number of players in this complex hierarchical network (see Figure 7-7) increases yearly.

Important for the topic of this chapter, when measured, the failing heart has lower levels of transcriptional and co-activator factors<sup>22,67,68</sup> and higher levels of Cdk7 and 9.<sup>69,70</sup> Using loss-of-function and gain-of-function approaches in engineered mice, information has been obtained about the role of these factors in cardiac development and heart failure. A few examples will be given here.

PPARs exist as a family of FA-activated nuclear receptors abundant in the heart. PPAR $\alpha$  is known to decrease in heart failure, and, as we have seen, loss-of-function in the bioengineered mouse heart recapitulates the heart failure phenotype of decreased FAO and increased glucose use. Gain-of-function studies using mouse hearts with PPAR $\alpha$ , PPAR $\beta/\delta$ , or PPAR $\gamma$  overexpression suggest pathway-specific regulation of each PPAR for glucose and FA use.<sup>71,72</sup> Overexpressing PPAR $\alpha$  led to decreased glucose uptake and use rates, increased FAO rates (as expected, the opposite of the heart failure metabolic phenotype) and increased triacylglyceride accumulation, leading to cardiomyopathy. Overexpressing PPAR $\beta/\delta$  had a different consequence: increased glucose uptake (via GLUT4) and use rates with no lipid accumulation and no cardiomyopathy. Overexpressing PPAR $\gamma$  led to increased FAO with no change in glucose metabolism and a dilated cardiomyopathy. While the exaggerated levels of expression of these transcriptional factors all lead to some form of cardiomyopathy that may have little to do with heart failure caused by pressure overload hypertrophy or secondary to myocardial infarction, they do help us identify how entire pathways for glucose and FA use may be regulated by PPARs: PPAR $\beta/\delta$  directs glucose metabolism while PPAR $\alpha$  and PPAR $\gamma$  directs FAO and, via classic feedback control, indirectly should reduce glucose use.

Estrogen-related receptors (ERRs) are not activated by estrogen but instead are activated by PGC-1 $\alpha$  and the closely related coactivator PGC-1 $\beta$ . ERRs may function to provide a long-term signal coupling the physiological response to hypertrophy (which can be short lived) and transcription. Using ERR $\alpha$  null mouse hearts at baseline and stressed by pressure overload hypertrophy,<sup>68</sup> it has been shown that the ERR $\alpha$ /PGC-1 $\alpha$  complex targets a set of promoters common

to genes encoding a wide spectrum of energy-producing (FA and glucose uptake,  $\beta$ -oxidation, OXPHOS, TCA cycle, electron transport chain), transferring (sMtCK and adenine nucleotide transporter), and utilizing proteins. Genes for ATP synthesis and transfer were all decreased while genes encoding the stress protein CK-B were increased. These experiments support the notion that normal ERR $\alpha$ /PGC-1 $\alpha$  complex is required to blunt the loss of capacity for ATP synthesis in pressure-overload hypertrophy.

ERR $\gamma$  and ERR $\alpha$  target a common set of promoters of genes involved in energy synthesis, transfer, and use in the adult heart.<sup>73</sup> In addition to the genes encoding proteins in ATP synthesis pathways, contractile protein isoforms and sarcoplasmic reticulum proteins were also identified as targets in ERR $\gamma$ . In separate work,<sup>74</sup> ERR $\gamma$  null mice exhibited newborn mortality, conduction abnormalities, and a complex energetic phenotype in the heart characterized by inability to fully metabolize pyruvate, disruption of the normal stoichiometry of the electron transport chain proteins, and decreased FAO. This phenotype suggests that ERR $\gamma$  plays a major role in the metabolic shift from carbohydrate metabolism to oxidative metabolism in the postnatal heart. The partial reversal to a nonoxidative phenotype in the hypertrophied and failing heart is likely under its control as well.

#### Using Transgenesis to Define the Consequences of Decreased Capacity for ATP Synthesis

Although there is no doubt that decreasing ATP synthesis rates lead to decreased contractile performance in acute settings such as hypoxia and ischemia, testing whether a chronic mismatch between ATP supply and demand as occurs in the failing heart leads to contractile dysfunction is more difficult. So many changes occur in the hypertrophied and failing myocardium that it is difficult to prove cause, but it is possible to define downstream consequences of a specific change. The use of genetically modified mouse hearts in which a single change has been made has been critical in advancing our understanding of the consequences of decreased capacity for ATP synthesis. Here we present some additional examples

where [ATP] and contractile performance have both been directly measured. Note that mice with genetically deleted transcription activators described previously all develop cardiomyopathy and/or demonstrate inability to sustain chronic hemodynamic load consistent with their importance in the molecular remodeling of ATP metabolism.

Modeling the observation that PGC-1 $\alpha$  is downregulated in a hypertrophied and failing heart,<sup>67</sup> PGC-1 $\alpha$  null mice have been used to define the consequences of reduced PGC-1 $\alpha$  on ATP synthesis and contractile reserve.<sup>75,76</sup> The absence of PGC-1 $\alpha$  not only led to reduced gene expression for proteins required for FAO and OXPHOS, but their enzyme activities were reduced. Importantly, [ATP] was decreased by approximately 20% (Figure 7-8), a surprisingly large decrease not unlike decreases observed in end-stage failing hearts caused by a variety of physiological stresses (see Table 7-1). This was also the case despite the presence of PGC-1 $\beta$ , which has many overlapping targets with PGC-1 $\alpha$ . Central to defining the consequences of reduced ATP synthesis, PGC-1 $\alpha$  null hearts had reduced contractile reserve (see Figure 7-8). Perhaps suggesting that PGC-1 $\alpha$  null hearts have greater reliance on glucose, contractile reserve (although decreased) was greater in PGC-1 $\alpha$  null hearts supplied with high concentrations of glucose and pyruvate for ATP synthesis than a mixture of substrates mimicking plasma levels of oxidizable substrates containing lower levels of glucose (see Figure 7-8). Consistent with these defects, PGC-1 $\alpha$  null mice subjected to pressure overload progress to failure more rapidly than wild-type hearts.<sup>77</sup>

Cdk9 is a cyclin-activated kinase necessary for myocyte growth. Experiments in which Cdk9 was activated in myocytes showed cell enlargement with decreased PGC-1 mRNA and protein levels that could be reversed by restoring PGC-1 levels.<sup>70</sup> mRNAs for proteins involved in  $\beta$ -oxidation of FA, TCA cycle, respiratory chain, subunits of F<sub>1</sub>F<sub>0</sub>-ATPase, and phosphoryl transfer by sMtCK were all observed targets. Activation of CDK9 promotes growth but suppresses genes for mitochondrial function by inhibiting PGC-1 promoter activity and, with mechanical stress, develop cardiomyopathy.

**FIGURE 7-8** Mimicking what is observed in heart failure, PGC-1 $\alpha$  null mouse hearts demonstrated increased contractile reserve, especially with glucose as the primary source of fuel for ATP synthesis (compare A vs. B) and decreased [ATP] similar to the failing heart. (Redrawn from Arany, Z., He, H., Lin, J., et al. (2005). Transcriptional coactivator PGC-1 $\alpha$  controls the energy state and contractile function of cardiac muscle. *Cell Metab*, 1, 259-271.)<sup>75</sup>

The Cdk7/cyclin H/MAT1 complex binds to PGC-1 where Cdk7 activates PGC-1 by phosphorylation. MAT1 null mouse hearts had lower mRNA and protein levels of PGC-1 and, as a result of reducing PGC-1 function, the ERR $\alpha$ -dependent program controlling energy metabolism was disrupted. Hearts developed mitochondrial dysfunction, impaired systolic function, and cardiomyopathy.<sup>69</sup> As these cyclins are activated in hypertrophy and end-stage heart failure, discovery of their role in regulating PGC-1s may make them major players in metabolic reprogramming of ATP synthesis and use pathways and the progression to failure.

Genetic manipulation in the mouse has identified many other players in the control of ATP production. For example, mouse hearts deficient in the mitochondrial transcription factor A (Tfam) gene develop progressive and rapid mitochondrial dysfunction and have a life span of only 10 to 12 weeks.<sup>78</sup> These hearts demonstrated an *early* shift in metabolism characterized by downregulation of genes encoding FAO proteins and, importantly, decreased activities of mitochondrial proteins. The late increase in mitochondrial mass and upregulation of genes important for glycolysis failed to compensate for these respiratory chain defects. Importantly, this metabolic remodeling took place early, suggesting cause and consequence. Lending further support to the essential role of ATP production to the failing heart, ablating muscle LIM protein in mice led to regional decreases in mitochondrial density and decreases in PGC-1 $\alpha$ .<sup>79</sup> Finally, the consequences of a decrease in energy reserve via CK on contractile performance have been studied using a variety of approaches, all of which have shown that loss of the energy reserve system leads to abnormal energetics with decreased rate of ATP synthesis via CK, increased free [ADP] (correlated with loss of sMtCK<sup>80,81</sup>), and a lower  $|\Delta G_{-ATP}|$ .

#### Rescuing the Heart by Regulating Gene Expression

In addition to using loss-of-function approaches to establish cause and effect, gain-of-function strategies are important in testing whether loss of metabolic reserve contributes to contractile dysfunction. This approach has proven to be technically difficult due to the robust nature of the promoter most widely used to overexpress genes encoding cardiac proteins in attempts to rescue the heart failure phenotype,  $\alpha$ -myosin heavy chain. A good example of this is the unintended consequences of increasing PGC-1 $\alpha$  expression in the mouse heart. Massive overexpression of PGC-1 $\alpha$  led to mitochondrial proliferation to such an extent that the sarcomeres became displaced, leading to cardiomyopathy and heart failure.<sup>82</sup> Short-term PGC-1 $\alpha$  overexpression, however, resulted in reversible contractile dysfunction,<sup>83</sup> suggesting causative links among PGC-1 $\alpha$  expression, mitochondrial biogenesis, ATP synthesis, and contractile performance.

#### Posttranscriptional Control of ATP Metabolism

Unlike the impressive progress made understanding the genomic events that control normal and hypertrophic growth and the development of cardiac dysfunction, much less is known about posttranscriptional control. We do know that the notion that there is a 1-to-1 correspondence in the number of mRNA transcripts and the number of functional proteins is not correct. A relevant example is the observation of a decrease in number of transcripts but an increase in activities of acyl-CoA dehydrogenases for rodent hearts with coronary artery ligation-induced heart failure.<sup>63</sup> Another is the mismatch among mRNA, protein amount, and activity of the CK-B and CK-M isozymes in the failing myocardium and during recovery from failure.<sup>84</sup> These examples show that protein activity is under posttranscriptional control and transcriptional control. As the relationships among the number of transcripts and enzyme activity and flux through metabolic

pathways can be and are different for every protein, care must be taken when extrapolating both genomic and proteomic results to protein function. Another caveat is that it is not obvious whether any change in protein activity is large enough to translate into altered flux through metabolic pathways. This is an important point because enzymes in most metabolic pathways have high capacity ( $V_{max}$ ); moreover, and flux is usually low compared with capacity and to overall flux through the pathway. Because of this redundancy in design, decreases of even 50% to 70% in the activity of one enzyme need not affect flux through the entire pathway.<sup>85,86</sup> The challenges for understanding metabolism in the failing heart are immense.

## CREATINE AND THE FAILING HEART

### Cr Progressively Falls in the Failing Heart

It has been known since the early 1930s that [Cr] (and therefore [PCr]) falls in hypertrophied and failing myocardium.<sup>87</sup> This observation has been rediscovered about every 20 years.<sup>88,89</sup> Most recently, <sup>31</sup>P and <sup>1</sup>H NMR spectroscopy has been used to show decreased PCr/ATP and decreased absolute levels of Cr, PCr, and ATP in hypertrophied and failing human myocardium due to a wide variety of causes, in complete accord with the large number of large and small animal studies.<sup>10,15</sup> Since [ATP] also falls in the failing myocardium, note that the fall in PCr/ATP underestimates the fall in [PCr]. The decrease in [Cr] occurs earlier, is faster, and occurs to a greater extent than the fall in [ATP].<sup>38</sup> Whereas the fall in [ATP] is not more than approximately 30%, the decrease in [Cr] can be as much as 50% to 70% in severely failing myocardium.<sup>10</sup>

### Mechanisms for Cr Uptake

In the myocardium, total [Cr] (i.e., the sum of free Cr + PCr), is 30 to 45 mM, of which 20 to 24 mM is phosphorylated by CK to PCr. [PCr]/[ATP] is approximately 2 in normal mammalian myocardium, making PCr the major high-energy phosphate compound in the heart. Cr is not made in excitable tissues, but rather is supplied to muscles and brain via the bloodstream through the action of the electrogenic transporter belonging to a superfamily of Na<sup>+</sup>, Cl<sup>-</sup>-coupled transporters of neurotransmitters, and amino acids. The Cr transporter (CrT) in the sarcolemma moves Cr against a large concentration gradient and is saturated at typical blood Cr levels. The primary sources for blood-borne Cr are dietary (meat) and from a two-step biosynthesis that occurs primarily in the kidney, liver, and pancreas. Figure 7-9 shows the steps for Cr biosynthesis and the structure of PCr. Briefly, Cr, a  $\beta$ -amino acid, is made by the transfer of glycine onto the arginine side chain catalyzed by arginine:glycine amidinotransferase (AGAT) to form guanidinoacetate. The methyl group is transferred to the guanidino group via guanidino methyltransferase (GAMT). Cr deficiency syndrome due to mutations in AGAT, GAMT, and CrT lead to severe neurological pathology and epilepsy with no apparent muscle involvement.<sup>90</sup>

Decreases in blood [Cr] cannot explain the decrease in myocardial Cr accumulation in hypertrophy and failure as skeletal muscle from heart failure animals has normal [Cr].<sup>31</sup> Instead, Cr transport and accumulation into the myocyte are well explained by the amount of CrT on the sarcolemma. While the original report<sup>91</sup> showing that the amount of CrT was decreased in the failing heart in proportion to the decrease in total [Cr] was limited by the use of a nonspecific antibody, other studies yield the same result. In a rat model of chronic heart failure, the 30% decrease in total [Cr] was well matched to the 26% decrease in the rate of Cr uptake.<sup>92</sup> Thus the recent report that human and rat myocardium expresses

**FIGURE 7-9** The primary sources for blood-borne creatine (Cr) are dietary (meat) and from a two-step biosynthesis that occurs primarily in the kidney, liver, and pancreas. Briefly, Cr, a  $\beta$ -amino acid, is made by the transfer of glycine onto the arginine side chain catalyzed by arginine:glycine amidinotransferase (AGAT) to form guanidinoacetate. The methyl group is transferred to the guanidino group via guanidino methyltransferase (GAMT). Cr accumulates in muscles and brain through the action of the Cr transporter (CrT) in the sarcolemma. Cr is trapped by phosphorylation to phosphocreatine (PCr, see structure) by creatine kinase (CK). (Redrawn with permission: lessons learned from the metabolism of ATP and creatine. *Curr Hypertens Rep* 2006;8(6):457-464.)<sup>11</sup>

AGAT and that expression is reversibly elevated in heart failure was unexpected.<sup>93</sup> Whether the heart is capable of local Cr synthesis as suggested in this report or whether AGAT is localized in the vessel wall as suggested by a developmental study<sup>94</sup> remains to be determined.

The amount of CrT on the plasma membrane is regulated in two ways. First, it is regulated by the amount of plasma [Cr], with less CrT protein on the membrane when plasma [Cr] is high and vice versa.<sup>95</sup> Second, trafficking of CrT to the plasma membrane is regulated by a cascade initiated by stress, insulin, growth factors, and mTOR. These agents activate the serum and glucocorticoid-inducible kinase, SGK1, which phosphorylates and thereby activates phosphatidylinositol-3-phosphate-5-kinase, leading to greater formation of the metabolite phosphatidylinositol-3,5-phosphate. The increase in phosphatidylinositol-3,5-phosphate increases CrT trafficking to the plasma membrane.<sup>96</sup> SGK1 is known to modify the activity and abundance of many ion channels in the plasma membrane, such as the Na,H-exchanger, and other transporters such as GLUT4. The unexplained observation that total Cr was higher in transgenic mice overexpressing GLUT4<sup>97</sup> may now be explained by recognizing that CrT and GLUT 4 trafficking to the plasma membrane are regulated in the same way. As the calcineurin inhibitor cyclosporine A also changes the fraction of CrT on the membrane,<sup>98</sup> the observation that Cr was higher in calcineurin-overexpressing hearts<sup>99</sup> is likely explained by increased CrT trafficking. These results open a new line of research on the regulation of CrT and [Cr] in the heart. Long-term regulation of CrT synthesis remains to be defined.

### Decreased Metabolic Reserve via Creatine Kinase

Because the velocity of the CK reaction is proportional to the product of [Cr] and  $V_{\text{max}}$  (or maximum activity), the decrease in [Cr] coupled with the known decrease in CK (primarily MM-CK and sMtCK) activity combine to limit this energy

reserve system in the hypertrophied and failing heart. In animal models of severe heart failure, approximately 30% and approximately 60% decreases in  $V_{\text{max}}$  and [Cr], respectively, combine to reduce the velocity of the CK reaction by approximately 70%. Direct measure of the unidirectional CK reaction velocity using saturation transfer NMR in failing human myocardium demonstrate lower CK flux, by 50%,<sup>100</sup> as predicted from analysis of the CK system in human myocardium<sup>30</sup> and observed for experimental models.<sup>10</sup>

### Manipulating [Cr]

Genetic modification in the mouse designed to manipulate the size of the myocardial Cr pool has expanded our understanding of the relationship between energy reserve via the CK system and contractile performance. Loss of function in the mouse was accomplished by replacing the Cr pool with its precursor guanidinoacetate by ablating GAMT in the pancreas and by taking care to ensure that Cr was not ingested by the mice (see Figure 7-9).<sup>101</sup> Hearts of these mice had undetectable levels of Cr and hence no PCr. As observed for hearts with low CK activity caused by a variety of maneuvers,<sup>10</sup> hearts from GAMT null mice had normal contractile performance at baseline but reduced contractile reserve when challenged with an inotropic agent and increased susceptibility to ischemic injury. Thus recapitulating the hypertrophied and failing heart, decreased energy reserve caused by decreasing the Cr pool led to decreased contractile reserve.

A gain-of-function strategy was used to test whether increasing CrT protein increased the cytosolic Cr pool in the mouse heart.<sup>102</sup> The myocardial Cr pool increased on average twofold but, unexpectedly, the fraction of Cr that was phosphorylated was lower by approximately 50%, despite normal CK activity. As a consequence of the lower PCr to Cr ratio, cytosolic [ADP] increased and the driving force for ATPase reactions,  $|\Delta G_{\text{ATP}}|$ , was lower. Importantly, these hearts developed left ventricular hypertrophy, dilation, and dysfunction. While this experiment supports a causal relationship between decreased energy reserve and contractile dysfunction, a longitudinal analysis defining the temporal sequence of these changes remains to be done. This experiment demonstrates that it is possible to manipulate cytosolic [Cr], suggesting a new experimental approach to the study of the energetics of the heart.

A different gain-of-function strategy is to create a model of recovery from heart failure to determine whether [Cr] returns toward control and whether this correlates with improved contractile function. Such models are rare, but recently, these measurements were made in myocardium obtained during recovery from pacing-induced heart failure in the dog. [Cr] and CK activity and contractile performance all returned toward normal.<sup>84</sup> While this positive result is correlative and not proof, a negative result would have argued against the importance of energy reserve in supporting contractile performance.

The consequences of decreasing PCr/Cr on contractile performance may be more profound than decreasing CK activity alone. In contrast to the experiments described above, CK-MM, CK-MtCK, and CK-MM/CK-MtCK null mouse hearts did not exhibit cardiac hypertrophy or failure.<sup>81,103-105</sup> CK-MM/CK-MtCK null mouse hearts had elevated [ADP] and hence a lower chemical driving force for ATPases; the cost of contraction was higher. Mitochondrial biology in these hearts was abnormal.<sup>22</sup>

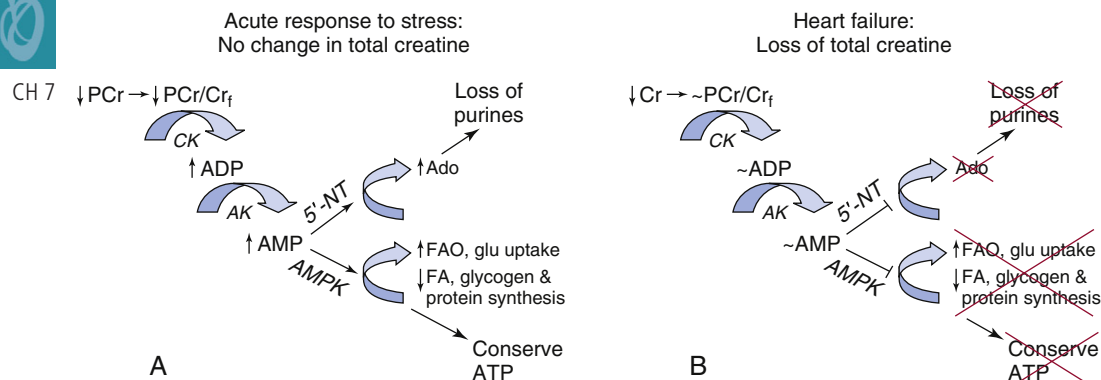

### Loss of Cr: Adaptive or Maladaptive?

The observations that increased free Cr leads to contractile dysfunction, hypertrophy, and dilation<sup>102</sup> raises the question of whether the loss of Cr in the failing heart is compensatory

## A QUESTION OF BALANCE

**FIGURE 7-10** A question of balance. **A**, In response to an acute stress, [PCr] falls. As consequences of CK and AK near equilibrium, [ADP] and [AMP] increase. Two consequences of increased [AMP] are activation of AMPK, the “low-on-fuel” sensor leading to increased glucose uptake and FAO and decreased ATP consuming reactions, and activation of 5'-nucleotidase leading to loss of purines. **B**, As [Cr] falls, [ADP] and [AMP] normalize, slowing the loss of purines (adaptive) but also metabolic remodeling (maladaptive?). Depending on the balance between these processes, metabolic remodeling may not support contractile function. (Redrawn from Ingwall JS. Energetics of the failing heart: new insights using genetic modification in the mouse. 2006; *Arch des Maladies du Cœur et des Vaisseaux* 99(9):839-847.)

or deleterious.<sup>38</sup> The notion that loss of Cr could be compensatory may seem counterintuitive. Loss of Cr reduces the velocity of the CK reaction, and thus reduces the primary energy buffer in the heart at a time when overall energy supply is compromised. However, loss of Cr also minimizes the increase in free [ADP] and hence maintains a near normal  $|\Delta G_{\sim \text{ATP}}|$ . Maintaining low cytosolic [ADP] also keeps free [AMP] low, reducing the loss of purines. This is quantitatively important because cytosolic [AMP] calculated using the AK equilibrium expression increases with the square of [ADP]. This schema is a direct consequence of the near equilibrium of the CK and AK reactions; unless the reaction mechanisms for these enzymes change due to chemical modification or binding to other proteins, it is unlikely that this scenario would be substantially modified. The model of cardiac energy metabolism identifying the tipping point for [ATP] referred to previously suggests that both lower and higher than normal [Cr] would lead to a lower driving force for ATPase reactions.<sup>40</sup>

It is worthwhile discussing the likely sequence of events that occurs as the acutely stressed heart transitions to the chronically stressed heart (Figure 7-10). In response to an acute increase in stress, [PCr] decreases, initially leading to increases in free [Cr], [ADP], [AMP], and [Pi]. The immediate consequences include (1) a decrease in CK reaction velocity, the major phosphoryl transferase; (2) a decrease in the phosphorylation ratio  $[\text{ATP}]/[\text{ADP}][\text{Pi}]$  and hence in  $|\Delta G_{\sim \text{ATP}}|$ , the driving force for myosin and ion pumps; (3) activation of cytosolic 5'-nucleotidase by increased [AMP], leading to a loss of purines; and (4) activation of AMPK by increased [AMP], a low-on-fuel sensor, leading to rapid reprogramming of metabolic pathways including increasing glucose uptake and use. With time, the progressive loss of Cr leads to reversal or normalization of points (2), (3) and (4), and (1) worsens. This analysis shows that the timing and magnitude of any change in [PCr]/[Cr] is critically important for understanding the metabolic remodeling that occurs during hypertrophy and failure, and ultimately the fate of ATP. It also suggests that whether loss of the ATP pool is attenuated or exacerbated depends on the balance between 5'-NT and AMPK activities. Surprisingly little is known about the time courses of the activation/deactivation of 5'-NT and AMPK in hypertrophy progressing to failure. The signals connecting physiological stresses and long-term metabolic remodeling by transcriptional activators and coactivators and how they fit into this schema remain to be defined. These are important areas for future studies.

## ON CAUSES AND CONSEQUENCES: ENERGETICS AND CONTRACTILE PERFORMANCE

Identifying “causes and consequences” of any molecular change characterizing the heart failure phenotype is a daunting task. Changes even in critically important proteins involved in energetics can usually be tolerated by the myocyte because the cell is designed to compensate for the loss of any important enzyme or pathway. As shown here, redundancy in the design of energy metabolism minimizes fluctuations in ATP and chemical driving forces and provides high capacity for tolerating increased ATP demand in the normal heart and in compensated hypertrophy. When this strategy fails, the heart can no longer recruit its contractile reserve and failure ensues. The major consequence of the molecular reprogramming of the pathways for ATP synthesis in the failing heart described in this chapter is that the total capacity for ATP synthesis decreases, demand for ATP outstrips supply, and [ATP] and [PCr] fall. The heart failure phenotype results from a significant and substantial change in normal metabolic regulation. As we have seen from the examples cited for the transcriptional activators, the heart failure phenotype can be elicited by many different molecular defects. It is a common endpoint phenotype. In this section, we will describe some examples of different kinds of *causes and consequences* with a focus on contractile performance.

The idea that sustained hemodynamic load causes changes in gene expression in some but not all proteins is well supported by studies showing that the decreases in MM-CK and sMtCK isozymes, but not in MB-CK, were reversed in heart failure patients given a ventricular assist device<sup>106</sup> and in an animal model of recovery from severe heart failure.<sup>84</sup> Myocyte size, their location in the heart, hemodynamic factors, and the ability to adapt to stress all play important roles leading to altered gene expression in the failing heart. This is illustrated by an early study in which cell size and enzyme activities of several proteins known to change in cardiac hypertrophy and failure were measured in myocytes isolated from different regions of hypertensive and nonhypertensive hypertrophied rat hearts.<sup>107</sup> The activities of some proteins increased in proportion to myocyte size while others were relatively diluted and still others increased out of proportion to myocyte size. This myocyte study also showed that gene expression changes in response to sustained hemodynamic load.

**FIGURE 7-11** Relationship between the increase in the concentration of adenosine diphosphate ([ADP]) and the increase in left ventricular end-diastolic pressure (LVEDP) in isolated perfused rat hearts in which [ADP] was altered by inhibiting creatine kinase to varying extents.<sup>69</sup> Because all other known regulators of end-diastolic pressure were held constant, these results show that increased [ADP] is sufficient to slow cross-bridge cycling in the heart.<sup>85</sup>

Diastolic dysfunction occurs in many forms of heart failure, often in the absence of systolic failure. It is the most common phenotype of hearts bearing missense mutations in sarcomeric proteins associated with FHC. Of the many ways that diastolic dysfunction can occur, one of them is increased cost of contraction manifest as increased [ADP] and decreased  $|\Delta G_{\sim\text{ATP}}|$ . Increased [ADP] is known to slow cross-bridge dissociation in skeletal muscle. Can the increase in [ADP] and consequent decrease in  $|\Delta G_{\sim\text{ATP}}|$  characteristic of the hypertrophied and failing heart cause diastolic dysfunction? Recall that  $|\Delta G_{\sim\text{ATP}}|$  is lower than normal when [ATP] falls, [ADP] increases, [Pi] increases, or any combination of these changes occurs (see Figure 7-4). The possibility that increasing cytosolic [ADP] is sufficient to slow dissociation of the cross-bridges enough to slow relaxation in the intact heart has been tested.<sup>85,86</sup> Cytosolic [ADP] was manipulated in whole heart preparations without substantially altering any of the other known regulators of contraction, namely, ATP, Pi, H<sup>+</sup>, or Ca<sup>2+</sup>; the rate of ATP synthesis from glycolysis was also constant. In the normal heart, this was accomplished by chemically inhibiting CK to varying degrees, thereby altering cytosolic [ADP]. In the heart hypertrophied due to aortic banding, the changes were the result of the perturbations in the CK-PCr system, which occur during hypertrophy and failure. In both settings, a monotonic relationship between increased LV end-diastolic pressure and increased [ADP] was found (Figure 7-11). Taken together, these studies demonstrate that increases in the average cytosolic [ADP] in the absence of changes in any of the other known regulators of myofilament function are sufficient to slow cross-bridge cycling and impair diastolic function. Thus the increases in [ADP] secondary to a decrease in [PCr] observed in many forms of hypertrophy and heart failure may be sufficient to slow cross-bridge cycling and thereby contribute to diastolic dysfunction. Similarly, the increased cost of contraction in hearts with FHC mutations likely explains, in part, diastolic dysfunction characterizing its phenotype.

Decreased capacity for phosphoryl transfer to resupply ATP via CK and AK increases the cost of mechanical work. Increasing work in mouse hearts deficient in MM-CK and sMtCK is more energy costly than for control hearts.<sup>80,81</sup> Studies using otherwise normal mouse hearts deficient in AK have shown that, even though flux through the CK reaction and glycolysis increased to compensate for the loss in AK, more ATP per contraction was used in AK-deficient muscle.<sup>108</sup> A consequence of the disruption of energy transfer relay via CK within the myocyte is well illustrated by increased electrical vulnerability of the heart caused by failure to supply ATP via CK to the K<sub>ATP</sub> channel in MM-CK null mouse hearts.<sup>43</sup>

Another consequence is illustrated by decreased contractile reserve in hearts with less than 2% CK activity. The relationship between energy reserve and contractile reserve was defined for the normal heart in which the energy reserve was acutely decreased by chemically inhibiting CK activity.<sup>109</sup> Hearts with very low levels of CK activity have less free energy from ATP hydrolysis available to support an increase in work, have lower contractile reserve, and use more free energy from ATP hydrolysis to support a smaller increase in work upon inotropic challenge. Based on experiments such as these in the normal heart and in animal models of heart failure showing a relationship between energy reserve via the CK system and contractile reserve of the heart, it seems likely that the decreased energy reserve of the human failing heart has a similar functional correlate. The failing heart is “energy starved” with respect to its capacity to rapidly resynthesize ATP. The energy-poor heart cannot recruit its contractile reserve without expending a disproportionate amount of energy.

A consequence of decreased capacity to increase ATP synthesis, regardless of cause, is high risk of acute mechanical failure during an abrupt increase in work state, a hypoxic

or ischemic insult, or an arrhythmia. One demonstration of the greater susceptibility of the energy-poor heart to acute stress is the faster rate of loss of systolic performance during zero-flow ischemia in isolated mouse hearts deficient in the MM- and sMtCK genes.<sup>110</sup> Another example is shown by studies of myocardial infarction in the rat.<sup>111</sup> Myocardial [PCr] and CK reaction velocity were decreased by approximately 90% and [ATP] by 18% (a profile not unlike the heart failure phenotype) in rats by feeding them with the Cr analog β-guanidinopropionic acid, a competitive inhibitor of CrT and the CK reaction. Unlike control rat hearts that survived acute myocardial infarction, the 24-hour mortality of rats with a severely compromised CK-PCr system was 100%.

## INTERVENTIONS DESIGNED TO ALTER ENERGETICS IN THE FAILING HEART: NEW STRATEGIES FOR THERAPY

There are two important lessons to be learned from this analysis of the energetics of the failing heart useful for guiding drug treatment of the decompensated heart. The first lesson is that the failing heart has limited energy reserve, and while it can increase work output, it does so at a higher cost of contraction. This increases susceptibility to arrhythmia and ischemic injury. The clinical observations that patients treated with drugs that increase ATP use to support acute increases in hemodynamics have poor long-term outcomes is most simply explained by the lack of energy reserve to support chronic increased ATP use.<sup>1,112</sup> Examples are positive inotropes such as digoxin (increased Na pump activity), dobutamine (increased contractility), and moxonidine (increased FA use). Research into ways of increasing systolic performance or reducing diastolic dysfunction by manipulating sarcomere function without increasing tension cost merits support. Studies of skinned fibers isolated from explanted hearts from patients with idiopathic dilated cardiomyopathy (IDCM) treated with either carvedilol or metoprolol illustrate this point.<sup>112</sup> Carvedilol treatment decreased tension-dependent ATP use, whereas metoprolol did not improve economy of contraction. Developing myosin activators that do not increase cost of contraction is a logical metabolic strategy.

Another pharmacological approach aims to take advantage of the small increase in the ratio of ATP production to O<sub>2</sub> consumed for glucose. Drugs that shift metabolism away from FAO and toward glucose metabolism improve the efficiency of ATP production. Drugs that target 3-ketoacyl CoA thiolase

(3-KAT), the last enzyme involved in  $\beta$ -oxidation (see Figure 7-2) such as trimetazidine, shift metabolism away from FAO and have shown promise in preserving ATP and PCR during ischemia (see Chapter 50).<sup>5</sup> Agents that target CPT-1, which transports FA across the inner mitochondrial membrane—such as etomoxir, perhexiline, and oxfenicine—all increase glucose use. A corollary would seem to be that decreasing plasma levels of FA and increasing glucose supply would be cardioprotective. However, this may not be the case. In patients with IDCM, acute FA depletion did not downregulate OXPHOS and efficiency fell, suggesting that both glucose and FA are required even for the failing heart.<sup>113</sup>

Direct manipulation of adenine nucleotide or Cr pools has been elusive clinically. Notable in this regard is the report studying experimental right ventricular hypertrophy<sup>114</sup> showing that folate treatment protected against loss of adenine nucleotides and diastolic dysfunction. The underlying mechanism is undefined. As folate is both readily available and inexpensive, strategies such as this may be useful in slowing the progression to failure. Beneficial effects of supplying D-ribose, a precursor of ATP, have also been reported.<sup>115</sup>

In any rational strategy, care should be taken to match intervention with the stage of disease. The different pathways for ATP synthesis are compromised at different times in the evolution of compensated to uncompensated hypertrophy. Loss of the energy reserve system supported by CK occurs first, and triggers an increase in glycolysis. As some models of hypertrophy show no decrease in FAO when glucose use increases, it seems likely that decreased ATP synthesis via FAO is last in this trio to change. Ideally, interventions designed to alter metabolic pathways must be matched to *stage of metabolic dysfunction*, analogous to NYHA classes.

Much more research needs to be done to test whether the metabolic remodeling of the failing heart is stable or worsens with advanced heart failure, whether the increase in glucose use (or the insufficient increase in glucose use) or decrease in fatty acid use is primary, whether there is a common molecular endpoint for all types of heart failure, and whether novel strategies based on informed knowledge of metabolic remodeling can rescue the failing human myocardium. Remodeling the “remodeled metabolome” in the failing heart would have significant clinical impact.

## ACKNOWLEDGMENTS

The author wishes to thank Linda Johnson for her work preparing this manuscript, particularly the illustrations. This work was supported in part by research funds from the Department of Medicine, Brigham and Women's Hospital, and the National Institutes of Health.

as “reverse remodeling.”<sup>1,2</sup> Although the precise cellular and molecular mechanisms that are responsible for the remarkable return toward normal LV size and shape are not completely understood, there is a fairly consistent biological theme with respect to the parameters that return toward the baseline following pharmacological or device therapy. The importance of understanding these changes at a basic molecular level is that they may lead to the identification of novel therapeutic targets for treating/reversing heart failure.

In the 1980s and early 1990s, it was generally believed that once the heart became markedly dilated, no form of therapy could reverse this process in a meaningful manner, which led to the generally held concept of irreversible, end-stage cardiomyopathy. The concept of reverse remodeling emerged in the early 1990s based on anecdotal case reports of patients exhibiting substantial recovery of the ventricular function following mechanical unloading with left ventricular assist devices (LVAD).<sup>3,4</sup> Subsequent studies that showed that the end-diastolic pressure-volume relationship were gradually shifted leftward when compared in patients undergoing a cardiac myoplasty,<sup>1</sup> and in explanted hearts from patients who had undergone LVAD support,<sup>2</sup> implying that the heart was not simply unloaded, but rather that there were fundamental changes in the biological properties of the heart that allowed the ventricle to return toward normal size and shape. These early observations with devices were then mirrored by studies in heart failure patients who were treated with angiotensin-converting enzyme (ACE) inhibitors and  $\beta$ -blockers, in whom there were significant decreases in LV end-diastolic volume, in comparison to patients who received a placebo.<sup>5-7</sup> These unexpected observations with cardiac circulatory assist devices and medical therapy challenged the dogma that heart failure is an irreversible process that culminates invariably in death or cardiac transplantation, and fostered a greater interest in understanding the biological processes that are responsible for the restoration of normal cardiac structure and function.

It is now recognized that “reverse remodeling” or myocardial recovery can be recognized and defined by a series of changes that occur within the cardiocytes (i.e., resident cardiac cells, including cardiac myocytes, fibroblasts, endothelial cells), in the composition of the LV myocardium and in the geometry of the left ventricle (Box 8-2).<sup>8</sup> These changes may ultimately lead to improvement in ventricular function and even sustained clinical recovery from heart failure in select cases. However, it bears emphasis that many of the cellular and molecular changes that occur during the process of myocardial recovery occur in the absence of sustained clinical recovery of the patient. The reasons for this observation are unknown, but may relate to an inadequate mass of cardiac myocytes that are necessary to sustain adequate LV pump function. Although considerable research time and effort have been expended

on understanding the basic mechanisms that promote LV remodeling (see Chapter 15), it is not clear whether a simple reversal of these same mechanisms will allow the heart to revert back to its normal size and shape. Accordingly, this chapter will focus only on those cellular and molecular changes that occur during reverse remodeling, as opposed to focusing on the cellular and molecular changes that occur when LV remodeling is prevented. Because of the paucity of the animal models to study myocardial recovery, the majority of our current knowledge with respect to the reverse remodeling process is derived from the clinical studies of patients undergoing heart failure therapies that improve LV structure and prolong survival.

## CHANGES IN THE BIOLOGY OF THE CARDIAC MYOCYTE DURING MYOCARDIAL RECOVERY

Numerous studies have suggested that failing human cardiac myocytes undergo a number of important changes that might be expected to lead to a progressive loss of contractile function, including decreased  $\alpha$ -myosin heavy chain gene expression with a concomitant increase in  $\beta$ -myosin heavy chain expression,<sup>9</sup> progressive loss of myofilaments in cardiac myocytes,<sup>10</sup> alterations in cytoskeletal proteins,<sup>10</sup> alterations in excitation-contraction coupling,<sup>11</sup> and desensitization of  $\beta$ -adrenergic signaling.<sup>12</sup> And indeed, when the contractile performance of isolated failing human myocytes has been examined under very simple experimental conditions, investigators have found that there is an approximately 50% decrease in cell shortening in failing human cardiac myocytes when compared with nonfailing human myocytes.<sup>13</sup> Moreover, this defect in cell shortening has a number of important components, which may act combinatorially to produce the observed phenotype of cellular contractile dysfunction. Thus the contractile dysfunction that develops within myocytes during the process of LV remodeling is likely to involve ensembles of genes, including those that regulate calcium handling, sarcomerogenesis,

120  $\beta$ -adrenergic signaling, and the cytoskeleton, all of which may interact in an exceedingly complex manner within the cardiac myocyte to produce contractile dysfunction. In the section that follows, we will review the experimental and clinical literature, which suggests that alterations in the biology and the contractility of the failing cardiac myocyte are reversible following conventional pharmacological therapies and/or treatment with cardiac devices, including LVADs, cardiac resynchronization therapy (CRT), and cardiac support devices (Table 8-1).

## Cardiac Myocyte Hypertrophy

One of the essential components of the LV remodeling process is the development of cardiac myocyte hypertrophy, which is characterized morphologically by the addition of sarcomeres in series or parallel in response to hemodynamic overload, leading to the development of eccentric or concentric hypertrophy, respectively (Figure 8-2).<sup>14</sup> Several lines of experimental evidence suggest that cardiac myocyte hypertrophy is a dynamic process that is reversible following removal of hemodynamic pressure or volume overloading.<sup>15</sup> Although information is limited, there is evidence that the regression of myocyte hypertrophy that occurs following hemodynamic unloading is accompanied by changes in the activation and/or activity levels of protein kinases that are linked to cell growth, including extracellular regulated kinase-1 (ERK-1) and ERK-2, p38 (Figure 8-3),<sup>16</sup> Akt and GSK-3 $\beta$  (a negative regulator of hypertrophy), and transcription factors (GATA4) that are linked to hypertrophic growth.<sup>17</sup> Additional support for the concept of the reversibility of cardiac myocyte hypertrophy has been demonstrated repeatedly in pharmacological intervention studies in animal models of heart failure, which have shown that angiotensin-converting enzyme inhibitors and  $\beta$ -blockers can reverse cardiac myocyte hypertrophy in remodeled hearts.<sup>18,19,20</sup> The use of LVADs in patients with end-stage heart failure has greatly expanded our understanding of the reverse remodeling process at the cellular level in humans with heart failure (see also Chapter 56). Clinical studies from patients undergoing LVAD implantation have consistently shown a regression of myocyte hypertrophy with mechanical circulatory support (Figure 8-4),<sup>17,21-25</sup> although one study demonstrated a slight increase in myocyte diameter.<sup>26</sup> Similarly, treatment with cardiac support devices significantly reduced cardiac myocyte hypertrophy in animal models of heart failure.<sup>27</sup> In a prospective clinical study, cardiac resynchronization for 3 months was shown to attenuate the growth in cardiac myocytes in some patients with heart failure.<sup>28</sup>

**FIGURE 8-1** The ventricular end-diastolic pressure-volume relation, initially shifted far rightward in heart failure, shifts, over time, back toward normal. **A**, Average end-diastolic pressure-volume relationships from normal human hearts, from failing hearts not supported with LVAD, hearts supported with an LVAD for less than 40 days, and hearts supported with an LVAD for more than 40 days. **B**, Heart size, indexed by V<sub>30</sub>, the volume required to achieve an end-diastolic pressure of 30 mm Hg as a function of the duration of LVAD support from individual hearts (see insert for symbol key). Also shown are values from normal hearts and from failing hearts not supported by LVAD. Underlying the reduction in heart size is regression of cellular hypertrophy. **C**, Cross-section of normal human myocardium. **D**, In chronic heart failure the myocytes are markedly hypertrophic. **E**, After LVAD support, LV myocardial hypertrophy regresses (individual myocyte cross-sectional area reduced). Increased interstitial fibrosis is also noted. All myocardial samples used for C-E were fixed in an unloaded state. (From Madigan JD, Barbone A, Choudhri AF, et al. Time course of reverse remodeling of the left ventricle during support with a left ventricular assist device. *J Thorac Cardiovasc Surg* 2001;121:902-908.)

MicroRNAs (miRNAs) are noncoding RNAs that regulate gene expression at the posttranscription level by promoting mRNA degradation or by inhibiting the translation of proteins from mRNA. Recent studies have identified a potentially important role for miRNAs in terms of modulating cardiac hypertrophic growth in the heart.<sup>29</sup> It is therefore of interest that in both rat models of mechanical unloading and in human hearts that have been supported with LVADs that there is a return in the level of expression of miRNAs toward normal values.<sup>30,31</sup> Matkovich et al showed that hearts that had been mechanically unloaded with an LVAD significantly had decreased expression of miR-195 when compared with patients with end-stage heart failure.<sup>31</sup> Given that overexpression of miR-195 in vitro was capable of inducing hypertrophic growth in neonatal ventricular cardiomyocytes, and that transgenic mice with cardiac restricted overexpression of miR-195 had a dramatic increase in the myocyte size compared with normal mice,<sup>32</sup> miR-195 may contribute to reversal of the heart failure phenotype. Taken together, the aggregate

experimental and clinical data suggest that the cardiac myocyte hypertrophy that occurs in heart failure is a reversible process, which has given rise to the concept of the “plasticity” of the hypertrophied/failing cardiac myocyte phenotype (reviewed in Swynghedauw<sup>33</sup>).

### Myocyte Gene Expression

The morphological changes that occur in a hypertrophied cardiac myocyte are accompanied by a series of changes in the biology of the myocyte that are secondary to reactivation of portfolios of genes, including atrial or B-type natriuretic peptides (ANP, BNP),  $\beta$ -myosin heavy chain ( $\beta$ -MHC), and  $\alpha$ -skeletal actin ( $\alpha$ -SKA) that are normally not expressed postnatally. The reactivation of these fetal genes, the so-called fetal gene program, is also accompanied by downregulation of a number of genes, most notably sarcoendoplasmic reticulum  $\text{Ca}^{2+}$  ATPase (SERCA) and  $\alpha$ -MHC, that are normally expressed in the adult heart. The extant literature suggests that many of the changes in gene expression are reversible with pharmacological therapies that have been shown to improve patient outcomes. Treatment with ACE inhibitors or ARBs were associated with an increase in  $\alpha$ -MHC and a decrease in  $\beta$ -MHC at the transcriptional level in experimental models of heart failure.<sup>34,35</sup> In patients with dilated cardiomyopathy,  $\beta$ -blockade by metoprolol (selective  $\beta_1$ -blocker) or carvedilol ( $\beta_1$ -,  $\beta_2$ -, and  $\alpha_1$ -blocker) inhibited expression of ANP and  $\beta$ -MHC and restored that of SERCA and  $\alpha$ -MHC at the mRNA level (Figure 8-5).<sup>36</sup>

Changes in the abnormal gene expression have also been observed with the use of mechanical circulatory assist devices (Table 8-2). For example, when gene expression profiling was performed in bridge-to-transplantation patients before and after LVAD support, there was a significant downregulation of  $\beta$ -MHC,  $\alpha$ -SKA, and BNP in patients with nonischemic cardiomyopathy who received LVAD support, whereas no differences were observed in patients with ischemic cardiomyopathy.<sup>37</sup> In a similar study that employed a proprietary gene array platform, there was a global increase in the expression of a variety of sarcomeric genes in the hearts of LVAD-supported ischemic and nonischemic cardiomyopathy patients, whereas  $\beta$ -MHC mRNA expression was downregulated, consistent with the previous reports.<sup>38</sup> In a select cohort

**FIGURE 8-2** Patterns of cardiac myocyte hypertrophy. **A**, Morphology of cardiac myocytes in response to hemodynamic pressure and volume overload. Phenotypically distinct changes in the morphology of myocyte occur in response to the type of hemodynamic overload that is superimposed. When the overload is predominantly due to an increase in pressure, the increase in systolic wall stress leads to the parallel addition of sarcomeres and widening of the cardiac myocytes. When the overload is predominantly due to an increase in ventricular volume, the increase in diastolic wall stress leads to the series addition of sarcomeres, and thus lengthening of cardiac myocytes. **B**, The pattern of cardiac remodeling that occurs in response to hemodynamic overloading depends on the nature of the inciting stimulus. When the overload is predominantly due to an increase in pressure (e.g., with systemic hypertension or aortic stenosis), the increase in systolic wall stress leads to the parallel addition of sarcomeres and widening of the cardiac myocytes, resulting in concentric cardiac hypertrophy. When the overload is predominantly due to an increase in ventricular volume, the increase in diastolic wall stress leads to the series addition of sarcomeres, lengthening of cardiac myocytes, and LV dilation, which is referred to as eccentric chamber hypertrophy. (Modified from Hunter JJ, Chien KR. Signaling pathways for cardiac hypertrophy and failure. *N Engl J Med* 1999;341:1276; and Colucci WS, editor. *Heart failure: cardiac function and dysfunction*, ed 2, Philadelphia, 1999, Current Medicine; and modified from Mann DL. Pathophysiology of heart failure. In Libby PL, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, ed 8, Philadelphia, 2004, Elsevier.)

of LVAD patients with clinical myocardial recovery leading to device explantation, mechanical unloading resulted in increased protein expression of myosin heavy and light chains, tropomyosin, and troponins I, C, and T.<sup>39</sup> Moreover, chronic hemodynamic unloading with an LVAD significantly reduced the expression of ANP, BNP, and natriuretic peptide

receptor-C mRNA in patients with end-stage heart failure.<sup>40</sup> Left ventricular endomyocardial biopsies obtained from heart failure patients who underwent cardiac resynchronization therapy (CRT) revealed a significant increase in  $\alpha$ -MHC and a nonsignificant decrease in  $\beta$ -MHC mRNA levels using quantitative real-time PCR.<sup>41</sup> Vayderheyden et al have demonstrated that CRT resulted in increased expression of  $\alpha$ -MHC and BNP mRNA levels, and reduced the expression of  $\beta$ -MHC mRNA in patients who improved clinically.<sup>42</sup> Changes in fetal gene expression were not seen in “nonresponders,” defined as failure to improve greater than 1 NYHA functional class score and a less than 25% relative increase in EF after 4 months of therapy. In a dog model of heart failure induced by intracoronary microembolization, therapy with cardiac support device resulted in a return in  $\beta$ -MHC,  $\alpha$ -MHC, ANP, and BNP toward values observed in sham-operated animals.<sup>43</sup> Taken together, these data suggest that both drug and device therapies contribute to reversal of the fetal gene program that has been associated with abnormal contractile function of the cardiac myocyte. However, what is not clear from the extant literature is which of the previous changes is/are necessary and/or essential for myocardial recovery.

### $\beta$ -Adrenergic Desensitization

One of the signatures of advancing heart failure is a reduction in  $\beta_1$ -adrenergic receptor density, isoproterenol-mediated adenylate cyclase stimulation, and isoproterenol-stimulated muscle contraction.<sup>12</sup> This process of agonist-induced  $\beta$ -AR desensitization requires phosphorylation of the agonist-occupied receptor by the cytosolic enzyme  $\beta$ -adrenergic receptor kinase 1 ( $\beta$ -ARK1). As will be discussed later,  $\beta$ -AR desensitization can be reversed with pharmacological and device therapies that have been shown to improve patient outcomes.

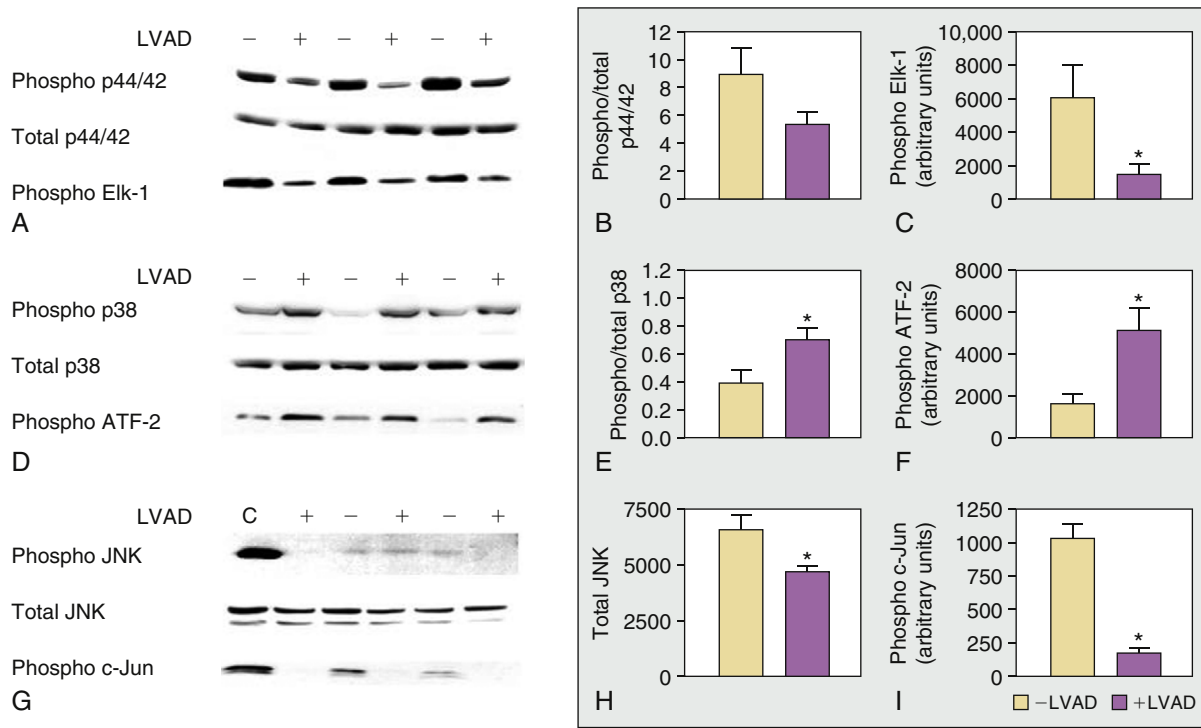

In a substudy of MDC (the Metoprolol in Dilated Cardiomyopathy) trial, treatment with selective  $\beta_1$ -blocker metoprolol resulted in significantly increased total  $\beta$ -receptor density in the heart. Interestingly, carvedilol had no effect on  $\beta$ -adrenergic receptor ( $\beta$ -AR) density despite the fact that it was associated with a marked improvement in myocardial function and a reduction in cardiac adrenergic activity.<sup>44</sup> In a randomized, double-blind, placebo-controlled study, the use of the ACE inhibitor lisinopril resulted in a significant increase in myocardial  $\beta$ -AR density in a subset of heart failure patients with high baseline cardiac adrenergic activity.<sup>45</sup>

Normalization of reduced  $\beta$ -adrenergic receptor density and enhanced inotropic responsiveness to isoproterenol have been demonstrated consistently in LVAD-supported failing hearts.<sup>46-48</sup> The enhanced  $\beta$ -adrenergic responsiveness with LVAD support was associated with a decrease in GRK2 protein levels and total GRK activity, but no significant change in GRK5 protein and mRNA levels.<sup>49</sup> Similar findings have been observed following CRT therapy. After 4 months of CRT,  $\beta_1$ -adrenergic receptor expression was significantly upregulated at the transcriptional level in heart failure patients.<sup>50</sup> Treatment with a cardiac support device resulted in increased inotropic responsiveness in a canine model of heart failure.<sup>51</sup>

### Excitation-Contraction Coupling

Alterations in  $\text{Ca}^{2+}$  cycling have been closely linked to myocardial contractile dysfunction in heart failure. As discussed in Chapter 3, changes in the abundance of critical  $\text{Ca}^{2+}$  regulatory proteins including sarcoplasmic endoreticular  $\text{Ca}^{2+}$  ATPase (SERCA), ryanodine receptor (RyR), L-type calcium channel (LTCC), and sarcolemmal  $\text{Na}^+/\text{Ca}^{2+}$  exchanger (NCX) likely play an important role in the contractile dysfunction of the failing cardiac myocyte. In a transgenic mouse model of heart failure overexpressing tropomodulin, treatment with  $\beta$ -blockers resulted in normalization of SERCA and NCX

**FIGURE 8-3** Effect of LVAD support on activation and activity levels of p44/42, p38, and JNK in the presence ( $n = 11$ ) and absence ( $n = 11$ ) of LVAD support. Panels A, D, and G show, respectively, representative Western blots for p44/42, p38, and JNK activation (upper lane); total p44/42, p38, and JNK (middle lane); and p44/42, p38, and JNK activity (lower lane). Panels B and E show, respectively, the results for group data for MAPK activation (phosphorylation), which is expressed as the ratio of the intensity of the bands corresponding to phosphorylated p44/42 and p38 divided by the intensity of the bands corresponding to total p44/42 and p38. Panel H shows the results for group data for total JNK before and after LVAD. Panels C, F, and I show, respectively, the results for group data for p44/42, p38, and JNK activity levels. Data were quantified by laser scanning densitometry and expressed as arbitrary units. (Key: + = LVAD; - = no LVAD; C = HeLa-cells treated with 200 U/mL TNF for 15 min (used as a positive control) (\* denotes  $P < .05$  compared to no LVAD support) (From Flesch M, Margulies KB, Mochmann HC, et al. Differential regulation of mitogen-activated protein kinases in the failing human heart in response to mechanical unloading. *Circulation* 2001;104(19):2273-2276.)

protein levels and LTCC density and function.<sup>52</sup> RyR phosphorylation was unchanged by treatment with  $\beta$ -blockers in this transgenic model. Clinical studies have shown that treatment with  $\beta$ -blockers results in increased myocardial SERCA mRNA and protein content (see Figure 8-5),<sup>36,53</sup> a trend toward a decrease in myocardial PLB and NCX protein content,<sup>53</sup> and reduced PKA-mediated hyperphosphorylation of RyR.<sup>54</sup> Similarly, administration of ACE inhibitors or ARBs in a post-MI rat model of heart failure significantly attenuates the reduction in myocardial SERCA, RyR, and PLB mRNA and protein levels.<sup>55,56</sup> Collectively, these changes in gene expression would result in increased  $\text{Ca}^{2+}$  that was available for activation of the actin and myosin cross-bridges, and hence improved myocyte contractility.

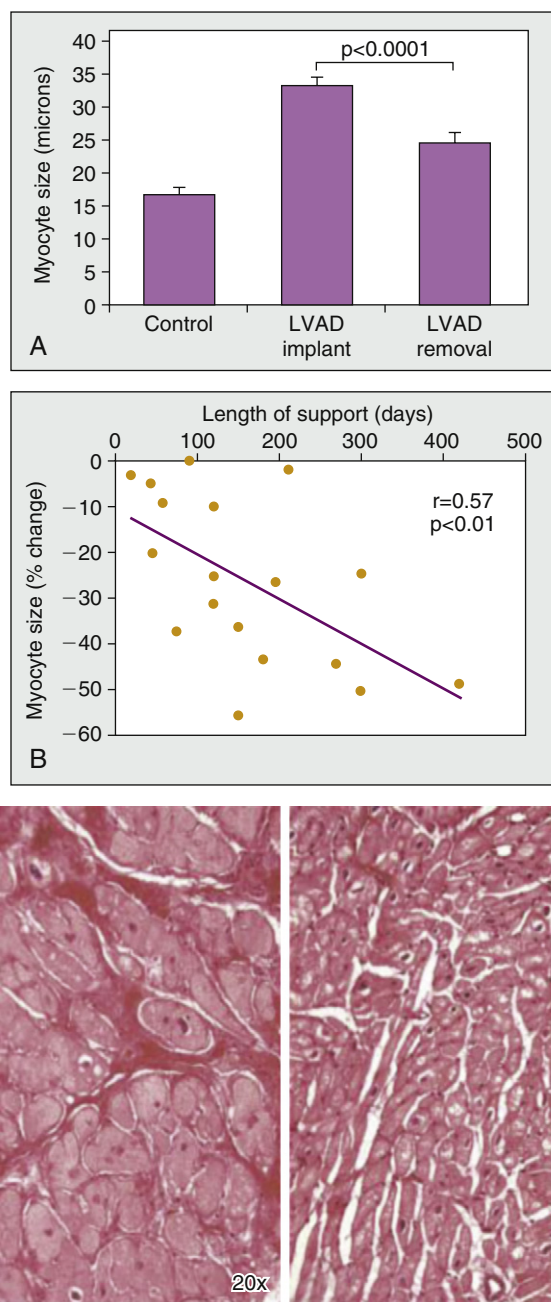

Mechanical unloading with LVAD support has provided the clearest insight into the importance of changes in excitation-contraction coupling during myocardial recovery. Perhaps the clearest evidence in support of this statement is the observation that there is increased shortening, faster time to peak concentration, and reduced time to 50% relaxation in cardiac myocytes that have been isolated from LVAD supported hearts.<sup>57</sup> As shown in Figure 8-6 the return of contractile function in failing hearts following LVAD-induced unloading is associated with altered gene expression of key  $\text{Ca}^{2+}$  regulatory proteins, including NCX, SERCA2a, RyR, and changes in calcium cycling.<sup>58,59</sup> Moreover, protein kinase A-mediated hyperphosphorylation of RyR was restored to normal in failing hearts following LVAD support.<sup>60</sup> Nonetheless, the significance of some of the reported changes in gene expression is uncertain insofar as only SERCA2 protein levels increased, whereas protein levels of the RyR and NCX were unchanged following LVAD support (Figure 8-7).<sup>61</sup> Cardiac resynchronization therapy significantly increased mRNA

expression for SERCA2a, RyR, and SERCA/NCX mRNA in heart failure patients.<sup>60</sup> Importantly, improvement in SERCA expression occurred only in patients who clinically responded to CRT.<sup>42</sup> Although treatment with a cardiac support device did not result in changes in SERCA2a and phospholamban expression, treatment with a cardiac support device resulted in increased sarcoplasmic reticular  $\text{Ca}^{2+}$  uptake in an experimental model.<sup>27</sup>

## Cytoskeletal Proteins

The cytoskeleton of cardiac myocytes (see Chapter 27) consists of actin, the intermediate filament desmin, the sarcomeric protein titin, and  $\alpha$ - and  $\beta$ -tubulin, which form the microtubules by polymerization. Vinculin, talin, dystrophin, and spectrin represent a separate group of membrane-associated proteins. In numerous experimental studies, the role of cytoskeletal and/or membrane-associated proteins has been implicated in the pathogenesis of heart failure, insofar as loss of integrity of the cytoskeleton and its linkage of the sarcomere to the sarcolemma and extracellular matrix would be expected to lead to contractile dysfunction at the myocyte level, and at the myocardial level.

Mechanical unloading with LVAD support also results in restoration of cytoskeletal organization. Vatta et al reported that there was loss of the N-terminal region of dystrophin (which links to the sarcomere through actin) in patients with both ischemic and dilated cardiomyopathy, and that mechanical unloading resulted in an increased N-terminal dystrophin expression (Figure 8-8).<sup>62</sup> The change in the level of expression of dystrophin was comparable in the right ventricle and the left ventricle after mechanical unloading; however, a greater degree of normalization was achieved in patients

**FIGURE 8-4** Decreased cardiac myocyte hypertrophy in LVAD supported hearts. **A**, Myocyte size was determined in control subjects without heart failure, failing hearts at the time of LVAD implant, and LVAD removal. After LVAD support (mean duration of  $159 \pm 25$  days), there was a significant reduction in myocyte cell size. However, while myocyte cell size decreased in all patients following LVAD implantation, the cell size post-LVAD removal was still larger than in controls. **B**, Relation of percent reduction in myocyte size and the length of LVAD support. **C**, A representative hematoxylin eosin stain of myocardial samples obtained at the time of LVAD implant and removal from an individual patient. (Modified from Bruckner BA, Stetson SJ, Perez-Verdia A, et al. Regression of fibrosis and hypertrophy in failing myocardium following mechanical circulatory support. *J Heart Lung Transplant* 2001;20(4):457-464.)

treated with pulsatile-flow LVADs than among those treated with continuous-flow LVADs.<sup>63</sup> Mechanical support with an LVAD has been reported to increase immunostaining for major sarcomeric proteins including actin, troponin C, troponin T, tropomyosin, and titin, with a small, nonsignificant decrease in myosin<sup>64</sup>; changes in the intracellular distribution of desmin, vinculin, and tubulin; and an increase in

desmin protein content, with no change in the content or distribution of  $\alpha$ -actinin.<sup>65</sup> Interestingly, in one small study there was a specific pattern of changes in mRNA expression levels for both sarcomeric and nonsarcomeric cytoskeletal proteins in the myocardium (increased  $\beta$ -actin,  $\alpha$ -tropomyosin,  $\alpha_1$ -actinin,  $\alpha$ -filamin A, with decreased troponin T<sub>3</sub>,  $\alpha_2$ -actinin, and vinculin) in patients who were bridged to recovery when compared with heart failure patients who were not supported, suggesting that alterations in cytoskeletal structure might play an important role in and serve as a marker of myocardial recovery.<sup>66</sup> Of note, myocardial titin,  $\alpha$ - and  $\beta$ -tubulin mRNA expression were shown to return to normal levels following 3 months of therapy with a cardiac support device (CorCap) in a dog model of chronic heart failure.<sup>43</sup>

## Myocytolysis

Myocytolysis refers to the degenerative loss (often reversible) of myofibrils that occurs in cardiac myocytes that have been subjected to increased myocardial stretch/strain, ischemia, and/or neurohormonal stimulation. The characteristic histopathological appearance of myocytolysis is cellular vacuolization with loss of actin and myosin myofibrils. The experimental literature suggests that  $\beta$ -adrenergic blockade restores cardiac myocyte contractility, and that this improvement in myocyte contractility has been linked to an increase in the density of myofilaments within the failing myocytes.<sup>67</sup> Several reports from patients who have been supported with LVADs also suggest that myocytolysis is reversible.<sup>68,69</sup> However, in some reports there has been persistent disruption of sarcomeres and disoriented mitochondria in mechanically unloaded hearts, suggesting that there may not be complete recovery of the myocyte at the ultrastructural level with LVADs.

## CHANGES IN THE MYOCARDIUM DURING MYOCARDIAL RECOVERY

The unfavorable alterations that occur in the failing myocardium may be categorized broadly into those that occur in the volume of cardiac myocytes, changes that occur in the volume and composition of the extracellular matrix, and changes that occur in angiogenesis. With respect to the changes that occur in cardiac myocyte component of the myocardium there is increasing evidence to suggest that progressive myocyte loss, through both necrotic and apoptotic cell death, may contribute to progressive cardiac dysfunction and LV remodeling (see Chapters 6 and 15). Insofar as prevention of loss of cardiac myocytes is more likely to play an important role in preventing disease progression than in myocardial recovery, this topic will not be discussed further in this chapter. The topic of myocardial regeneration, which can contribute to the process of myocardial recovery, is reviewed in Chapter 4. As will be discussed later, there is evidence that changes in the volume and composition of the extracellular matrix may contribute to myocardial recovery and changes in angiogenesis.

## Myocardial Fibrosis

Studies in the failing human heart have shown that there is a quantitative increase in collagens I, III, VI, and IV, fibronectin, laminin, and vimentin, and that the ratio of type I collagen to type III collagen is decreased in patients with ischemic cardiomyopathy.<sup>70</sup> Moreover, progressive loss of cross-linking of collagen has been demonstrated in the failing myocardium. Disruption of the extracellular matrix would be expected to lead to LV dilation as a result of mural realignment ("slippage") of myocyte bundles and/or individual myocytes within the LV wall,<sup>71</sup> and LV dysfunction as

**FIGURE 8-5** Changes in fetal gene expression in patients who received  $\beta$ -blockers. **A** and **B**, Changes between baseline and the end of the 6-month study in the abundance of myocardial mRNA for six contractility-regulating or hypertrophy-regulating proteins in patients who received a placebo or  $\beta$ -blocker. The changes in patients who had an improvement in left ventricular ejection fraction by at least five ejection fraction [EF] units were compared with the changes in patients who did not have such a response. Gene expression is shown as molecules of mRNA per microgram of total RNA on a logarithmic scale. The asterisk indicates  $P < .10$  for the change between the baseline value and the value measured at 6 months by the paired  $t$ -test, the daggers  $P < .05$  for the comparison with the placebo group by the test for interaction, the double daggers  $P < .05$  for the change between the baseline value and the value measured at 6 months by the paired  $t$ -test, and the section marks  $P < .05$  for the comparison with patients who did not have a response. Each panel shows the results for patients with complete data for the indicated mRNA and receptor protein measurements. (Modified from Lowes BD, Gilbert EM, Abraham WT, et al. Myocardial gene expression in dilated cardiomyopathy treated with  $\beta$ -blocking agents. *N Engl J Med* 2002;346:1357; and Mann DL. Management of patients with a reduced ejection fraction. **FIGURE 8-6** Summary of changes in excitation-contraction coupling in cardiac myocytes from hearts that have been supported with a left ventricular assist device. As shown there is an increase in the inward  $\text{Ca}^{2+}$  current through the L-type  $\text{Ca}^{2+}$  channel, a decrease in the levels and activity of the sodium-calcium exchanger (NCX), increased  $\text{Ca}^{2+}$  content of the sarcoplasmic reticulum (SR), decreased activity of the ryanodine receptor (RyR), and increases in FKB 12.6 levels (a regulatory protein that prevents  $\text{Ca}^{2+}$  release from the RyR). Collectively these changes would be expected to lead to improved myocyte contractility. (Key: the arrows indicate increases (↑) or decrease (↓) in various parameters) (Modified from Soppa GK, Barton PJ, Terracciano CM, et al. Left ventricular assist device-induced molecular changes in the failing myocardium. *Curr Opin Cardiol* 2008;23:206-218.)

**FIGURE 8-7** **A**, Representative Northern blot depicting three nonfailing hearts (normal) and six individual hearts before and after LVAD support. **B**, Representative Western blot depicting SERCA2a, RyR, and  $\text{Na}^+/\text{Ca}^{2+}$  exchanger (NCX) protein in nonfailing (normal) heart along with samples obtained from individual failing hearts before and after LVAD support. Semi-quantitative densitometric analysis of Western blots with values demonstrated no change in protein levels for RyR and NCX, with a significant increase in SERCA2a following LVAD support. (Modified from Heerd PM, Holmes JW, et al. Chronic unloading by left ventricular assist device reverses contractile dysfunction and alters gene expression in end-stage heart failure. *Circulation* 2000;102:2713-2719.)

a result of dyssynchronous contraction of the left ventricle, thereby engendering LV dysfunction. Thus, both the amount and the organization of the collagen are important determinants of myocardial structure and function in the failing heart.  $\beta$ -blockade with metoprolol significantly decreased replacement fibrosis in a dog model of heart failure.<sup>19</sup> Consistent with this finding, treating patients with dilated cardiomyopathy with  $\beta$ -blockers for 4 months resulted

**FIGURE 8-8** Effect of LVAD support on dystrophin levels in failing hearts. **A**, Immunohistochemical staining with the N-terminal-specific antibody of myocardial sections from a control sample (left), and paired samples from patients with end-stage cardiomyopathy before (middle) and after (right) LVAD support. Immunostaining for the N-terminal portion of dystrophin was present on the myocyte cell membranes of control hearts, absent in cell membranes from cardiomyopathy, and restored in cardiomyopathic hearts following LVAD support. **B**, Semiquantitative staining scores for N-terminal dystrophin in paired samples before and after LVAD support. (Modified from Vatta M, Stetson SJ, Perez-Verdia A, et al. Molecular remodelling of dystrophin in patients with end-stage cardiomyopathies and reversal in patients on assistance-device therapy. *Lancet* 2002;359:936-941.)

in decreased myocardial collagen type I and III mRNA expression in paired myocardial RV biopsy samples.<sup>72</sup> Experimental studies suggest that ACE inhibitors reduce collagen deposition in the failing myocardium in various models of heart failure, and this salutary effect is mediated, at least in part, by kinins.<sup>73,74</sup> Similarly, treatment of patients with ischemic cardiomyopathy with captopril resulted in

**FIGURE 8-9** Effect of the duration of LVAD support on myocardial collagen content. Trichrome-stained sections of LV free wall demonstrating relative myocardial collagen content for (A) normal, (B) non-LVAD, and (C) LVAD<sub>40+day</sub> groups. D, Relative myocardial collagen content versus duration of LVAD support (squares, LVAD<sub>0-40</sub> days; triangles, LVAD<sub>40+day</sub>; diamonds, non-LVAD; circles, normal; dashed line). (Modified from Madigan JD, Barbone A, Choudhri AF, et al. Time course of reverse remodeling of the left ventricle during support with a left ventricular assist device. *J Thorac Cardiovasc Surg* 2001;121(5):902-908.)

decreased total collagen content, decreased collagen type III levels, and normalization of the collagen type I:III ratio, when compared with untreated heart failure patients.<sup>75</sup> Angiotensin receptor type I (AT<sub>1</sub>) receptor blockers also reduce myocardial collagen content in experimental heart failure models; however, this decrease was not attenuated by blockade of the bradykinin B<sub>2</sub>-receptor, suggesting that antagonism of the renin-angiotensin system alone is sufficient to reverse myocardial fibrosis.<sup>74</sup> Treatment with eplerenone in a dog model of heart failure significantly attenuated LV collagen volume fraction by reducing both interstitial and replacement fibrosis<sup>76</sup> and normalized mRNA and protein expression of MMPs 1, 2, and 9, but had no effect on mRNA levels of TIMP-1,2.<sup>77</sup>

Mechanical circulatory support with LVADs also leads to important changes in the extracellular matrix and myocardial fibrillar content and organization. There are conflicting reports on the effect of LVAD support on LV myocardial collagen content, with several reports showing increased myocardial collagen content relative to levels observed in failing hearts that have not been supported with LVADs,<sup>26,78-81</sup> while other reports suggest that the collagen volume fraction decreases.<sup>82,83</sup> Although the reason(s) for this discrepancy is not known, it may be related to difference in heart failure cause and, differences in the degree of inotropic and/or pharmacological support and the duration of LVAD support. Of note, one report suggests that a longer duration of LVAD support results in increased myocardial collagen volume fraction in a time-dependent manner (Figure 8-9).<sup>23</sup> The biological basis for these changes is suggested by two studies which show that LVAD support resulted in decreased levels of MMP 1, 9 and increased expression of TIMP-1,2, resulting in decreased MMP-1/TIMP-1 ratio (favoring collagen accumulation), and an increase in the ratio of insoluble to total soluble collagen (a measure of collagen cross-linking).<sup>78,79</sup> Moreover, these changes were partially abrogated by concomitant therapy with ACE inhibitors during the period of LVAD support.<sup>84</sup> Serial myocardial biopsies from heart failure patients revealed a significant reduction in the collagen volume fraction following CRT,<sup>28,85</sup> with a significant decrease in MMP-9 levels in the group of patients who underwent reverse remodeling (i.e., “responders”).<sup>86</sup> Passive cardiac restraint has been shown to reduce collagen volume fraction and to preserve the integrity of the collagen cross-links between cardiomyocytes (Figure 8-10).<sup>87</sup>

**FIGURE 8-10** Scanning electron micrographs of the interstitial space between two adjacent myocytes (M) from left ventricular myocardium of a normal dog (top), a dog with heart failure that was not treated (middle), and a dog with heart failure treated for 3 months with the cardiac support device. Note the tangential or oblique orientation (arrow) of the matrix cross-links in the untreated heart failure dog compared with the normal suggestive slippage and the restoration of near normal cross-linking integrity following CSD therapy. (Modified from Sharov VG, Todor AV, Sabbah HN. Left ventricular histomorphometric findings in dogs with heart failure treated with the Acorn Cardiac Support Device. *Heart Fail Rev* 2005;10:141-147.)

## Angiogenesis

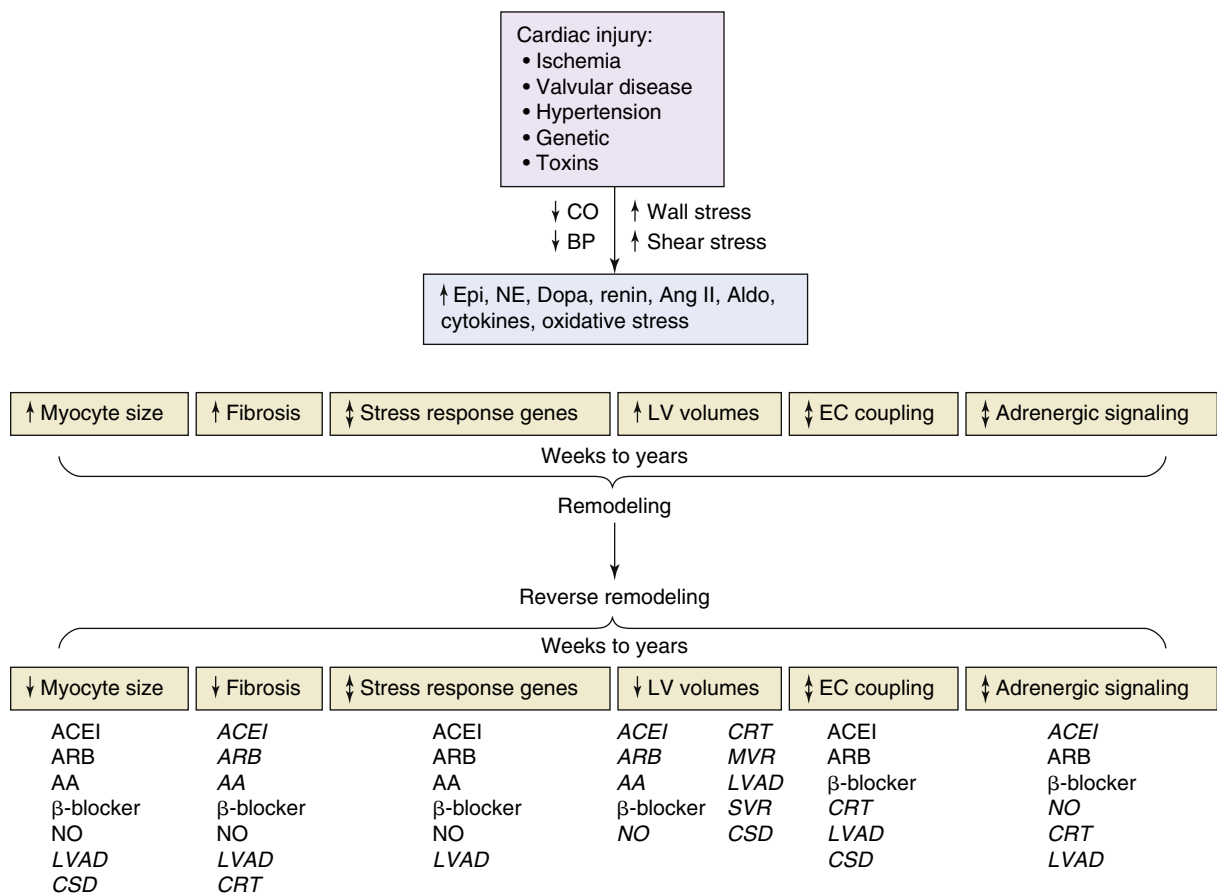

Cardiac hypertrophy and angiogenesis are coordinately regulated during physiological cardiac growth.<sup>88</sup> Disruption of this coordinated growth stress following hemodynamic overload

and/or cardiac injury may lead to contractile dysfunction and cell death, both of which may contribute to the development of heart failure. Of note, myocardial capillary density is reduced in patients with dilated cardiomyopathy.<sup>89,90</sup> Thus impaired capillary growth may contribute to the development and/or progression of heart failure. Experimental studies suggest that myocardial capillary density is restored toward normal values following treatment with pharmacological therapies that have been shown to improve patient outcomes in heart failure.<sup>19,74,76</sup> Moreover, some of these same therapies also lead to improved myocardial blood flow in patients with heart failure.<sup>91-93</sup> Whether the improved myocardial blood flow is related to increased angiogenesis, altered hemodynamic loading conditions, or both is not known. Analysis of changes in gene expression before and after LVAD support revealed significant alterations in genes that are involved in the regulation of vascular networks, including upregulation of Sprouty-1 and downregulation of neurophilin (VEGF receptor), stromal derived factor-1, FGF9, and endomucin.<sup>94</sup> Sprouty-1 was immunolocalized to the microvasculature, and the upregulation of Sprouty-1 in endothelial cells was associated with a decrease in VEGF-induced endothelial proliferation, which suggests that Sprouty-1 may serve as an intrinsic mediator of cardiac remodeling by regulating angiogenesis.<sup>94</sup> Studies in heart failure patients who underwent CRT revealed increased myocardial capillary density and an improvement in the distribution pattern of myocardial blood flow.<sup>85,95</sup> Sabab et al have demonstrated enhancement of capillary density, and upregulation of angiogenetic factors bFGF and VEGF

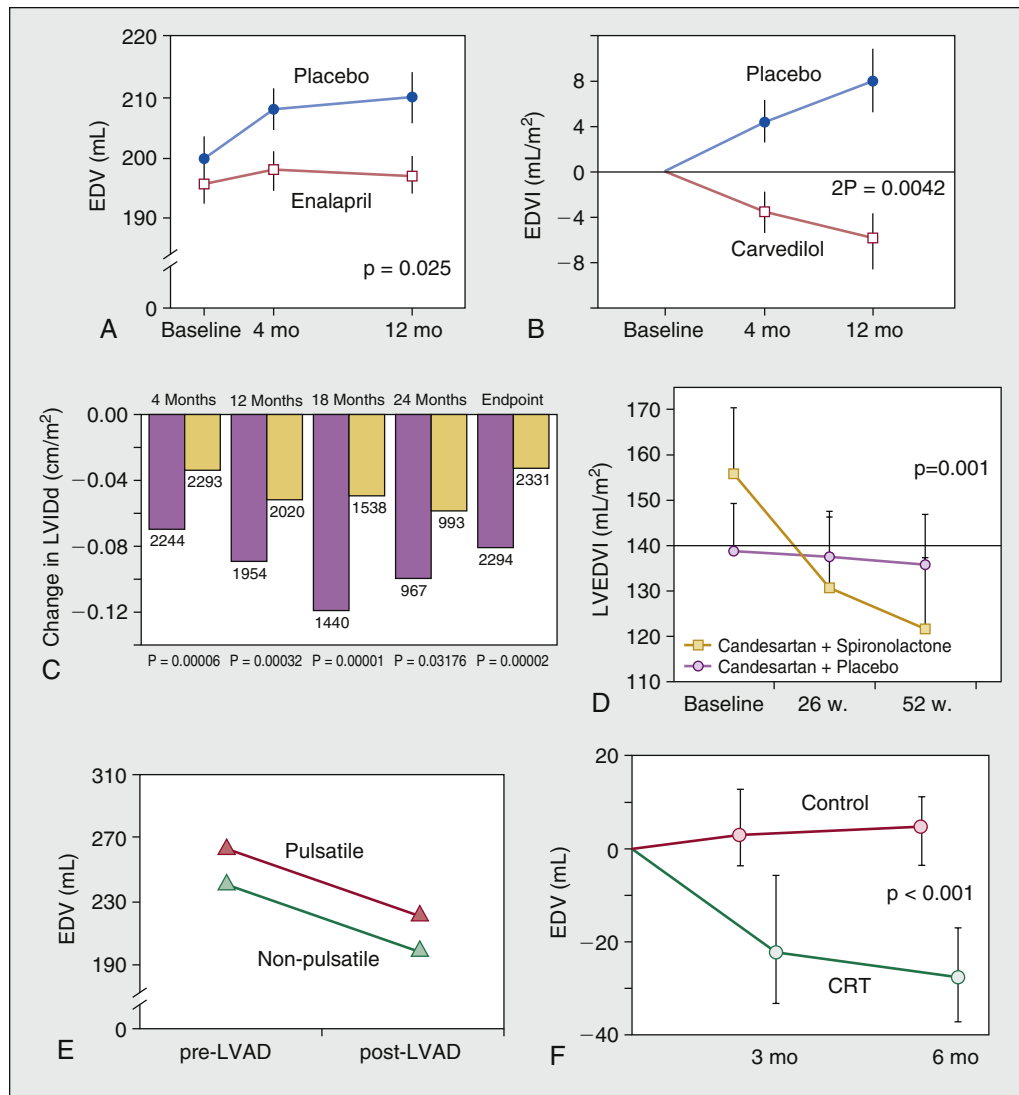

mRNA following treatment with a cardiac support device in a canine model of heart failure.<sup>96,97</sup>

CHANGES IN LEFT VENTRICULAR GEOMETRY DURING MYOCARDIAL RECOVERY

As noted previously, clinical studies with ACE inhibitors,  $\beta$ -blockers, aldosterone antagonists, LVADs, and CRT have shown that these treatment modalities lead to return of cardiac myocyte biology toward normal, and to changes in the extracellular matrix that favor increased structural integrity of the heart and reverse remodeling (Figure 8-11). In the following section, we will review the literature that shows that drugs and devices that favorably impact clinical outcomes are accompanied by reverse LV remodeling. As shown in Figure 8-12, A, treatment with ACE inhibitors prevented worsening LV remodeling but did not lead to reverse remodeling in a substudy of SOLVD,<sup>6</sup> whereas treatment with  $\beta$ -blockers resulted in decreased LV end-diastolic volumes when compared with a placebo (diuretics and ACE inhibitors) in a substudy of the ANZ (Australia New Zealand) trial (see Figure 8-12, B).<sup>98</sup> In an echocardiographic substudy of the Val-HeFT (Valsartan in Heart Failure) trial, treatment with valsartan added to an ACE inhibitor and/or  $\beta$ -blocker significantly resulted in decreased LV internal diastolic diameter (LVIDd)/body surface area from 4 months to more than 24 months (see Figure 8-12, C).<sup>99</sup> Similarly, the addition of spironolactone to

**FIGURE 8-11** Structural, molecular, and cellular changes after cardiac injury leading to remodeling and those therapies that have been shown to contribute to reverse remodeling. Therapies that have been shown in humans to alter the specific reverse remodeling subheadings are bold and italicized. (Key: AA, aldosterone antagonists; ALB, angiotensin-converting enzyme inhibitor, Aldo, aldosterone; Ang II, angiotensin II; ARB, angiotensin receptor blocker; BP, blood pressure; CO, cardiac output; CRT, cardiac resynchronization; CSD, cardiac support device; Dopa, dopamine; EC, excitation-contraction; Epi, epinephrine; LVADL, left ventricular assist device; MVR, mitral valve repair; NE, norepinephrine; NO, nitric oxide; SVR, surgical ventricular restoration). (From Mudd JO, Kass DA. Reversing chronic remodeling in heart failure. *Expert Rev Cardiovasc Ther* 2007;5:585-598.)

**FIGURE 8-12** Reverse cardiac remodeling following pharmacological and device therapies in patients with heart failure. **A**, Changes in LV end-diastolic volume in placebo- and enalapril-treated patients in SOLVD compared with a placebo. **B**, Changes in LV volume index from baseline during the 12-month follow-up period in the ANZ trial compared with a placebo. **C**, Changes in LV end-diastolic dimension in patients treated with valsartan added to an ACE inhibitor and/or  $\beta$ -blocker significantly resulted in decreased LV internal diastolic diameter (normalized to body surface area [BSA]). **D**, Changes in LV volume index in patients treated with spironolactone and candesartan compared with candesartan alone. **E**, Changes in LV end-diastolic volume in pulsatile versus continuous flow LVADs. **F**, Change in LVEDV at 3 and 6 months after CRT compared with the control group in the MIRACLE trial. (A-F modified, respectively, from Greenberg B, Quinones MA, Koilpillai C, et al. *Circulation* 1995;91:2573-2581; Doughty RN, Whalley GA, Gamble G, et al. Left ventricular remodeling with carvedilol in patients with congestive heart failure due to ischemic heart disease. *J Am Coll Cardiol* 1997;29:1060-1066; Wong M, Staszewsky L, Latini R, et al. Valsartan benefits left ventricular structure and function in heart failure: Val-HeFT echocardiographic study. *J Am Coll Cardiol* 2002;40:970-975; Chan AK, Sanderson JE, Wang T, et al. Aldosterone receptor antagonism induces reverse remodeling when added to angiotensin receptor blockade in chronic heart failure. *J Am Coll Cardiol* 2007;50:591-596; Klotz S, Deng MC, Stypmann J, et al. Left ventricular pressure and volume unloading during pulsatile versus nonpulsatile left ventricular assist device support. *Ann Thorac Surg* 2004;77:143-149; modified from St John Sutton MG, Plappert T, Abraham WT, et al. Effect of cardiac resynchronization therapy on left ventricular size and function in chronic heart failure. *Circulation* 2003;107:1985-1990.)

candesartan resulted in a significant decrease in the LV volume index at 1 year when compared with candesartan alone (see Figure 8-12, D).<sup>100</sup>

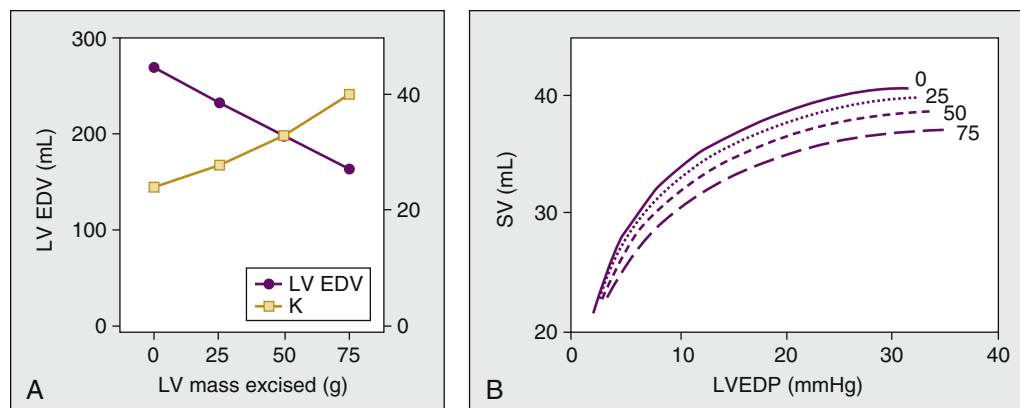

Device therapies also lead to reverse remodeling of the ventricle. Although pulsatile-flow devices provide a greater degree of ventricular unloading than continuous-flow devices,<sup>101</sup> the continuous-flow LVADs appear to be as effective as pulsatile-flow LVADs with regard to the degree of LV reverse remodeling (see Figure 8-12, E).<sup>101,102</sup> As noted previously, the initial clinical experience with mechanical assist devices demonstrated that there were varying degrees of structural and functional recovery of myocyte and myocardial recovery that are associated with reverse remodeling. The improvement in LV function was sufficient to allow explantation of the device in approximately 5% to 9% of explanted

patients.<sup>103,104</sup> However, although cardiac function improves significantly after device implantation, and although there is cellular recovery and favorable remodeling of the extracellular matrix, the degree of clinical recovery is insufficient for device explantation in most patients with chronic heart failure. In the MIRACLE (Multicenter In-Synch Randomized Clinical Evaluation) trial, CRT led to improvements in LVEF, mitral regurgitant area, and LV end-diastolic diameter at 6 months in patients with moderate to severe heart failure and prolonged QRS (see Chapter 47).<sup>105</sup> Similar findings have been reported in the MUSTIC (Multisite Stimulation in Cardiomyopathy) and CARE-HF (Cardiac Resynchronization in Heart Failure) studies, which employed a longer follow-up period (see also Chapter 47).<sup>106,107</sup> Passive cardiac restraint in the Acorn Randomized Trial showed that there

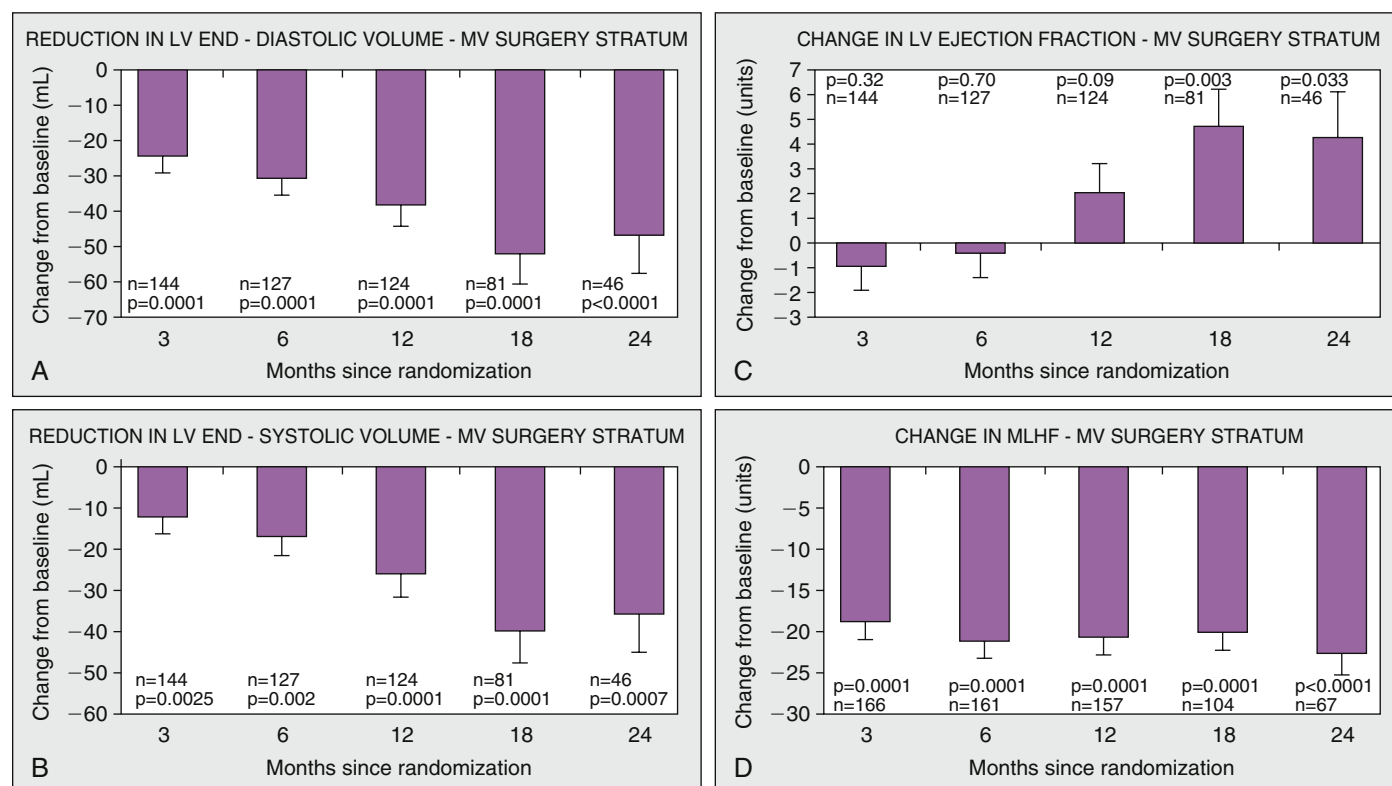

was a significant reduction in LV end-diastolic volume over the 12-month course of the study,<sup>108</sup> which was sustained at 3 years in patients with and without concomitant mitral valve surgery.<sup>109</sup>

In addition to the drugs and devices discussed previously, a variety of surgical techniques have been introduced to reverse the maladaptive ventricular remodeling in patients with heart failure. As discussed in Chapter 23, myocardial revascularization should be considered in patients with evidence of myocardial viability and depressed LV dysfunction. Clinical studies have demonstrated an increase in EF and a decrease in LV volume indices in patients with

ischemic cardiomyopathy following coronary artery bypass surgery.<sup>110,111</sup> Partial left ventriculectomy, which was a technique developed by Batista in the early 1990s, involves surgical removal of part of the left ventricle to reduce LV volumes. While an interesting hypothesis, studies ultimately found this technique was ineffective,<sup>112</sup> suggesting that changes in volume alone are not sufficient to allow the heart to recover. One additional explanation that has been provided for the lack of efficacy of partial ventriculectomy is that acute reductions in LV mass result are accompanied by unfavorable changes in the diastolic properties of the ventricle (i.e., increased stiffness [Figure 8-13]), which in turn negatively affects the

**FIGURE 8-13** Effects of excision of LV mass from 0 to 75 g on LV diastolic distensibility and LV function. **A**, LV end-diastolic volume (LV EDV; filled circles) and the LV stiffness coefficient of the end-diastolic pressure-volume relation (K; open squares) as a function of LV mass excised. This measurement reflects the decrease in chamber compliance associated with LV mass reduction. **B**, Frank-Starling relationship relating stroke volume to LVEDP at the four mass reduction conditions (0 to 75 g of tissue excision). Notice that mass reduction is associated with a downward shift of the Frank-Starling curves, indicating a reduction in pump function. (From Dickstein ML, Spotnitz HM, Rose EA, et al. Heart reduction surgery: an analysis of the impact on cardiac function. *J Thorac Cardiovasc Surg* 1997;113:1032-1040.)

**FIGURE 8-14** Clinical outcomes in mitral surgery treatment arm in the Acorn Trial. **A**, Change in LV end-diastolic volumes; **B**, change in LV end-systolic volumes; **C**, change in LVEF; **D**, change in Minnesota Living with Heart Failure (MLHF) score. (From Acker MA, Bolling S, Shemin R, et al. Mitral valve surgery in heart failure: insights from the Acorn clinical trial. *J Thorac Cardiovasc Surg* 2006;132:568-577.)

Frank-Starling relationship (see Figure 8-13, B).<sup>113</sup> Surgical ventricular reconstruction of the left ventricle (SVR) is a specific surgical procedure that was developed for the treatment of LV dysfunction in patients with large akinetic areas of non-viable myocardium secondary to coronary artery disease (see Chapter 55). Despite encouraging early results in nonrandomized studies, which showed that SVR could improve patient symptoms and reduce end-diastolic volumes,<sup>114</sup> the NIH sponsored STICH trial (Surgical Treatment for Ischemic Heart failure) that compared coronary artery bypass grafting (CABG) versus CABG with SVR, failed to show an improvement in patient symptoms or exercise tolerance or a reduction in the rate of death or hospitalization for cardiac causes.<sup>111</sup> Various explanations have been provided for the failure of SVR to improve clinical outcomes in STICH, including inappropriate patient selection, lack of a standardized surgical approach, and decreased diastolic distensibility from undersizing the left ventricle. Correction of functional mitral regurgitation in patients with ischemic cardiomyopathy was first described by Bolling et al to treat the functional regurgitation that develops in patients with heart failure (Chapter 55). Subsequent studies by this group demonstrated that there were improvements in LV volumes, EF, and the sphericity index as assessed over 1 year by echocardiography.<sup>115</sup> And indeed, similar findings were observed in the Acorn trial (Figure 8-14).<sup>116</sup> However, although mitral valve repair is technically feasible, and has been associated with improved patient quality of life (see Figure 8-14, D), long-term outcomes have not been shown to confer a mortality benefit for mitral valve annuloplasty as a primary treatment for patients with LV dysfunction.<sup>117</sup>

## SUMMARY AND FUTURE DIRECTIONS

Currently available medical and device therapies for heart failure have consistently demonstrated the reversibility of the abnormal biology of the failing cardiac myocyte, reversibility of the unfavorable changes in the composition of the extracellular matrix, and the adverse geometry of the failing heart, indicating that the heart failure phenotype exhibits remarkable “plasticity” (see Figure 8-11). This statement notwithstanding, it bears emphasis that although the various components of the phenomenon of reverse remodeling have been studied carefully and characterized meticulously in experimental and clinical studies, it is unclear how these changes contribute to restoration of normal LV structure and function. That is, we simply do not understand what the essential biological “drivers” of reverse remodeling are, nor do we understand how they are coordinated. For example, it is not known whether changes in the biology of the myocyte precede, follow, or occur *pari passu* with changes in the extracellular matrix as the end-diastolic pressure volume curve shifts leftward and LV volume decreases. Moreover, it is unclear which of the changes in the biology of the myocyte is essential for the return of function in isolated failing cardiac myocytes and which of the changes is unrelated to recovery. Another question is why the heart failure phenotype is reversible at the level of the cell, the tissue, and the intact failing heart following mechanical circulatory support, and yet the number of patients who undergo sustained myocardial recovery following withdrawal of LVAD support is less than 10%. As noted previously, the reasons for this observation are unclear, but may be related to an inadequate volume of remaining functional myocytes to sustain pump function. Alternatively, there may be a degree of “hysteresis” during the process of reverse remodeling, such that the reverse remodeled ventricle is less able to withstand the same degree of hemodynamic overloading as a ventricle that has never undergone remodeling. The quest for the answers to these important questions extends well beyond simple intellectual curiosity about the biology of heart failure. Indeed, the

answers to these questions may allow for the development of therapies that directly target myocardial recovery, rather than continuing to target signaling pathways that attenuate remodeling (see Chapter 15). Given the complexities of the biology of reverse remodeling outlined in the foregoing chapter, it is likely that the learning curve will be extremely steep, now and for the foreseeable future.

# Activation of the Renin-Angiotensin System in Heart Failure

Rajesh Kumar, Kenneth M. Baker, and Jing Pan

## THE RENIN-ANGIOTENSIN SYSTEM

The renin-angiotensin system (RAS) is a major determinant of cardiovascular and renal function. RAS inhibitors often provide the first line of treatment for hypertension, afterload reduction, and prevention and treatment of heart failure (see Chapter 45).<sup>1</sup> In the simplest form, the RAS consists of a cascade of enzymatic reactions involving three components: angiotensinogen (Ao), renin, and angiotensin-converting enzyme (ACE), which generate angiotensin (Ang) II as the biologically active product. Ang II

### Angiotensinogen

Ao is a 485–amino acid protein with an N-terminal signal peptide, which is cotranslationally removed to yield the 452–amino acid mature protein, the only known substrate for renin. Though Ao is expressed in multiple tissues, plasma Ao levels are determined primarily by the rate of production by hepatocytes, which constitutively secrete Ao.<sup>12</sup> Circulating levels of Ao are close to the Michaelis constant for renin; thus a small increase in Ao will increase Ang II synthesis and blood pressure.<sup>13</sup> Several studies in genetically modified mice and rats have demonstrated hypertensive effects of increasing Ao gene copy number or overexpression.<sup>14,15</sup> Ao occurs in unglycosylated and multiple glycosylated forms, the significance of which is not entirely known.<sup>16</sup> A variety of stimuli regulate circulating levels of Ao, including glucocorticoids, estrogens, thyroid hormone, insulin, and several cytokines.<sup>17,18</sup> Ang II exerts positive feedback regulation on Ao expression through the AT<sub>1</sub>R.<sup>19–21</sup> Polymorphisms in the Ao gene have been reported, which affect transcriptional regulation of the gene and may provide a genetic mechanism for hypertension.<sup>22</sup>

### Renin

Juxtaglomerular cells, in the terminal afferent arteriole of the kidneys, are the major source of circulating renin. Renin is synthesized as pre-prorenin, which is converted into prorenin after removal of the signal peptide during transfer to the endoplasmic reticulum. Prorenin, which is enzymatically inactive, is proteolytically activated by removal of the 43–amino acid prosegment to produce renin. The prosegment can also be displaced nonproteolytically by low pH or binding to a newly discovered specific receptor<sup>23</sup> to expose the catalytic site. Juxtaglomerular cells constitutively secrete the majority of prorenin, with the remainder targeted at dense core secretory granules, where the prosegment is removed and renin is released in a regulated manner.

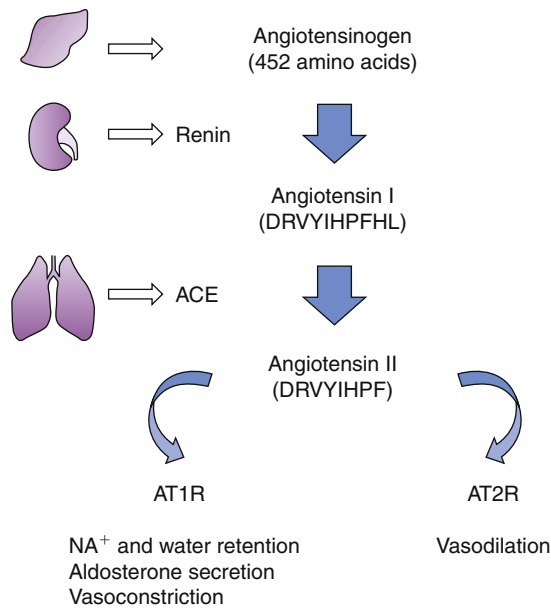

binds to two types of specific receptors, angiotensin type-1 (AT<sub>1</sub>R) and type-2 (AT<sub>2</sub>R). Both receptors belong to the family of seven transmembrane domain, heterotrimeric G protein–coupled receptors (GPCR). The majority of the deleterious actions of Ang II have been attributed to interaction with the AT<sub>1</sub> receptor, which is the predominant receptor in adult tissues, while AT<sub>2</sub> generally produces beneficial effects.<sup>2</sup> Several classes of drugs have been developed to block the RAS, either at the level of Ang II synthesis, by inhibiting the enzymatic reactions catalyzed by renin or ACE, or by preventing Ang II interaction with the AT<sub>1</sub>R.

The most proximal component of the RAS, renin, was identified more than 100 years ago by Tigerstedt and Bergman.<sup>3</sup> Discoveries in the past 2 decades have resulted in characterization of the RAS, as both systemic and local or tissue systems.<sup>4</sup> The relative contribution of the systemic versus a local RAS to various cardiovascular pathologies, such as hypertension and heart failure, is still being debated.<sup>5</sup> In addition to categorization, several new aspects of the RAS have been identified, which include novel angiotensin peptides, enzymes that catalyze synthesis of these peptides, receptors for these novel peptides, and new roles for renin and prorenin.<sup>6–9</sup>

## THE SYSTEMIC RAS

The systemic RAS is also known as the classical, circulatory, or endocrine RAS, with Ao and renin secreted into the circulation from the liver and kidneys (juxtaglomerular apparatus), respectively, and the final step of Ang II synthesis occurring in the circulation by the action of ACE (membrane bound on endothelial cells), which results in conversion of the decapeptide Ang I to Ang II (Figure 9-1). Circulating Ao and renin appear to contribute to Ang II synthesis locally at tissue sites, blurring the distinction between the systemic and local systems.<sup>10</sup> The circulating RAS is mainly involved in acute responses to maintain plasma volume and electrolyte homeostasis. These include vasoconstriction, a direct effect on tubular sodium reabsorption and aldosterone secretion. Though some of the previously described effects could be attributed to the local RAS in kidneys, recent studies have addressed this issue using tissue-specific knockout of AT<sub>1</sub>R. It appears that while both renal and vascular AT<sub>1</sub>R contribute equally toward the maintenance of normal blood pressure, the hypertensive effects of Ang II require AT<sub>1</sub>R in the kidney.<sup>11</sup>

**FIGURE 9-1** The systemic renin-angiotensin system. The systemic RAS is comprised of liver-derived Ao, kidney-derived renin, and endothelium-derived ACE. The latter is particularly abundant in pulmonary endothelial cells. The sequential action of renin and ACE on Ao produces the octapeptide Ang II in the circulation. Ang II acts via binding to AT<sub>1</sub>R and AT<sub>2</sub>R, which generally produce opposite effects. AT<sub>1</sub>R is the predominant receptor in adult tissues. The systemic RAS is involved in acute effects to maintain salt and water homeostasis and blood pressure.

Recent evidence suggests that collecting ducts, in addition to juxtaglomerular cells, are an important source of circulating prorenin in diabetes.<sup>24</sup> Pregnant women have high levels of circulating prorenin, which is largely from the ovaries.<sup>25</sup> There is no evidence of extrarenal proteolytic conversion of prorenin to renin; thus the physiological role of circulating prorenin has been uncertain until the recent discovery of the (pro)renin receptor,<sup>23</sup> which will be described later.

Renin synthesis and secretion are promoted by low blood pressure, sympathetic stimuli, and prostaglandins, and are inhibited by high blood pressure, salt, and volume overload.<sup>26</sup> Ang II also exerts a negative feedback on renin production by the juxtaglomerular cells,<sup>27</sup> which is the reason for the observed reactive rise in renin with RAS blockade.

### Angiotensin-Converting Enzyme

ACE is a dicarboxypeptidyl peptidase of 150 to 180 kDa, which cleaves the two terminal amino acids off of the decapeptide angiotensin I (Ang I), a product of the Ao and renin reaction, to form the octapeptide Ang II. Unlike renin, ACE is not specific to a single substrate but cleaves several peptides such as bradykinin, substance P, and the tetrapeptide *N*-acetyl-Ser-Asp-Lys-Pro (Ac-SDKP).<sup>28</sup> Some of the beneficial effects of ACE inhibitors have been attributed to prevention of bradykinin and Ac-SDKP degradation. In addition to vascular endothelial cells of lung, retina, and brain, ACE is also highly expressed on the proximal tubular brush border of epithelial cells in the kidneys.<sup>29</sup> While most ACE is anchored to the cell membrane by a C-terminus hydrophobic region, shedding of ACE releases active enzyme into various body fluids. The extracellular region of ACE contains two homologous and independent catalytic domains termed N- and C-domains. An isoform of ACE that contains only the C-domain is expressed in the testis, resulting in categorization of ACE as somatic and testis ACE. A recent study in genetically modified mice has shown that the C-domain of ACE is the predominant site of Ang I cleavage *in vivo*.<sup>30</sup>

Localization of ACE on endothelial cell membranes generates Ang II in close proximity to vascular smooth muscle, which is important for vasoconstrictive effects of the peptide. ACE knockout mice have low blood pressure, with hematopoietic and developmental defects.<sup>31</sup>

### THE LOCAL RAS

In the past 2 decades, it has become evident that several tissues, other than those that contribute to the circulating RAS, express all components of the RAS and generate Ang II locally at tissue sites. This has been most clearly demonstrated in the brain, where circulating components cannot enter due to the blood-brain barrier. The benefits of RAS inhibitors, which cannot be explained solely on the basis of blood pressure reduction, strengthened the concept of local generation and effects of Ang II. Advancements in research technology, due to the availability of transgenic and knockout animal models (of RAS components), further confirmed the significance of the local RAS in various pathologies. Local RASs have tissue-specific roles and are regulated independently of the circulating system. The major controversy associated with local RASs is regarding the expression of renin in extrarenal tissues, particularly the heart. However, this has not really undermined the concept of a local RAS, as alternative enzymes, such as cathepsins and chymase, have been identified in several tissues, and which are involved in the conversion of Ao to Ang II. A local RAS has convincingly been demonstrated in the brain, heart, vasculature, kidneys, eyes, pancreas, reproductive organs, and lymphatic and adipose tissues.<sup>4</sup> Recent evidence has indicated that while the circulating RAS exerts acute hemodynamic effects, the tissue RASs are involved in long-term effects of chronic RAS activation associated with target organ damage, such as renal failure and cardiac remodeling.<sup>4</sup> Local system functions of the RAS include cell growth and remodeling in the heart, regulation of blood pressure, central effects on food and water intake, and hormone secretion in the pancreas.<sup>32</sup>

### The Cardiac RAS

Most evidence supports cardiac Ang II as being synthesized *in situ* and not originating by uptake from the circulation (Figure 9-2). A quantitative study using radiolabeled Ao infusion has shown that more than 90% of cardiac Ang I and 75% of cardiac Ang II are synthesized at cardiac sites.<sup>33</sup> The RAS precursor components for Ang II biosynthesis are present in both cardiac myocytes and fibroblasts.<sup>34</sup> The interstitial concentration of Ang II in the heart is about 100-fold more than that of plasma, though the myocardial concentration of renin and Ao is only 1% to 4% that of plasma.<sup>35,36</sup> There is debate as to which and in what amount RAS components are synthesized locally or are taken up from the plasma. Much of the controversy surrounds the source of renin in the heart.<sup>10</sup> Active uptake from the plasma by endothelial cells, cardiomyocytes, and fibroblasts, in addition to *de novo* synthesis, has been proposed.<sup>37-39</sup> Two uptake mechanisms have been described: one that is mediated by the mannose-6-phosphate receptor and another that is not.<sup>40</sup> The former mainly represents a clearance mechanism of circulating glycosylated prorenin by heart cells, while the latter involves uptake of nonglycosylated prorenin and results in intracellular generation of angiotensin peptides.<sup>41</sup> Emerging evidence suggests that under specific conditions renin is synthesized in cardiovascular tissues. Renin mRNA has been detected in cardiac atria, ventricles, and primary cultures of neonatal and adult rat ventricular myocytes.<sup>34,42</sup> Increased cardiac levels of renin mRNA have been reported in patients following myocardial infarction and in the ventricles of animals with experimental

**FIGURE 9-2** The cardiac renin-angiotensin system. The cardiac RAS is defined by interstitial Ang II synthesis and direct actions in the heart. A small contribution of circulatory Ang II may also be relevant in addition to the locally synthesized pool. Cardiac cells may also sequester (pro)renin from the circulation. The latter would bind to specific (pro)renin receptors on cardiac cells and convert locally produced Ao to Ang I, which is further cleaved to form Ang II by the actions of membrane-bound ACE. Both types of angiotensin receptors, AT<sub>1</sub> and AT<sub>2</sub>, are expressed on cardiac cells. The major effects of Ang II in the heart include cardiac myocyte hypertrophy, cardiac fibroblast proliferation, oxidative stress, and extracellular matrix deposition.

models of infarction.<sup>43</sup> Renin mRNA and protein have been detected in canine cardiac myocytes, the levels of which are upregulated by ventricular-pacing-induced cardiac failure.<sup>44</sup> A second renin transcript, lacking the coding region for the secretory signal peptide and termed Exon 1A renin, has been detected in the brain, adrenal glands, and heart.<sup>45</sup> Interestingly, Exon 1A renin is the only transcript of renin expressed in the heart. The latter observation may help to explain the discrepancy in the literature regarding cardiac renin expression. Methods used in studies with negative results might not have detected this newly identified transcript. Interestingly, this potentially intracellular renin coding mRNA is upregulated in the left ventricle following myocardial infarction.<sup>45</sup> Thus the possibility of two cardiac RASs has been suggested, one the intracardiac RAS, and another an intracellular RAS driven by Exon 1A renin.<sup>41</sup>

The local production of Ao and ACE is less controversial. Ao mRNA and protein have been detected in human, dog, and rat heart, and in rat cardiac myocytes and fibroblasts in primary cell culture.<sup>34</sup> Upregulation of the Ao gene in the heart, in an experimental model of pressure overload, has been reported.<sup>46</sup> ACE has been detected in the human and rat heart, with higher amounts in atria compared with the ventricles.<sup>47,48</sup> Endothelial cells and fibroblasts appear to be the major cell types of the heart that express ACE. ACE has also been detected in primary cultures of adult and neonatal cardiac myocytes.<sup>42,49</sup> There also exist other enzymes such as cathepsins and chymase that can substitute for renin and ACE in the processing of Ao in the heart. Cathepsin D has been shown to increase in cardiac myocytes from failing, paced canine hearts, and cathepsin G was increased in mast cells of failing hearts in humans.<sup>44,50</sup> The role of cathepsin D involvement in Ang II generation is evident in VSMC, where cathepsin D is the predominant aspartic proteinase.<sup>51</sup> Cathepsin D participates in enhanced Ang II synthesis in response to high glucose or a change in VSMC, from the contractile to a synthetic phenotype.<sup>52,53</sup> Cathepsin D cleaves Ao into Ang I and chymase converts Ang I to Ang II. Chymase is highly specific for Ang I and does not degrade bradykinin and vasoactive intestinal peptide. In myocardial extracts from human and dog, chymase accounted for approximately 90% of Ang II forming activity; however, the contribution in intact tissue is not clear.<sup>54,55</sup> Dual pathways of Ang II generation, by chymase and ACE, were demonstrated to have an important role in cardiac remodeling, in pressure-overloaded hamster hearts, and in transgenic mice overexpressing human chymase in the heart.<sup>56,57</sup> Using an ACE-resistant Ang I peptide, a role for chymase-mediated Ang II generation in vasoconstriction in

human dorsal hand veins has been demonstrated.<sup>58</sup> In addition to Ang II formation, chymase can produce Ang II-independent effects through conversion of latent TGF- $\beta$  to active TGF- $\beta$  and type-1 procollagen to collagen.<sup>59</sup> Consistent with an active role of chymase in cardiac remodeling, specific chymase inhibitors have been shown to have protective effects in animal models of myocardial infarction, cardiomyopathy, and tachycardia-induced heart failure.<sup>60</sup> Thus alternative pathways of Ang II synthesis are present in the heart; though it remains unclear in which situations renin-independent or ACE-independent Ang II synthesis occurs.

Cardiac RAS activity is under the control of tissue-specific regulatory influences and differs from that of the systemic RAS. For example, an increase in left ventricular mass produced by abdominal aortic constriction can be prevented by an ACE inhibitor with no change in afterload.<sup>61</sup> The activity of the cardiac RAS is influenced by several pathophysiological conditions. Volume overload is associated with increased expression of renin and ACE, while pressure overload increases the expression of Ao and AT<sub>1</sub>.<sup>34</sup> Mechanical stretch of cardiac myocytes increases Ang II release from cells.<sup>62</sup> Ao gene expression is increased in the heart by cardiotrophin-1, glucocorticoids, estrogen, and thyroid hormone.<sup>34,63</sup> Ang II stimulates the production of atrial natriuretic peptide, which in turn regulates renin and Ao mRNA levels.<sup>34</sup> Ang II has a differential effect on renin and Ao expression in cardiac myocytes and fibroblasts, positively regulating the former, while negatively regulating the latter.<sup>62,64</sup> Together, these observations suggest that the cardiac RAS represents a self-sustaining paracrine/autocrine loop, involving both cardiac myocytes and fibroblasts.<sup>65</sup>

### The Intracellular Cardiac RAS

In addition to the systemic and local RAS, recent studies have provided evidence of a complete, functional RAS within cells, described as an “intracrine” or intracellular RAS (Figure 9-3).<sup>7</sup> The intracellular RAS is characterized by the presence of the components inside the cell, synthesis of Ang II intracellularly, and actions of Ang II originating from the intracellular location. As alluded to earlier, Ao and renin are generally secreted from the cells in which synthesis occurs, making the concept of the intracellular synthesis of Ang II seem implausible. However, recent studies have demonstrated that under certain conditions, cells redistribute Ao and renin, resulting in intracellular synthesis and retention of Ang II.<sup>66</sup> Alternative enzymes, such as cathepsin D and chymase, may also substitute for renin and ACE, respectively,

**FIGURE 9-3** The intracellular renin-angiotensin system. The intracellular RAS is defined by the synthesis and resultant actions of Ang II inside a cell. The precise intracellular sites of Ang II synthesis and actions are not known. Current evidence suggests that synthesis of Ang II occurs either in secretory vesicles or other cytoplasmic locations, depending on the cell type and nature of the stimulus. Intracellular Ang II likely acts through AT<sub>1</sub>-like receptors on the nuclear envelope, direct chromatin binding, or through unidentified intracellular receptors. Ang II can also likely freely enter the nucleus, owing to the small size (8 amino acids). The effects of intracellular Ang II include cell growth, gene expression, extracellular matrix production, and cardiac hypertrophy.

in an intracellular system.<sup>53</sup> Studies have shown that participation of alternative mechanisms for Ang II synthesis may depend on the stimulus and cell type.<sup>67</sup> Several cells, such as cardiac myocytes, fibroblasts, renal mesangial, and vascular smooth muscle cells (VSMC), have been shown to synthesize intracellular Ang II under hyperglycemic conditions.<sup>53,66,67</sup> Diabetic patients have also been reported to have higher cardiac levels of intracellular Ang II, which are further increased in association with hypertension.<sup>68</sup> In addition to Ang II synthesis, functional intracellular Ang II binding sites have been demonstrated on renal and hepatocyte nuclei and on chromatin.<sup>69-72</sup> Though nuclear Ang II binding sites are AT<sub>1</sub>R-like, the nature of chromatin binding is not known. Coupling of chromatin and nuclear membrane Ang II receptors to increased RNA synthesis and gene transcription of Ao, renin, and platelet-derived growth factor (PDGF) has been demonstrated.<sup>73</sup>

Intracellular actions of Ang II have been termed “intracrine” actions.<sup>74</sup> Intracellular production of Ang II in cultured cardiac myocytes and in the mouse heart using a specific promoter resulted in hypertrophic cell growth and biventricular hypertrophy, respectively.<sup>75</sup> The *in vivo* model was accompanied by an increase in gene expression, but without any change in blood pressure. Microinjection of Ang II into rat VSMC has been shown to increase cytosolic and nuclear Ca<sup>2+</sup> ([Ca<sup>2+</sup>]<sub>i</sub>), which was secondary to an influx of extracellular Ca<sup>2+</sup>.<sup>76</sup> In addition, intracellular Ang II participates in diabetes-induced oxidative stress and cardiac fibrosis in rat hearts. Studies on cultured neonatal rat cardiac myocytes have shown that intracellular Ang II upregulates Ao, renin, and AT<sub>1</sub>R receptor through a positive feedback mechanism.<sup>66</sup> Several of the intracrine effects of Ang II are not blocked by angiotensin receptor blockers (ARBs) due either to limited cell penetration of these drugs or to possible AT<sub>1</sub>R-independent mechanisms.<sup>75,77</sup>

The pathophysiological significance of the intracellular cardiac RAS remains to be determined in the general clinical population.<sup>78</sup> Diabetes is a major stimulus for the activation of the intracellular RAS. Since cardiac myocyte Ang II synthesis in diabetes is chymase dependent and intracellular Ang II effects are not blocked by ARBs, therapeutic modalities, other than ARBs and ACE inhibitors, that would block intracellular synthesis or intracrine effects of Ang II, might provide a better outcome in diabetic patients, by reducing end organ damage.

## NOVEL ASPECTS OF THE RAS

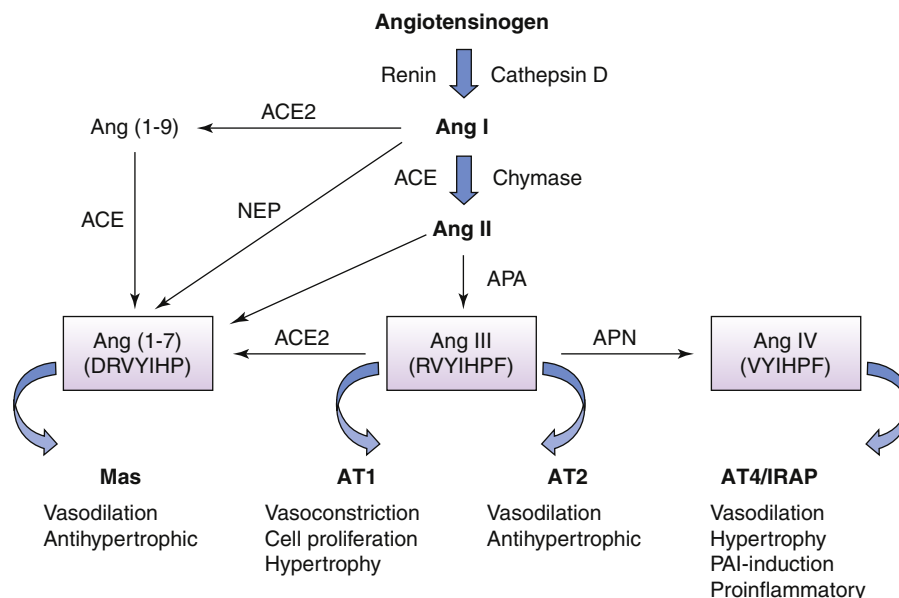

Ang II has traditionally been considered the biologically active end product of the RAS. Recent evidence indicates that additional shorter chain angiotensins also serve as effector peptides in this system (Figure 9-4). These shorter chain peptides include Ang (1-7), a heptapeptide that lacks the C-terminal phenylalanine of Ang II; Ang III, a heptapeptide lacking the N-terminal aspartate residue; and Ang IV, a hexapeptide, lacking the two N-terminal amino acids. Modulation of the peptide levels and the enzymes that generate these peptides has been associated with cardiovascular regulation, as discussed in the following section. In addition to these peptides, new functions of (pro)renin have been described that will likely have a significant impact on our therapeutic approaches to cardiovascular diseases.

### Ang (1-7) and ACE2

Ang (1-7) is formed either by the action of neutral endopeptidase on Ang I or by the recently discovered monocarboxypeptidase, angiotensin-converting enzyme 2 (ACE2), on Ang II. Ang (1-7) elicits cardiovascular responses, such as antihypertensive, antihypertrophic, antifibrotic, and antithrombotic, that are generally opposite to those mediated by Ang II. The effects of Ang (1-7) may be mediated through direct signaling as a result of binding to the G protein-coupled Mas receptor, a product of the Mas oncogene, or by the modulation of AT<sub>1</sub>-receptor signaling, as a result of heterodimerization of Mas and AT<sub>1</sub> receptors.<sup>79,80</sup> ACE2 affects Ang II levels by converting Ang I into Ang (1-9) and Ang II into Ang (1-7), though the latter is the preferred pathway. Local generation of Ang (1-7) in the myocardium of dogs and elevation of Ang (1-7) in cardiac myocytes during development of heart failure subsequent to coronary artery ligation have been reported.<sup>81,82</sup> In addition, intravenous infusion of Ang (1-7) attenuates the development of heart failure after myocardial infarction, suggesting a role for this peptide in cardiac remodeling.<sup>83</sup> ACE2 gene expression is significantly increased in the failing human heart.<sup>84</sup> ACE2-knockout mice have left ventricular dysfunction and wall thinning, along with increased Ang II levels. The ACE and ACE2 double-knockout completely prevents cardiac abnormalities and the increase in Ang II production.<sup>85</sup> Lentiviral-mediated ACE2 overexpression has amelioratory effects on blood pressure

**FIGURE 9-4** Novel components of the renin-angiotensin system. The major reactions of Ao to Ang II conversion may also be catalyzed by alternative enzymes, such as cathepsin D and chymase. In addition, Ang I may be converted to Ang (1-9) by an isoform of ACE, known as ACE2. Ang (1-9) can be converted to Ang (1-7) by ACE. Alternatively, Ang (1-7) can be formed by a direct action of NEP on Ang I. Ang (1-7) is a biologically active peptide that binds to a specific receptor, which is a product of the Mas oncogene. The effects of Ang (1-7) are beneficial to the cardiovascular system. Ang II can also be further cleaved by APA to produce Ang III, which binds to the same receptors as Ang II and produces similar effects. Some of the renal and brain effects, which were initially thought to be produced by Ang II, require conversion of Ang II to Ang III. Ang III can be further cleaved by APN to form Ang IV, which binds to a specific receptor that has been identified as insulin-regulated aminopeptidase (IRAP).

and cardiac fibrosis in spontaneously hypertensive rats. Similarly, there is a protective effect on the heart through preservation of cardiac function, left ventricular wall motion and contractility, in a myocardial infarction model.<sup>86</sup> However, transgenic mice with increased cardiac ACE2 expression show a high incidence of sudden death due to ventricular tachycardia and fibrillation as a result of gap junction remodeling.<sup>87</sup> ACE2 can effectively alter the balance between vasoconstrictive and the cell proliferating effects of Ang II and the vasodilatory and antiproliferating effects of Ang (1-7).<sup>88</sup> The age-dependent cardiomyopathy in ACE2 null mice was related to increased Ang II-mediated oxidative stress and neutrophilic infiltration in the absence of ACE2.<sup>89</sup> Structure-based screening of therapeutic compounds in development identified candidates that enhanced ACE2 activity in vitro and reduced blood pressure in spontaneously hypertensive rats.<sup>90</sup> In addition, improvement in cardiac function and reversal of myocardial, perivascular, and renal fibrosis was observed with these compounds.

## Ang III

Ang III, also called Ang-(2-8), is generated from Ang II by aminopeptidase A (APA), which cleaves the Asp<sup>1</sup>-Arg<sup>2</sup> bond in Ang II. The major physiological role of Ang III is in the brain, where it has been shown to be more important than Ang II, in the central regulation of hypertension and vasopressin release.<sup>91</sup> Ang III has affinity for AT<sub>1</sub>R and AT<sub>2</sub>R receptors that is comparable to that of Ang II.<sup>91</sup> APA is also highly expressed in the kidneys. It was recently shown that renal conversion of Ang II to Ang III is critical for AT<sub>2</sub>R-mediated natriuresis and may have a significant role in disorders characterized by Na<sup>+</sup> and fluid retention, such as hypertension and congestive heart failure.<sup>92</sup> Ang III, APA, and aminopeptidase N (APN) could provide a putative central therapeutic target for the treatment of hypertension.<sup>93</sup>

## Ang IV

Ang III is metabolized to angiotensin IV (Ang IV) by APN. Ang IV mediates physiological functions in the central nervous system, including blood flow regulation, learning, and memory.<sup>94</sup> Ang IV binds to a type II integral membrane protein, termed AT<sub>4</sub>, which was recently identified as insulin-regulated aminopeptidase (IRAP).<sup>95</sup> AT<sub>4</sub>/IRAP is expressed in

multiple tissues, including brain, kidneys, blood vessels, and heart. Actions of Ang IV, mediated through the AT<sub>4</sub> receptor, may be related to the activation of several intracellular signaling pathways or by inhibition of the enzymatic activity of IRAP, the physiological substrates of which include vasopressin.<sup>96</sup> Several studies have suggested a role for Ang IV in cardiovascular diseases in that Ang IV enhances cell growth in cardiac fibroblasts, endothelium, and VSMC.<sup>94</sup> In VSMC, Ang IV activates the proinflammatory transcription factor NF-κB, which regulates expression of several genes involved in atherosclerosis and thrombosis.<sup>97</sup>

## Pro(renin) Receptor

Pro(renin), the inactive precursor of renin, has reported levels in blood that are up to tenfold higher than renin, particularly in diabetes.<sup>24,98</sup> Interestingly, no extrarenal activation site of prorenin is known, which had led to the speculation that prorenin does not have any significant physiological role. However, recent identification of a specific (pro)renin receptor has changed our understanding about the roles of (pro)renin in pathophysiological processes.<sup>23</sup> The (pro)renin receptor is a 350-amino acid protein, with a single transmembrane domain that is expressed in multiple tissues, including the heart. The (pro)renin receptor specifically binds both renin and prorenin. Following binding to the receptor, a conformational change makes prorenin catalytically active, which can produce Ang II locally and therefore available to bind to Ang II receptors.<sup>99</sup> Thus circulating prorenin might contribute significantly to tissue Ang II production.<sup>23</sup> The catalytic efficiency of renin for Ang II generation is also enhanced when bound to this receptor. In addition to providing an enhanced capability of local Ang II generation, the (pro)renin receptor mediates intracellular signaling events, which likely contribute to the pathological effects of RAS activation.<sup>100</sup> When bound to the (pro)renin receptor, renin and prorenin activate extracellular signal-related MAPKs (ERK1/2), induce DNA synthesis, and stimulate release of TGF-β and plasminogen activator inhibitor-type 1 (PAI-1) in mesangial cells, which may contribute to renal fibrotic disease, particularly when therapeutic Ang II blockade elevates levels of plasma renin.<sup>23,101,102</sup> It has been shown that prorenin stimulates ERK phosphorylation in VSMC, through receptor-mediated activation of tyrosine kinase and subsequently MEK, independent of the generation of Ang II or the activation of AT<sub>1</sub>R.<sup>103</sup> It has also been

**FIGURE 9-5** Intracellular effects of (Pro)renin receptors. Binding of renin and/or prorenin to the renin/prorenin receptor leads to activation of the enzymatic action of prorenin and enhancement of catalytic activity, resulting in elevated concentrations of Ang II in proximity to the cell surface. Renin and prorenin also independently activate intracellular signaling pathways. Pro(renin) receptor-mediated activation of the MEK/ERK1/2 cascade through tyrosine kinases leads to generation of transforming growth factor  $\beta$  (TGF- $\beta$ ) and plasminogen activator inhibitor-type 1 (PAI-1), resulting in hypertrophic growth and fibrosis. Pro(renin) receptor-induced activation of p38 MAPK leads to activation of heat shock protein 27 (Hsp27), which is associated with abnormal actin filament dynamics. Activation of these latter pathways is independent of Ang II.

reported that prorenin exerts angiotensin-independent effects in cardiomyocytes.<sup>100</sup> Prorenin also induced stimulation of the p38 MAPK/HSP27 pathway, resulting in alterations in actin filament dynamics that may underlie the severe cardiac hypertrophy described in rats with hepatic prorenin overexpression.<sup>104</sup> Interestingly, these effects occurred without production of Ang II or stimulation of AT<sub>1</sub>. A direct functional role of the renin/prorenin receptor might contribute to disease processes such as hypertension, heart failure, and diabetes mellitus-induced cardiovascular complications.<sup>105</sup> In conclusion, the pro(renin) receptor may serve as a new treatment target (receptor blockers), which prevents both Ang II generation at tissue sites and prorenin-induced, Ang II-independent effects (Figure 9-5).

## ANGIOTENSIN II-MEDIATED SIGNALING PATHWAYS IN HEART FAILURE (see Chapter 45)

### Angiotensin II Receptors

Ang II, the major bioactive peptide of the renin-angiotensin system, has a critical role in controlling cardiovascular homeostasis. It is important in various cardiovascular diseases, such as hypertension, atherosclerosis, restenosis after angioplasty, and congestive heart failure.<sup>106-108</sup> The multiple actions of Ang II are mediated via specific, highly complex, intracellular signaling pathways that are stimulated following initial binding of the peptide to specific receptors. In mammalian cells, Ang II mediates effects via (at least) two high-affinity plasma membrane receptors: AT<sub>1</sub> and AT<sub>2</sub>. Both receptor subtypes have been cloned and pharmacologically characterized.<sup>109,110</sup> The two receptors, which belong to the superfamily of G protein-coupled receptors (GPCR), have

different signaling pathways and functions.<sup>111,112</sup> The AT<sub>1</sub> receptor (AT<sub>1</sub>R) subtype is expressed ubiquitously and is involved in most of the well-known biological actions of Ang II. The AT<sub>1</sub>R was first cloned in 1991<sup>109,113</sup> and consists of 359 amino acids with a molecular mass of 41 kDa. Two AT<sub>1</sub>R subtypes have been described in rodents, AT<sub>1a</sub> and AT<sub>1b</sub>, with greater than 94% amino acid sequence identity<sup>114</sup> and which have similar pharmacological properties and tissue distribution. The human AT<sub>1</sub> gene has been mapped to chromosome 3.<sup>115</sup> The AT<sub>1</sub>R is a glycoprotein containing extracellular glycosylation sites at the amino terminus (Asn<sup>4</sup>) and the second extracellular loop (Asp<sup>176</sup> and Asn<sup>188</sup>). The transmembrane domain at the amino-terminal extension and segments in the first and third extracellular loops are responsible for G protein interactions with the receptor.<sup>116</sup> AT<sub>1</sub>R interacts with various heterotrimeric G proteins, including Gq/11, Gi/o, G $\alpha$ 12, and G $\alpha$ 13, which couple to distinct signaling cascades. The AT<sub>1</sub>R transactivates growth pathways and mediates the major effects of Ang II, such as vasoconstriction, aldosterone secretion, increased cardiac contractility, renal tubular sodium reabsorption, cell proliferation, vascular and cardiac hypertrophy, inflammatory responses, and oxidative stress.<sup>117</sup> Like most GPCR, AT<sub>1</sub>R is also subject to internalization when stimulated by Ang II, a process dependent on specific residues located on the cytoplasmic tail.<sup>118</sup> Internalization of GPCR involves receptor phosphorylation, which may be mediated in part via caveola.<sup>119</sup> Studies have shown that a serine/threonine-rich segment of the carboxy terminus is essential for phosphorylation and internalization of the receptor<sup>120</sup> and that G protein receptor kinase (GRK)-mediated serine phosphorylation of AT<sub>1</sub>R has an important role in desensitization of the agonist-occupied receptor.<sup>121</sup>

In contrast to AT<sub>1</sub>R, the physiological role of AT<sub>2</sub>R has been less well characterized. AT<sub>2</sub>R is distinct from AT<sub>1</sub>R in genomic organization, tissue-specific expression, and in signaling mechanisms. The AT<sub>2</sub>R is characterized by a high affinity for the nonpeptide receptor antagonists PD123319, PD123177, and CGP42112, and a very low affinity for losartan and candesartan (selective AT<sub>1</sub>R antagonists).<sup>117</sup> Ang II binds to the AT<sub>2</sub>R with similar affinity as to the AT<sub>1</sub>R.<sup>122</sup> AT<sub>2</sub>R has been cloned in a variety of species, including humans, rats, and mice.<sup>110,123,124</sup> The AT<sub>2</sub>R is a seven-transmembrane domain receptor, encoded by a 363-amino acid protein with a molecular mass of 41 kDa, but it shares only 34% sequence identity with the AT<sub>1</sub>R.<sup>124</sup> Interestingly, the gene coding for AT<sub>2</sub>R is located on chromosome X. Stimulation of AT<sub>2</sub>R by Ang II, in contrast to AT<sub>1</sub>R, is not followed by interaction of the activated receptor with  $\beta$ -arrestins and subsequent internalization,<sup>125</sup> suggesting that classical,  $\beta$ -arrestin-mediated mechanisms do not participate in the homologous desensitization of the AT<sub>2</sub>R, and that its regulation is different from the AT<sub>1</sub>R and most other GPCR. AT<sub>2</sub>R is highly expressed in fetal tissues, with expression dramatically decreasing after birth, and being restricted to only a few organs, including the cardiovascular system. The AT<sub>2</sub>R is reexpressed in the adult animal following cardiac and vascular injury and during wound healing, suggesting a role for this receptor in tissue remodeling, growth, and/or development. The AT<sub>2</sub>R often induces opposite responses to the AT<sub>1</sub>R, including vasodilation, antiproliferative, antihypertrophic, and cardioprotective effects.<sup>126-128</sup> AT<sub>2</sub> exerts antiproliferative and apoptotic effects in VSMC and decreases neointimal formation in response to injury by counteracting Ang II actions mediated by the AT<sub>1</sub>R.<sup>129</sup> In the heart, AT<sub>2</sub> expression is upregulated in pathological states, inhibiting growth and remodeling, and inducing vasodilation.<sup>130</sup> After myocardial infarction (MI), AT<sub>2</sub>R overexpression assists in preservation of left ventricular (LV) function, indicating a beneficial role for AT<sub>2</sub> in post-myocardial infarction remodeling.<sup>127,131</sup> Overexpression of AT<sub>2</sub>R in the left ventricle of pressure-overloaded rats reduces

myocardial fibrosis and myocyte diameter, indicating that AT<sub>2</sub>R overexpression in cardiac myocytes alters the pathological response to aortic banding-induced ventricular hypertrophy.<sup>132</sup> Using AT<sub>2</sub>R knockout mice, it has been demonstrated that AT<sub>2</sub>R mediates antiproliferative and antifibrotic effects in DOCA-salt or L-NAME-induced hypertensive rats<sup>133</sup> and has a significant role in the protection against early development of LV dilation and in decreasing the early mortality after MI. The cardioprotective effects of AT<sub>1</sub>R antagonists in post-MI remodeling are likely related in part to Ang II-mediated responses via the AT<sub>2</sub>R.<sup>127,128</sup>

Two other Ang II receptors have been described: AT<sub>3</sub> and AT<sub>4</sub>. The AT<sub>3</sub>R is peptide-specific, recognizing mainly Ang II. This subtype does not bind nonpeptide ligands, such as losartan or PD123319 (selective AT<sub>2</sub>R antagonist), and has only been observed in cell lines. The AT<sub>4</sub>R, which is distributed in heart, lung, kidney, brain, and liver, binds to Ang IV,<sup>134</sup> but not losartan or PD123319. AT<sub>4</sub>R was identified in 1992 as a specific high-affinity binding site for the hexapeptide Ang IV (VYIHPF),<sup>135</sup> an insulin-regulated aminopeptidase.<sup>95,136</sup> AT<sub>4</sub> and AT<sub>1</sub>/AT<sub>2</sub> receptors are distinct entities with different ligand specificities and differential tissue distributions.<sup>134</sup> Ang IV induces vasorelaxation in various vascular beds, enhances endothelial intracellular calcium release, and increases endothelial nitric oxide synthase (eNOS) activity.<sup>137-140</sup> Ang IV also stimulates phosphatidylinositol-3 kinase (PI3K) and phosphatidylinositol-dependent kinase 1 (PDK1) activity and induces phosphorylation of protein kinase B and ERK1/2.<sup>141</sup> These multiple kinase pathways are thought to regulate the cellular proliferative effects of the peptide. Ang IV induced plasminogen activator inhibitor 1 expression in endothelial cells, suggesting a role for Ang IV in fibrinolysis.<sup>142</sup> Ang IV also activates the NF- $\kappa$ B pathway and increases proinflammatory genes in VSMC.<sup>97</sup> The AT<sub>4</sub>R has also been characterized in the heart, where Ang IV stimulates protein synthesis in cardiac fibroblasts<sup>143</sup> and reduces left ventricular pressure generation and ejection fraction and the expression of the immediate early genes *c-fos* and *egr-1* in the isolated heart.<sup>144,145</sup> These data suggest that this Ang II degradation peptide could participate in the pathogenesis of cardiovascular diseases. However, the overall importance of AT<sub>4</sub>R-mediated signaling in cardiovascular diseases needs to be further clarified. In this chapter, our primary focus will be on the signaling pathways mediated by AT<sub>1</sub> and AT<sub>2</sub>.

### AT<sub>1</sub>-Mediated Intracellular Signaling

**Classical G Protein-dependent Signaling Pathways.** Like other seven membrane spanning domain receptor family members, agonist binding to the AT<sub>1</sub>R initiates a multitude of intracellular events. AT<sub>1</sub>R couples to the Gq/11 protein, which stimulates phospholipase C (PLC) to generate the second messengers diacylglycerol (DAG) and inositol triphosphate (IP<sub>3</sub>). DAG activates protein kinase C (PKC) and IP<sub>3</sub> binds to its receptor on the sarcoplasmic reticulum, opening a channel that allows calcium efflux into the cytoplasm. Ang II-induced phospholipase D (PLD) activation results in hydrolysis of phosphatidylcholine to choline and phosphatidic acid (PA). PA is rapidly converted to DAG, leading to sustained activation of PKC. Both PKC- and calcium-mediated signaling are involved in vasoconstriction and cardiac hypertrophy.<sup>146-149</sup> Ang II has been shown to phosphorylate and activate phospholipase A<sub>2</sub> (PLA<sub>2</sub>), which leads to production of arachidonic acid (AA), the precursor molecule for the generation of prostaglandins, and which is involved in the Ang II-induced growth of VSMC and cardiac hypertrophy.<sup>150</sup> AT<sub>1</sub>R also couples to G<sub>i/o</sub>, inhibiting adenylyl cyclase in several target tissues, thereby attenuating the production of the second messenger cAMP.<sup>151</sup> When production of this latter vasodilator is decreased due to AT<sub>1</sub>

activation, there is resulting vasoconstriction. AT<sub>1</sub> is also involved in the opening of Ca<sup>2+</sup> channels and an influx of extracellular Ca<sup>2+</sup> into cells.<sup>152,153</sup> The activation of L-type Ca<sup>2+</sup> channels is mediated by AT<sub>1</sub>R coupled to G<sub>12/13</sub> proteins (Figure 9-6).<sup>154</sup>

**AT<sub>1</sub>-mediated Tyrosine Phosphorylation.** Ang II induces actions through activation of tyrosine kinases, which in turn phosphorylate many downstream targets, which are associated with cellular growth and apoptosis, differentiation, transformation, and vascular contraction. Tyrosine kinases activated by Ang II/AT<sub>1</sub>R include many receptor tyrosine kinases (RTK), such as epidermal growth factor receptor (EGFR), platelet-derived growth factor receptor (PDGFR), and insulin-like growth factor receptor (IGFR), and non-receptor tyrosine kinases such as the Src family kinases, Janus kinases (JAKs), focal adhesion kinase (FAK), Ca<sup>2+</sup>-dependent tyrosine kinases (e.g., Pyk2), p130Cas, and PI3K (Figure 9-7).<sup>150,155-157</sup> Ang II stimulation of cellular growth has been described in cardiac myocytes and VSMC. These effects are associated with increased tyrosine phosphorylation and activation of MAPKs and related pathways, which result in increased expression of early response genes, such as *c-fos*, *c-jun*, and *c-myc*, thereby controlling cellular proliferation and growth.<sup>155</sup> These actions have been linked to cardiovascular diseases, including hypertension, cardiac hypertrophy, heart failure, and atherosclerosis. The role of tyrosine kinases in Ang II-mediated signaling has been extensively reviewed in Touyz et al<sup>150,156,158</sup> and only recent developments will be discussed here.

**Receptor Tyrosine Kinases.** In recent years, it has become apparent that transactivation of RTKs by GPCR agonists is a general phenomenon that has been demonstrated for many unrelated GPCRs and RTKs.<sup>159,160</sup> The mitogenic effects of Ang II can be mediated through transactivation of RTKs. AT<sub>1</sub>R-mediated transactivation has been demonstrated for EGFR, PDGFR, and IGFR.<sup>161</sup> The EGFR is endogenously expressed in numerous cell types and is an important receptor in the control of many fundamental cellular processes.<sup>162</sup> Transactivation is mediated by several intermediary signaling molecules, including Ca<sup>2+</sup>, PKC, Pyk2, Src, reactive oxygen species (ROS), and metalloproteinases that generate EGF-like ligands.<sup>161,163-165</sup> Blocking EGFR kinase activity abolishes Ang II-mediated downstream signaling, such as activation of ERK1/2 in VSMC and cardiac myocytes,<sup>161,166</sup> suggesting that transactivation of EGFR accounts for the majority of growth-promoting responses induced by Ang II. Studies have demonstrated that EGFR activation is involved in Ang II-induced vascular contraction, cell growth, cardiac hypertrophy, and hypertension.<sup>167</sup> It has recently been shown that Ang II-induced transactivation of the IGF-1 receptor is a critical mediator of PI3K activation by Ang II.<sup>168,169</sup> In contrast to EGFR transactivation, Ang II-induced PDGFR transactivation may be ligand independent, requiring an ROS-sensitive kinase distinct from Src or JAK2.<sup>170</sup> Ang II-induced transactivation of the PDGFR has also been shown to contribute to cardiac hypertrophy and vascular remodeling.<sup>171-173</sup>

### Nonreceptor Tyrosine Kinases

**Src Family Kinases.** Studies have demonstrated that Src family kinases, such as *c-Src*, have an important role in regulation of growth responses induced by Ang II.<sup>174,175</sup> The Src kinase family consists of at least 14 members, of which the 60-kDa *c-Src* is a prototype of the cellular members of the Src family kinases (Src, Fyn, Yes, Fgr, Lck, Lyn, Hck, Blk, and Yrk). All Src family members share common functional domains, including an N-terminal myristoylation sequence for membrane targeting, SH2 and SH3 domains for protein binding, and a kinase domain and C-terminal noncatalytic domain.<sup>176</sup> *c-Src* is abundantly expressed in VSMC and cardiomyocytes

**FIGURE 9-6** Classical signal transduction pathways mediated by AT<sub>1</sub>R. Binding of Ang II to AT<sub>1</sub> leads to G protein–coupled activation of PLC (phospholipase C) via G<sub>q</sub>, resulting in phosphatidylinositol hydrolysis and formation of IP<sub>3</sub> (inositol triphosphate) and DAG (diacylglycerol) accumulation. IP<sub>3</sub> mobilizes Ca<sup>2+</sup> from sarcoplasmic reticular stores and DAG activates PKC (protein kinase C). Both PKC- and calcium-mediated signaling are involved in vasoconstriction and cardiac hypertrophy. AT<sub>1</sub>R couple to G<sub>i/o</sub>, resulting in inhibition of adenylyl cyclase and attenuation of cAMP production, leading to vasoconstriction. Activation of phospholipase A<sub>2</sub> (PLA<sub>2</sub>) leads to production of arachidonic acid (AA) and the generation of prostaglandins. AT<sub>1</sub>R coupling to G<sub>12/13</sub> results in the opening of L-type Ca<sup>2+</sup> channels and increases the influx of extracellular Ca<sup>2+</sup>.

**FIGURE 9-7** Ang II induces activation of tyrosine kinases through AT<sub>1</sub>R. Ang II influences the activity of receptor tyrosine kinases, such as EGFR (epidermal growth factor receptor) and PDGFR (platelet-derived growth factor receptor). The transactivation event is mediated by several intermediary signaling molecules, including Ca<sup>2+</sup>, PKC, Pyk2, Src, and reactive oxygen species (ROS). The transactivated EGFR serves as a scaffold for downstream adapters, leading to activation of MAPKs. Ang II also phosphorylates multiple nonreceptor tyrosine kinases, such as JAK-STAT, FAK, Pyk2, p130Cas, and PI3K. Activated tyrosine kinases phosphorylate many downstream targets, which regulate Ang II-induced cellular effects.

and rapidly activated by Ang II.<sup>177</sup> It has been shown that *c-Src* is activated by Gβγ in an ROS-dependent manner and is involved in activation of a variety of downstream pathways. Src-induced activation of PLCγ, which is a substrate for members of the Src kinase family, promotes release of Ca<sup>2+</sup> from intracellular stores. Src is also required for Ang II-induced activation of ERK1/2, Pyk2, and several downstream proteins including FAK, paxillin, JAK2, STAT1, caveolin, and the adapter protein Shc,<sup>178</sup> indicating that activation of Src has a pivotal role in Ang II-mediated cytoskeletal reorganization, focal adhesion formation, cell migration, and growth. Increased activation of Src by Ang II may be an important mediator of cardiac hypertrophy and vascular remodeling.

**FAK and PYK2 Activation.** FAK and PYK2, also referred to as cell adhesion kinase, related adhesion focal tyrosine kinase, or calcium-dependent protein tyrosine kinase,<sup>179</sup> are localized prominently within focal adhesions, and have a signaling role in regulating cell behavior resulting from integrin interaction with the extracellular matrix. Previous studies

have demonstrated that activation of FAK and PYK2 have been implicated in the progression of cardiomyocyte hypertrophy and have an important role in Ang II-mediated cellular effects.<sup>180-183</sup> As a consequence of association with *c-Src*, FAK undergoes further tyrosine phosphorylation, resulting in FAK binding to Grb2, Sos, and Ras, leading to ERK1/2 activation.<sup>179</sup> Ang II rapidly induces tyrosine phosphorylation of FAK, allowing for cell adhesion to the extracellular matrix and activation of cytoskeletal proteins, including p130Cas, Pyk2, paxillin, and talin, all of which interact to regulate cell shape and movement.<sup>158</sup> It has also been shown that the interaction between p130Cas, Pyk2, and PI3K activates ribosomal p70<sup>S6</sup> kinase, which has an important role in Ang II-mediated protein synthesis. Pyk2, a FAK homologue, is activated by AT<sub>1</sub> and is dependent on increased intracellular Ca<sup>2+</sup> and PKC.<sup>184,185</sup> Since Pyk2 is a candidate to regulate *c-Src* and links G protein–coupled vasoconstrictor receptors with protein tyrosine kinase-mediated contractile, migratory, and growth responses, it may represent a point of convergence

between  $\text{Ca}^{2+}$ -dependent signaling pathways and protein tyrosine kinase pathways in cardiovascular cells.

**p130Cas.** p130Cas was initially characterized as a phosphotyrosine-containing protein in v-Crk- and v-Src-transformed cells,<sup>186</sup> serving as an adapter molecule, the proline-rich sequences and SH3 domain of which allow for an interaction with Pyk2 in the presence of Ang II and provides binding motifs for the SH2 domains of Crk and Src.<sup>187</sup> p130Cas is important for integrin-mediated cell adhesion through recruitment of cytoskeletal signaling molecules, such as FAK, paxillin, and tensin to focal adhesions.<sup>188</sup> The phosphorylation of p130Cas is dependent on  $\text{Ca}^{2+}$ , *c-Src*, and PKC and requires an intact cytoskeletal network. Other studies have reported that Ang II-induced activation of p130Cas is  $\text{Ca}^{2+}$  and PKC independent.<sup>189</sup> Ang II-induced tyrosine phosphorylation of Src and p130Cas has been shown to be essential in Ang II-stimulated migration of VSMC through activation of ERK1/2 and JNK.<sup>190</sup> Though the exact functional significance of Ang II-induced activation of p130Cas is unclear, it may contribute to the regulation of  $\alpha$ -actin expression, cellular proliferation, migration, and cell adhesion.

**JAK/STAT Activation.** The Janus kinase (JAK)-signal transducer and activator of transcription (STAT) pathway is involved in a wide range of distinct cellular processes, including inflammation, apoptosis, cell-cycle regulation, and development.<sup>191,192</sup> There are four JAK proteins in mammalian cells: JAK1, JAK2, JAK3, and TYK2.<sup>193</sup> JAK proteins, named after the Roman two-faced mythical god Janus, function as cytosolic tyrosine kinases and induce a cascade of phosphorylation steps that result in the activation of STAT proteins. Tyrosine phosphorylation of STATs leads to STAT homodimerization and heterodimerization. STAT dimers are rapidly transported from the cytoplasm to the nucleus, where they activate gene transcription.  $\text{AT}_1$  activates JAK2 and Tyk2 in the cardiovascular system.<sup>194</sup> In VSMC, JAKs apparently phosphorylate the STAT proteins p91/84 (STAT1 $\alpha/\beta$ ), p113 (STAT2), and p92 (STAT3) in response to Ang II, suggesting a role for this pathway in the activation of early growth response genes by Ang II. The JAK-STAT signaling pathway activates early growth response genes, which may be a mechanism for Ang II-mediated vascular and cardiac growth, remodeling, and repair.<sup>195,196</sup> It has been demonstrated that STATs have an important role in angiotensinogen gene expression in the heart. Ischemia-reperfusion or myocardial infarction-induced activation of STAT5A and STAT6 promotes the binding of STATs to the St-domain of angiotensinogen, resulting in increases in the gene expression of angiotensinogen.<sup>197,198</sup> Blockade of  $\text{AT}_1\text{R}$  signaling or inhibition of JAK2 activation suppresses formation of the STATs/St-domain complex and reduces the gene expression of angiotensinogen. These studies support a role for an Ang II autocrine loop in JAK-STAT signaling and cardiac injury. Ang II-induced activation of JAK2 is also an important step in the development of diabetic vascular complications.<sup>199</sup>

**Phosphoinositide 3-OH Kinase.** PI3Ks are a family of lipid and protein kinases responsible for the phosphorylation of PtdIns at position D3 of the inositol ring. These molecules act as secondary messengers and influence a variety of cellular responses, including proliferation, survival, cytoskeletal remodeling, and have recently also been identified as having an important role in the regulation of cardiomyocyte and VSMC growth.<sup>200-202</sup> PI3Ks are classified by substrate specificity and subunit organization.<sup>203</sup> Class I enzymes produce  $\text{PtdIns}(3,4,5)\text{P}_3$  in vivo. Class IA PI3Ks are heterodimeric proteins, each of which consists of a catalytic subunit of 110 to 120 kDa (p110 $\alpha$ ,  $\beta$ , and  $\delta$ ) and an associated regulatory subunit (p85 $\alpha$  and  $\beta$ ) that are essential for interaction of these PI3Ks with receptor tyrosine kinases. The class IB PI3K (PI3K $\gamma$ ) is activated by heterotrimeric G protein subunits and associates with a p101 adaptor required for full responsiveness to

G $\beta\gamma$  heterodimers. Class II PI3Ks do not produce  $\text{PtdIns}(3,4,5)\text{P}_3$ , but appear to produce both  $\text{PtdIns}(3,4)\text{P}_2$  and  $\text{PtdIns}3\text{P}$  in vivo. Class II PI3Ks are distinguished by a carboxy-terminal C2 domain, which is not found in other PI3Ks. Class III PI3K, Vps34, only produces  $\text{PtdIns}3\text{P}$ .<sup>204</sup> PI3K $\alpha$ , which is activated by RTK, appears to have a critical role in the induction of physiological cardiac growth, but not pathological growth, and appears essential for maintaining contractile function in response to pathological stimuli.<sup>205</sup> PI3K $\gamma$  appears to negatively control cardiac contractility through different signaling mechanisms and as a key mediator of NADPH oxidase activation in response to Ang II.<sup>89,206,207</sup> Ang II-induced ERK1/2 phosphorylation is augmented by PI3K, in SHR VSMC, indicating a role of PI3K in Ang II-induced vascular remodeling.<sup>208</sup> Akt/PKB has been identified as an important downstream target of PI3K, in Ang II-activated cardiomyocytes, and VSMC.<sup>209</sup> It regulates protein synthesis by activating p70 S6-kinase and modulates Ang II-mediated  $\text{Ca}^{2+}$  responses by stimulating  $\text{Ca}^{2+}$  channel currents. Akt/PKB has also been implicated in promoting cell survival by influencing Bcl-2 and *c-myc* expression and inhibiting caspases. Though the exact role of PI3K in Ang II signaling has not been established, it is possible that this complex pathway may control the balance between mitogenesis and apoptosis.

**Mitogen-activated Protein Kinases.** Mitogen-activated protein kinase (MAPK) consists of a series of successively acting kinases that function as central regulators of cell growth, differentiation, and transformation. All of the MAPK members are catalytically inactive in resting cells and are activated in response to the appropriate stimulus, by phosphorylation on both threonine and tyrosine residues that appear in a threonine-X-tyrosine motif, close to the active site. This phosphorylation is regulated through a dual specificity MAPKK (MAP kinase kinase), which in turn is activated through phosphorylation by a MAPKKK (MAP kinase kinase kinase).<sup>210</sup> Once activated, these terminal effector kinases directly phosphorylate a diverse array of cytoplasmic, nuclear, and mitochondrial proteins to modulate gene expression, cellular metabolism, cellular physiology, and cell death.<sup>211</sup> At least four distinctly regulated groups of MAPKs are expressed in mammals, extracellular signal-related kinases (ERK)-1/2, *c-Jun* N-terminal kinases (JNK1/2/3), p38 proteins (p38 $\alpha/\beta/\gamma/\delta$ ), and ERK5, all of which are activated by specific MKKs: MEK1/2 for ERK1/2, MKK3/6 for p38, MKK4/7 for the JNKs, and MEK5 for ERK5 (Figure 9-8). Each MKK can be activated by more than one MEKK, increasing the complexity and diversity of MAPK signaling.<sup>212</sup> Ang II induces phosphorylation of Ras, Raf, and Shc, leading to the activation of MEKKs and MEKs, resulting in tyrosine and threonine phosphorylation of ERK1/2, JNK2, and p38.<sup>213</sup> Ang II-induced activation of ERK1/2 is associated with increased expression of the early response genes *c-fos*, *c-myc*, and *c-jun*; DNA/protein synthesis; cell growth and differentiation; and cytoskeletal organization in cardiovascular cells.<sup>214</sup> Recent data have demonstrated that the ERK1/2 signaling pathway has an important role in mediating the effects of the brain RAS on sympathetic nerve activity in heart failure, suggesting that manipulating brain ERK1/2 signaling could ameliorate the adverse effects of the brain RAS on cardiovascular and renal function during the progression of heart failure.<sup>215</sup> In addition to ERKs, Ang II activates JNKs, which regulate cardiomyocyte and VSMC growth.<sup>216,217</sup> Ang II induces activation of JNK via p21-activated kinase (PAK), which is dependent on intracellular  $\text{Ca}^{2+}$  mobilization and PKC activation.<sup>218</sup> In the heart, activation of p38 MAPK has been observed in pressure-overload or MI-induced cardiac hypertrophy and heart failure in both human and animal models.<sup>219-221</sup> Cardiac-specific activation of p38 MAPK markedly attenuated cardiac contractility.<sup>222</sup> In addition, inhibition of p38 MAPK protected the heart against ischemic injury, attenuated cardiac remodeling, and improved cardiac

**FIGURE 9-8** Schematic diagram of the major MAPK cascades stimulated by AT<sub>1</sub>R. The MAPK pathway is a three-module cascade of phosphorylating kinases: MEK(MAP3K)(MEK)(MAPKK)(MAPK). This pathway consists of several sub-families among which are the ERK, JNK, and p38 MAPK pathways. Each is activated by heterotrimeric G proteins coupled to AT<sub>1</sub>R; by Ang II-induced transactivation of EGFR; by small G proteins (such as Ras, cdc42, Rac); by protein kinases (such as Src); by PKC, via activation of PLC; and by ROS.

function in mice with heart failure after myocardial infarction.<sup>223</sup> Studies have also demonstrated that p38 activation is preferentially associated with the direct effects of Ang II on cardiac cells, whereas stimulation of ERK and JNK occurs in association with Ang II-induced mechanical stress.<sup>224</sup> These results suggest that MAPKs may provide a novel therapeutic approach to the Ang II-dependent pathophysiology that accompanies progression of heart failure.

**Small GTP-binding Proteins.** The small GTP-binding protein (small G protein) superfamily comprises a multitude of monomeric proteins (more than 150 members in humans), with relative molecular masses of  $\lambda$  21 kDa, that regulate a wide variety of cellular processes, such as cell division, migration, and differentiation. They are structurally classified into at least five families, including the following: Ras (e.g., Ras, Rap, and Ral); Rho (RhoA, Rac1, and cdc42); Rab; Sar1/Arf; and Ran.<sup>225</sup> Small G proteins cycle between a GDP-bound inactive form and a GTP-bound active form, a process regulated by guanine nucleotide exchange factors (GEFs), which catalyze the exchange of GDP for GTP; GTPase activating proteins, which stimulate hydrolysis of GTP to GDP; and guanine nucleotide dissociation inhibitors (GDIs), which inhibit the dissociation of GDP and maintain small G proteins in inactive states (Figure 9-9).<sup>226</sup> Activated Ras proteins interact with multiple downstream effectors (Raf/MEK1/2/ERK1/2 and PI3K)<sup>225</sup> to regulate gene expression, cell proliferation, differentiation, and survival; the Rho GTPases (RhoA/Rac1/cdc42) regulate cytoskeletal reorganization and gene expression; the Rab and Sar1/Arf families regulate vesicle trafficking; and the Ran family regulates nucleocytoplasmic transport and microtubule organization.<sup>227</sup> It has been shown that small G proteins (Ras, RhoA, and Rac1) have an important role in cardiac hypertrophy and heart failure.<sup>225,228</sup> Transgenic mice with temporally regulated V12Ras induction in the adult heart developed ventricular hypertrophy and arrhythmias, which accompanied electrophysiological remodeling.<sup>229</sup> Ang II-induced activation of p21 Ras is regulated through activation of the Src family kinases and tyrosine phosphorylation of the adapter protein Shc, with subsequent recruitment of the Grb2-Sos1 complex to the

membrane fraction (see Figure 9-9).<sup>230</sup> It has been demonstrated that Rho/Rho kinase-mediated signaling is involved in AT<sub>1</sub>R-stimulated cardiovascular cell growth, remodeling, atherosclerosis, and vascular contraction.<sup>231,232</sup> Inhibition of Rho/Rho kinase attenuates Ang II-induced hypertrophy of cardiomyocytes and VSMC and expression of plasminogen activator inhibitor protein-1.<sup>233</sup> Rho A is also involved in Ang II-induced activation of NF  $\kappa$ B, which controls the expression of inducible cytokines, chemokines, cell adhesion molecules, and vasoactive and antiapoptotic proteins important in the cellular stress response.<sup>234,235</sup> Ang II also activates Rac1, another Rho GTPase, which is an upstream regulator of p21-activated kinase (PAK) and JNK. Rac1 participates in cytoskeletal organization, cell growth, inflammation, and cardiac hypertrophy.<sup>236,237</sup> Recent data have shown that the Ang II/Rac1/STAT3 pathway is important in the atrial myocardium, mediating structural remodeling, and atrial fibrillation.<sup>238</sup> It has been demonstrated that Rac-derived superoxide in the cardiovascular system has a diverse array of functions.<sup>239</sup> Rac1 controls intracellular superoxide production by regulating the activity of NADPH oxidase. NADPH oxidase-produced superoxide is an essential mediator of the hypertensive and hypertrophic responses to Ang II.<sup>240,241</sup> These results indicate that Rac1 is critical for the progression of cardiac remodeling and suggest that therapies which target myocardial Rac1 may be beneficial in the treatment of cardiac hypertrophy and heart failure.

**Generation of Reactive Oxygen Species.** Accumulating evidence suggests that production of ROS and activation of reduction-oxidation (redox)-dependent signaling cascades are critically involved in Ang II-induced actions<sup>242,243</sup> and have an important role in the development and progression of heart failure regardless of cause.<sup>244,245</sup> ROS function as important intracellular and intercellular second messengers to modulate downstream signaling molecules (Figure 9-10), such as protein tyrosine phosphatases, protein tyrosine kinases, transcription factors, MAPKs, and ion channels, and have a physiological role in vascular tone and cell growth and a pathophysiological role in inflammation, ischemia-reperfusion, hypertension, and atherosclerosis.<sup>246,247</sup> All

**FIGURE 9-9** Regulation of Ang II-induced cellular responses through activation of small GTPases. Ang II stimulates Ras, RhoA, and Rac1 through a process dependent upon activation of a G protein-coupled receptor at the plasma membrane. Small GTPases cycle between a GDP-bound inactive form and a GTP-bound active form. Activated Ras mediated by Gq and Gi regulates the activation of PI3K (phosphatidylinositol-3 kinase) and Raf, the latter being one of the earliest components in the ERK MAPK cascade, which regulates cell survival and cardiac hypertrophy. PI3K modulates cell survival and protein synthesis through Akt and p70S6K. Rac1 activates NADPH oxidase, which in turn regulates generation of ROS. Rac1 also induces the activation of the JNK pathway, through PAK. RhoA regulates cytoskeleton- and hypertrophy-related gene expression, through Rho kinase.

**FIGURE 9-10** ROS-mediated signaling in Ang II-induced cardiac remodeling. Major enzymatic sources for intracellular ROS generation in response to Ang II are mitochondria, xanthine oxidases, and the non-phagocytic NADPH oxidases (Noxs). NADPH oxidase is a multisubunit enzyme, comprised of gp91phox, p22phox, p47phox, p67phox, and p40phox, that is regulated by Rac1, via AT<sub>1</sub>R. Intracellular ROS modify the activity of protein tyrosine kinases (PTK), such as Src, Ras, JAK2, Pyk2, PI3K, and EGFR, and MAPKs. ROS also influence gene and protein expression by activating transcription factors, such as NF-κB and activator protein-1 (AP-1). ROS stimulate ion channels, such as plasma membrane Ca<sup>2+</sup> and K<sup>+</sup> channels, leading to changes in cation concentrations. Activation of these redox-sensitive pathways results in numerous cellular responses, which if uncontrolled, could contribute to the Ang II-induced cardiovascular remodeling process, including cardiac hypertrophy, fibrosis, apoptosis, and impaired heart function.

cardiovascular cell types are capable of producing ROS, and the major enzymatic sources in heart failure are mitochondria, xanthine oxidases, and the nonphagocytic NADPH oxidases (Noxs). A markedly increased myocardial activity of the NAD(P)H oxidase has been observed in human failing, as compared with nonfailing hearts, suggesting the importance of this enzyme system for LV remodeling and dysfunction after MI.<sup>248</sup> Deficiency of the NAD(P)H oxidase subunit p47<sup>phox</sup> prevented LV remodeling and dysfunction after MI and reduced cardiomyocyte hypertrophy, apoptosis, and interstitial fibrosis, and was associated with improved survival. NAD(P)H oxidase activity is significantly enhanced and

involved in Ang II-induced cardiac and vascular remodeling.<sup>249-251</sup> Studies have demonstrated that mitochondria are the predominant source of ROS in failing hearts (see Chapter 12).<sup>252,253</sup> Chronic increases in free oxygen radical production in mitochondria can lead to a catastrophic cycle of mitochondrial DNA damage and functional decline, resulting in oxygen radical generation and cellular injury.<sup>254,255</sup> Inhibition of mitochondrial oxidative stress and DNA damage may provide an effective treatment strategy for heart failure. Ang II-induced mitochondrial oxidative damage has been implicated in the dysfunction of endothelial cells and VSMC.<sup>256,257</sup> An elevation of xanthine oxidase expression

TABLE 9-1 Abbreviations

Abbreviation	Full Name	Abbreviation	Full Name
Ang	Angiotensin	MKP	Mitogen-activated protein kinase phosphatase
Ao	Angiotensinogen	MMP	Matrix metalloproteinase
AA	Arachidonic acid	mTOR	Mammalian target of rapamycin
ACE	Angiotensin-converting enzyme	MYPT	Myosin phosphatase
Ac-SDKP	N-acetyl-Ser-Asp-Lys-Pro tetrapeptide	NADPH	Nicotinamide adenine dinucleotide phosphate
Akt(PKB)	Protein kinase B	NEP	Neutral endopeptidase
APA	Aminopeptidase A	NF $\kappa$ B	Nuclear factor kappa B
APN	Aminopeptidase N	NO	Nitric oxide
ARBs	Angiotensin receptor blockers	PA	Phosphatidic acid
ASK	Apoptosis signal-regulating kinase	PAI-1	Plasminogen activator inhibitor-1
AT <sub>1</sub> R	Angiotensin II type 1 receptor	PAK	P21-activated kinases
AT <sub>2</sub> R	Angiotensin II type 2 receptor	PC	Phosphatidylcholine
BCL-2	B-cell lymphoma 2	PDGF	Platelet-derived growth factor
c-AMP	Cyclic adenosine monophosphate	PDGFR	Platelet-derived growth factor receptor
c-GMP	Cyclic guanosine monophosphate	PKA	Phosphoinositide-dependent kinase 1
DAG	Diacylglycerol	PI3K	Phosphoinositide 3-kinase
EGFR	Epidermal growth factor receptor	PIP2	Phosphatidylinositol bisphosphate
ERK	Extracellular signal-regulated kinases	PLA2	Phospholipase A2
FAK	Focal adhesion kinase	PLC $\gamma$	Phospholipase C
Grb2	Growth factor receptor-bound protein 2	PLD	Phospholipase D
GPCR	G protein-coupled receptors	PKC	Protein kinase C
GEF	Guanine nucleotide exchange factor	PP2A	Protein phosphatase 2A
GDI	Guanosine nucleotide dissociation inhibitor	Pyk2	Proline-rich tyrosine kinase 2
HSP27	Heat shock protein 27	p38 MAPK	p38 mitogen-activated protein kinase
IGFR	Insulin-like growth factor receptor	p70S6K	p70 ribosomal protein S6 kinase
IP <sub>3</sub>	Inositol 1,4,5-triphosphate	p130Cas	Crk-associated substrate, 130 kDa
IRAP	Insulin-regulated aminopeptidase	PTK	Protein tyrosine kinase
JAK	Janus kinase	RAS	Renin-angiotensin system
JNK	c-jun N-terminal kinases	Rho A	Ras homolog gene family, member A
LV	Left ventricle	ROS	Reactive oxygen species
MAPK	Mitogen-activated protein kinase	Shc	Src homology 2 domain containing transforming protein
MEK	MAP kinase kinase	SHP-1	SH2 domain-containing protein tyrosine phosphatase 1
MEKK	MAP kinase kinase kinase	Sos	Son of sevenless
MI	Myocardial infarction	STAT	Signal transducers and activator of transcription
MLC	Myosin light chain	TAK1	Transforming growth factor $\beta$ -activated kinase 1
MLK	Mixed-lineage kinase	TGF- $\beta$	Transforming growth factor $\beta$
M6P-R	Mannose-6-phosphate receptor	VSMC	Vascular smooth muscle cells

These studies represent the initial observations that may lead to the use of ceramide signaling components as a therapeutic intervention for cardiovascular disease.

Although AT<sub>2</sub>R can couple to multiple signaling molecules, in a fashion similar to many other hormone/neurotransmitter G protein-coupled receptors, it is apparent that much additional effort will be necessary to fully establish the various intracellular pathways that are coupled to AT<sub>2</sub>R.

## SUMMARY AND FUTURE DIRECTIONS

The RAS is a hormonal cascade that regulates cardiovascular, renal, and adrenal function. The circulatory system is important for regulation of fluid and electrolyte homeostasis and arterial pressure and plays an important role in the development and progression of heart failure (see Chapter 45). The RAS has also been more recently characterized as the local, self-contained, paracrine, autocrine, and intracrine systems. Tissue RASs are likely important in normal physiological responses, and in pathophysiological states such as hypertension, cardiac hypertrophy, congestive heart failure, and remodeling following myocardial infarction. The intracellular RAS likely does not represent an independent entity but an extension or alternative form of a local RAS, which may be manifested only under select pathophysiological conditions. This suggests a unique evolutionary role for the intracellular RAS. What remains to be determined are the mechanisms of regulation and actions and a more precise understanding of the role of the intracellular RAS in (patho)physiology. Several novel components of the RAS, such as ACE2, Ang (1-7),

Ang IV, and (pro)renin receptor, have an important role in cardiovascular pathophysiology. Future research will likely target these new components for the development of therapeutic interventions. Though major progress has been made in our understanding of the physiology and pathophysiology of the circulating RAS, it will be important to elucidate more completely the role of tissue RASs in normal physiology and in the pathophysiology of cardiovascular diseases.

## Activation of the Adrenergic Nervous System in Heart Failure

J. David Port, Carmen Sucharov, and Michael R. Bristow

In response to a variety of physiological and pathophysiological stresses, the need for increased cardiac myocardial performance is met by a commensurate increase in cardiac adrenergic drive. To facilitate this increase, norepinephrine (NE), the primary neurotransmitter of the adrenergic system, is released from sympathetic nerve endings in the heart. Upon binding to adrenergic receptors, multiple signaling pathways are activated resulting in increases in heart rate and force of contraction and relaxation, the result being an almost immediate increase in cardiac output. In the setting of acute heart failure, adrenergic activation initially occurs in response to hemodynamic overload and/or to an intrinsic reduction in pump function. However, in the setting of chronic heart failure, a response that is normally physiological and transient must

include  $\beta$ -blocking agents (see chapter 46) and inhibitors of the renin-angiotensin system (see chapter 45), which indirectly lower adrenergic drive (Figure 10-2).

Although the “cardiotoxic” effects of catecholamines and, in particular, NE have been recognized for almost a century,<sup>5</sup> we are only just beginning to understand the detailed molecular mechanisms by which they occur. Treatment of isolated cardiac myocytes with concentrations of NE present in the failing human heart can cause dramatic changes in cell morphology, and, within a matter of days, up to a 60% loss of myocyte viability.<sup>6</sup> This effect can be mimicked by exposing myocytes to varying concentrations of the nonselective  $\beta$ -agonist isoproterenol, an effect that is inhibited pharmacologically by propranolol, suggesting that the acute toxic effects of NE are mediated almost exclusively through  $\beta$ -ARs rather than through  $\alpha$ -ARs.<sup>7</sup>

Elevated plasma concentrations of NE are a well-recognized hallmark of CHF.<sup>8,9</sup> Cardiac NE stores, the increased release of which is stimulated in the early stages of heart failure, are eventually depleted as adrenergic activation persists.<sup>10</sup> Eventually, other tissue sources of catecholamines (i.e., the adrenal medulla) are also stimulated, leading to generalized sympathetic activation and spill-over of cardiac-derived NE into the systemic circulation.<sup>4,11</sup> As plasma NE levels increase, so does mortality in patients with heart failure,<sup>2,9,12</sup> illustrating the profoundly injurious effects of excess adrenergic drive on the heart. These observations have been validated further by evidence from numerous clinical trials of  $\beta$ -blocker therapy, demonstrating enhanced systolic function and improved survival in patients with heart failure who receive  $\beta$ -blocker therapy long-term.<sup>13-18</sup> A recent realization is that insufficient adrenergic drive in individuals with CHF can also increase mortality.<sup>13,19</sup> More specifically, in contrast to  $\beta$ -blocking agents, sympatholytic agents can actually increase mortality, presumably via excessive withdrawal of adrenergic support to the failing heart. In contrast,  $\beta$ -blocking agents are pharmacologically reversible, mass-action agents, and in their presence, adrenergic support to the failing heart can be accessed if needed simply by increasing cardiac adrenergic drive.

instead be sustained in an attempt to maintain myocardial performance at a homeostatic level. Under these conditions, an initially beneficial mechanism becomes maladaptive, contributing directly to the progressive natural history of heart failure.

In this chapter the long-term consequences of sustained adrenergic activation in the context of chronic heart failure (CHF) will be reviewed. Particular emphasis will be placed on the alterations in  $\beta$ -adrenergic signal transduction and gene expression patterns that occur in the failing human heart and the impact of these changes on myocardial disease progression. Adrenergic receptor pharmacology relevant to heart failure and recent data from transgenic animals and model systems that demonstrate the myopathic potential of individual components of the adrenergic signaling cascade will also be reviewed.

### ROLE OF INCREASED ADRENERGIC DRIVE IN THE NATURAL HISTORY OF HEART FAILURE

In patients with CHF, the adrenergic nervous system is critical to the support of myocardial function. However, its chronic activation contributes concomitantly to progressive myocardial dysfunction. Regardless of cause, an intrinsic decrease in myocardial function results in cardiac adrenergic nerves releasing more norepinephrine (NE).<sup>1,2</sup> This increase in adrenergic signaling activates  $\beta$ -adrenergic receptors ( $\beta$ -ARs), increasing the heart rate and myocardial contractile function. The increase in contractile function favorably affects both systolic and diastolic function and, through the Frank-Starling relationship, increases cardiac output. As heart failure worsens, adrenergic drive continues to increase in an attempt to compensate for the progressive loss of cardiac function<sup>1</sup> (Figure 10-1). Unfortunately, long-term exposure to high levels of NE has profound adverse effects on myocardial and cardiac myocyte biology, and on the  $\beta$ -AR signal transduction systems themselves.<sup>3,4</sup> Repercussions from these effects are further increases in adrenergic drive, progressive myocardial dysfunction, and worsening heart failure, a cycle requiring therapeutic intervention. Known inhibitors of adrenergic signaling that have demonstrated favorable effects on heart failure natural history

Historical studies suggested that one underlying mechanism of NE toxicity involves cAMP-mediated increases in intracellular calcium.<sup>6</sup> More specifically, increased formation of the second messenger cAMP leads to activation of protein kinase A (PKA), which in turn phosphorylates a variety of target proteins involved in regulating intracellular calcium, including two key targets, phospholamban (PLB) and L-type calcium channels (Figure 10-3). Enhanced phosphorylation of calcium channels in turn leads to an increased flux of extracellular calcium into the cell-activating downstream effectors including proteases, kinases, and phosphatases. Activation of the  $\beta_1$ -AR subtype also appears to promote increased calcium influx via cAMP-independent mechanisms.<sup>20</sup>  $\beta_1$ -ARs are also cAMP-independent activators of calcium/calmodulin-dependent kinase II (CaMKII),<sup>21,22</sup> which, as described later, can be a particularly adverse signaling pathway in cardiac myocytes. Regardless of the exact mechanism(s) invoked, excessive  $\beta$ -AR stimulation results in oxidative stress and calcium overload, conditions promoting cell death through a number of mechanisms, including necrosis and apoptosis.

In addition to the effects described previously, long-term adrenergic activation has been shown to cause changes in the gene expression profile of cardiac myocytes, the canonical response being activation of the fetal gene program (see Chapter 2).<sup>23,24</sup>

In the failing heart,  $\beta$ -ARs and certain downstream effectors in the  $\beta$ -adrenergic signaling cascade undergo time-dependent downregulation and desensitization, presumably

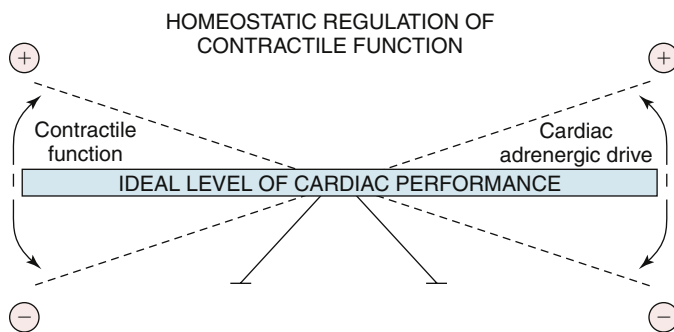

in an attempt to protect the heart from an excess of deleterious signaling. These changes result in a marked attenuation of the failing heart's ability to respond to catecholamines. In other words, the amount of cAMP that is generated in response to a given amount of adrenergic stimulation is significantly decreased in chronic heart failure. Evidence for this has been provided through experiments using isolated, denervated preparations of human heart tissue revealing that failing hearts have a reduced cAMP content compared with nonfailing controls.<sup>25</sup> From a clinical standpoint, reduced responsiveness to catecholamines translates into a decrease in myocardial reserve, which is most commonly manifested as an impaired ability to exercise. In more severe heart failure, reduced myocardial function as a result of  $\beta$ -AR desensitization may also be apparent at rest.

In summary, the role of increased adrenergic drive in the natural history of heart failure is a paradoxical one. On the one hand, adrenergic activation is essential to maintain myocardial function in the failing heart; on the other hand, chronic adrenergic stimulation is a major contributor to progressive myocardial dysfunction and remodeling that characterizes heart failure.

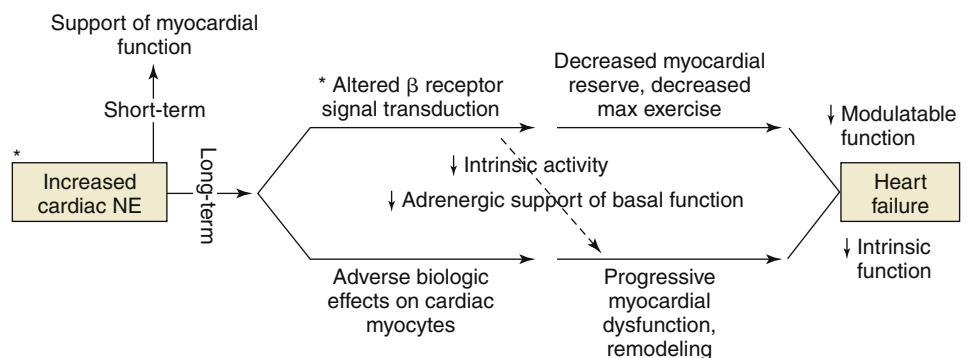

## ADRENERGIC RECEPTOR PHARMACOLOGY

As far back as the 1940s, Ahlquist et al<sup>26</sup> recognized that adrenergic receptors could be subdivided into two major classes,  $\alpha$ -ARs and  $\beta$ -ARs, both of which are binding sites for the endogenous catecholamines: epinephrine and norepinephrine. In turn, each of these broad classes is subdivided further into a number of different receptor subtypes encoded by distinct gene products. Based on the groundbreaking work of Khorana et al,<sup>27</sup> subsequent work by Lefkowitz et al<sup>28-30</sup> described the molecular cloning of a number of G protein-coupled receptors, including the  $\alpha$ - and  $\beta$ -ARs. More than any previous advance, this knowledge has permitted the analysis of adrenergic receptor biology in exquisite detail and allowed for an appreciation of the true complexity of adrenergic receptor signaling including the definition of a multitude of gene regulatory motifs and the recognition of highly organized multiprotein signaling complexes.

Relevant to the human heart, there are two major subclasses of  $\alpha$ -ARs:  $\alpha_1$  and  $\alpha_2$ .  $\alpha_1$ -ARs, of which there are several subtypes,<sup>31</sup> are coupled to the Gq/G11-family of G proteins. The Gq pathway is linked to stimulation of phospholipase C (PL-C) that promotes phosphoinositide (PIP<sub>2</sub>) turnover. The two primary products of this reaction are inositol triphosphate (IP<sub>3</sub>), which stimulates the release of intracellular

**FIGURE 10-1** Homeostatic regulation of contractile function. Adrenergic drive acts as a servo-control regulator of normal cardiac contractile function. When cardiac contractile function is adequate to sustain normal homeostasis, adrenergic drive is low or reduced. In contrast, when contractile function is inadequate to support homeostasis, cardiac adrenergic drive increases to a commensurate degree. (Adapted with permission from Port JD, Bristow MR. Altered  $\beta$ -adrenergic receptor gene regulation and signaling in chronic heart failure. *J Mol Cell Cardiol* 2001;33:887-905.)

\* = Maladaptive abnormality in adrenergic nervous system

**FIGURE 10-2** Role of increased adrenergic drive in the natural history of heart failure. A primary maladaptive response to chronic heart failure is a net increase in cardiac interstitial norepinephrine (NE) concentration, resulting from increased release and/or decreased reuptake. Increased NE results in a second maladaptive response to heart failure, that of altered  $\beta$ -AR signaling. These changes, in combination with the direct adverse biological effects of catecholamines, results in decreased myocardial reserve and progressive myocardial dysfunction, the ultimate result being decreases in both “modulatable” and intrinsic myocardial function.

calcium, and diacylglycerol (DAG), which stimulates protein kinase C (PKC) activity. Increases in intracellular calcium and PKC-mediated phosphorylation of target proteins both activate signaling pathways and gene expression patterns which, depending on the PKC subtype, ultimately result in a hypertrophic myocardial phenotype and vasoconstriction.<sup>32</sup> Examples of other Gq-coupled receptors whose stimulation also results in a hypertrophic phenotype are angiotensin II AT<sub>1</sub> receptors and endothelin-1 receptors. Each of these receptor pathways represents pharmacological targets central to the management of heart failure and/or its precursors, such as systemic or pulmonary hypertension.

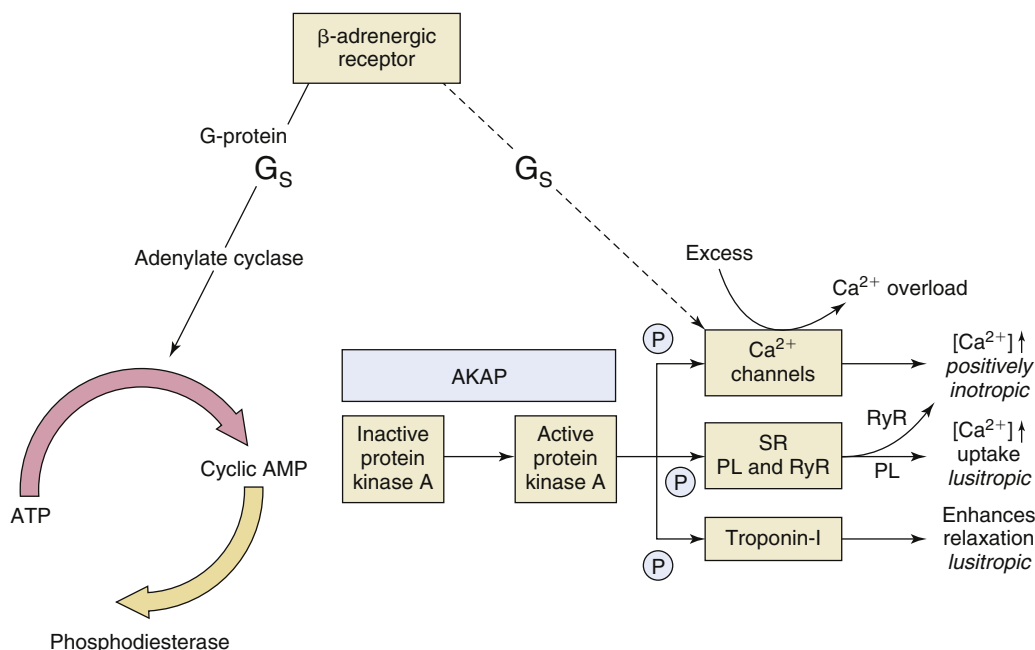

In contrast to  $\alpha_1$ -ARs,  $\alpha_2$ -ARs are generally considered to be inhibitory presynaptic or prejunctional neuronal receptors functioning to suppress the release of NE. The potential importance of this function in the setting of heart failure has been contextualized by Small et al,<sup>33</sup> where a naturally occurring “loss-of-function” polymorphism of the  $\alpha_{2C}$ -AR, when present in combination with a “gain-of-function” polymorphism of the  $\beta_1$ -AR, produces a significantly increased risk of heart failure in certain populations. These and other  $\beta$ -AR polymorphisms and their relevance to chronic heart failure are discussed in greater detail later.

$\beta$ -ARs are also subdivided, with three distinct receptor subtypes— $\beta_1$ -,  $\beta_2$ -, and  $\beta_3$ -ARs—having been described first by pharmacological response<sup>34,35</sup> and then by molecular cloning.<sup>28,29,36</sup>  $\beta_3$ -ARs are generally associated with regulation of metabolic rate and, to a much lesser degree, with changes in cardiac contractility. In distinct contrast,  $\beta_1$ - and  $\beta_2$ -ARs have clear functional significance to myocardial performance, and both are expressed at a significant abundance in the human heart.<sup>37-39</sup> The biochemical and pharmacological differences between these two receptors have been investigated extensively. Pharmacologically,  $\beta_1$ - and  $\beta_2$ -ARs, which respond equally well to the full agonist isoproterenol, are distinguished primarily by their affinity for NE ( $\beta_1$ -AR has a tenfold to thirtyfold greater affinity than  $\beta_2$ -AR),<sup>35,40</sup> and, more distinctly, by the relative affinity of highly selective receptor antagonists. In the context of

heart failure, the most clinically relevant compounds distinguishing these receptors are the  $\beta_1$ -AR-selective antagonists metoprolol and bisoprolol. Additional functional and biochemical differences in  $\beta_1$ - and  $\beta_2$ -AR signaling are discussed in detail later.

## ALTERED $\beta$ -AR SIGNAL TRANSDUCTION IN THE FAILING HEART

Downregulation and desensitization of  $\beta$ -AR receptor signaling are major contributing factors in the contractile dysfunction of the failing human heart.<sup>38</sup> In response to heightened adrenergic activation, alterations in gene expression and/or catalytic activity have been demonstrated to occur at a number of levels including that of  $\beta_1$ - and  $\beta_2$ -ARs themselves,<sup>37,38,41,42</sup> the inhibitory G protein (Gi),<sup>43</sup> the effector enzyme, adenylyl cyclase,<sup>44</sup> and the regulatory enzyme,  $\beta$ -adrenergic receptor kinase ( $\beta$ -ARK1, also known as GRK2).<sup>45</sup> In the nonfailing, nonaged human heart,  $\beta_1$ -ARs constitute approximately 70% to 80% of all  $\beta$ -ARs. However, in individuals with heart failure, the  $\beta_1$ -AR is selectively downregulated, resulting in an approximate 60:40 ratio of  $\beta_1$ - to  $\beta_2$ -ARs.<sup>38,41,46</sup> In the failing heart, both receptor subtypes are distinctly uncoupled from their signaling pathways, as has been made evident in the clinical setting, by the increased concentrations of the minimally  $\beta_1$ -AR-selective agonist (dobutamine) necessary to evoke a stimulatory response.<sup>47</sup> These effects are due to downregulation of the  $\beta_1$ -AR but more generally to receptor desensitization secondary to phosphorylation of both receptor subtypes by specific kinases (Figure 10-4). The most relevant of these kinases are members of the GRK family, specifically GRK2 ( $\beta$ -ARK1), which phosphorylates both receptor subtypes in an agonist occupancy-dependent manner,<sup>48</sup> and GRK5,<sup>49</sup> a kinase of considerable importance linking  $\beta_1$ -ARs to epidermal growth factor receptor (EGFR) transactivation and cardioprotective effects.<sup>50,51</sup>  $\beta$ -ARs can also be phosphorylated and desensitized by other kinases including PKA and PKC.<sup>52</sup>

**FIGURE 10-3** Key role of protein kinase A in the  $\beta$ -adrenergic response. The major intracellular effects of  $\beta$ -agonist catecholamines are by formation of cyclic AMP, which increases the activity of the cAMP-dependent protein kinase A (PKA). The latter achieves its optimal intracellular site by localizing to the scaffolding protein, A-Kinase Anchoring Protein (AKAP), whereupon PKA phosphorylates various proteins concerned with contraction and relaxation. SR, sarcoplasmic reticulum; PL, phospholamban; RyR, ryanodine receptor. (From Opie LH. *Heart physiology, from cell to circulation*, Philadelphia, 2004, Lippincott Williams & Wilkins. Figure copyright LH Opie, 2004; and Opie LH. Mechanisms of cardiac contraction and relaxation. **FIGURE 10-4** Mechanisms of  $\beta$ -adrenergic receptor desensitization and internalization. Note links between the internalized receptor complex with growth stimulation via mitogen-activated protein (MAP) kinase.  $\beta$ -ARK, GRK2,  $\beta$ -agonist receptor kinase or G-coupled receptor kinase; PKA, protein kinase A. (Modified from Hein L, Kobilka BK. Adrenergic receptors. From molecular structures to in vivo function. *Trends Cardiovasc Med* 1997;7:137-145; and Opie LH. Mechanisms of cardiac contraction and relaxation. In Libby P, Bonow RO, Mann DL, et al, editors. *Braunwald's heart disease*, Philadelphia, 2008, Elsevier.)

The major consequence of  $\beta$ -AR downregulation and desensitization is that for a given level of adrenergic activation, less of the second messenger cAMP is produced. Decreased formation of cAMP, in turn, leads to diminished activation of PKA. However, decreased PKA activity does not necessarily translate into decreased phosphorylation of all putative PKA substrates in the failing heart. Two of the more noteworthy targets are (a) the cardiac ryanodine receptor (RyR), a calcium release channel localized to the sarcoplasmic reticulum (SR); and the target of calcium-induced calcium release initiated by L-type calcium channels, and b) phospholamban (PLB), a small pentapeptide negative regulator of the sarcoplasmic reticulum (SR) ATP-dependent  $\text{Ca}^{++}$  pump, SERCA2. Related to the previous discussion, although PKA activity is decreased in heart failure, cardiac RyR2s have been shown to be hyperphosphorylated.<sup>53</sup> The net phosphorylation “state” of the RyR and PLB, and thus their activities, is due to the balance between kinase and phosphatase activities and other constituents of their respective intracellular microdomains, such as phosphodiesterases. Specifically, there is evidence for the downregulation of phosphatases (PP1 and PP2A) associated with the RyR2 and to changes in PKA activity.<sup>53-55</sup> Alternatively, recent studies have shown that RyR2 can be phosphorylated by CaMKII,<sup>56-58</sup> an activity that is in fact increased in the failing heart. Similarly, and perhaps counterintuitively, PKA-mediated phosphorylation of PLB appears to be unchanged in CHF.<sup>25</sup> However, PLB phosphorylation appears to be decreased in the failing heart, presumably due to the activation of the phosphatase, PP1,<sup>59</sup> which in a complex regulatory paradigm is regulated by protein phosphatase inhibitor I, PPI-1, a protein whose abundance is itself downregulated in heart failure.<sup>60-62</sup> The reduced phospholamban phosphorylation results in a greater inhibition of SERCA II, resulting in an impaired ability of the heart to

relax.<sup>63</sup> In contrast, hyperphosphorylation of the RyR results in defective channel function during excitation-contraction coupling (see chapter 3).<sup>64</sup> Together, these changes result in decreased contractility in response to adrenergic stimulation.

Substantial evidence from model systems points to significant differences between  $\beta_1$ - and  $\beta_2$ -ARs and their ability to stimulate apoptosis in cardiomyocytes<sup>7,65</sup> with stimulation of the  $\beta_1$ - but not the  $\beta_2$ -AR pathway, resulting in an increased rate of cardiomyocyte apoptosis.<sup>7</sup> However, disruption of  $\beta_2$ -AR coupling to Gi by treatment with pertussis toxin can abrogate the potential protective, antiapoptotic signaling pathways rendering the  $\beta_2$ -AR pro-apoptotic.<sup>66</sup> Chesley et al,<sup>67</sup> have provided evidence to support the supposition that the antiapoptotic effects of  $\beta_2$ -AR are mediated in part by the stimulation of the PI3K and the Akt-PKD pathways.

In addition to the mechanisms described previously, the proapoptotic effect of the  $\beta_1$ -AR pathway may also be due to increased CaMKII activity. Zhu et al<sup>68</sup> have shown that  $\beta_1$ -AR stimulation results in myocyte apoptosis that is independent of PKA activation, but dependent on CaMKII activation, suggesting that  $\beta_1$ -AR stimulation may selectively result in CaMKII activation independent of effects on PKA. These studies demonstrate that inhibition of CaMKII, L-type calcium channel phosphorylation, or buffering of intracellular  $\text{Ca}^{2+}$ , results in an attenuation of  $\beta_1$ -AR-mediated apoptosis; conversely, overexpression of CaMKII $\delta_c$  induces apoptosis. More recently, Yoo et al,<sup>22</sup> using transgenic mice with knockouts of  $\beta$ -AR subtypes, have demonstrated convincingly that postinfarct, isoproterenol-mediated increases in CaMKII signaling and apoptosis are dependent on the  $\beta_1$ -AR only.

In addition to mediating cardiac myocyte apoptotic effects, excessive  $\beta_1$ -AR signaling also activates the fetal gene program.<sup>21,24</sup> The change in myosin heavy chain isoform expression (see Chapter 2) to favor the lower ATPase activity, slow

contracting  $\beta$ -isoform would be expected to decrease contractile function, as would the downregulation in SERCA II, another adult gene that is considered part of the adult-fetal program. Although the signaling cascades responsible for this activation are complex, CaMKII appears to play a prominent role,<sup>21</sup> and the altered expression of so-called fetal and adult genes is mediated by  $\beta_1$ - and not  $\beta_2$ -AR stimulation.<sup>21,24</sup> CaMKII activity is upregulated in the failing human heart,<sup>69,70</sup> suggesting that despite the desensitization that occurs in more proximal  $\beta_1$ -receptor signaling steps, adverse signaling through CaMKII may be maintained or even enhanced.

## MOLECULAR BASIS OF $\beta$ -ADRENERGIC RECEPTOR SIGNALING

Canonically,  $\beta_1$ - and the  $\beta_2$ -ARs couple to stimulatory G proteins, Gs, which are composed of two subunits, an  $\alpha$  subunit, and a  $\beta\gamma$ -heterodimeric subunit, (Figure 10-5). Both the  $\alpha$  and  $\beta\gamma$  subunits are competent to signal independently. G $\alpha_s$  is a member of the much larger class of G protein  $\alpha$  subunits, of which there are approximately 20 subtypes. Their heterogeneity is a central basis of specificity for G protein-coupled receptor signaling, a subject reviewed in detail elsewhere.<sup>71</sup> Additional layers of signaling diversity are afforded by combinatorial permutations of various  $\beta\gamma$ -heterodimeric subunits (5  $\beta$ -subtypes and 11  $\gamma$ -subtypes) with the  $\alpha$  subunits.

As a result of agonist stimulation, G protein  $\alpha$  and  $\beta\gamma$  subunits dissociate with the free  $\alpha_s$  subunit acting to stimulate adenylyl cyclases (AC), for which there are multiple isoforms.<sup>72</sup> In cardiac tissues, the most abundant isoforms are AC V and VI, with the activities of each being feedback inhibited by increases in cytosolic calcium. Adenylyl cyclase stimulation increases production of cAMP, which in turn binds to the regulatory subunits of PKA heterotetramer. Binding causes the dissociation of the regulatory and catalytic subunits of PKA, with the catalytic subunits proceeding to phosphorylate consensus serine (S) and threonine (T) residues on a broad spectrum of intracellular target proteins.

In a number of tissues including cardiac, PKA and its targets are in close approximation because of A-kinase anchoring proteins or AKAPs.<sup>73</sup> An association between the  $\beta_2$ -AR and AKAP79 has been described.<sup>74,75</sup> Additionally, there is recent clarity as to the scaffolding proteins that interact with  $\beta_1$ -ARs in cardiac tissues.<sup>76</sup> Thus unique interactions between  $\beta_1$ - and  $\beta_2$ -ARs and specific AKAPs and/or other anchoring proteins would support the building “microdomain” concept of receptor subtype-specific signaling discussed in greater detail later.

Via the traditional G $\alpha_s$ /adenylyl cyclase pathway,  $\beta$ -AR stimulation results in the phosphorylation by PKA of a number of proteins including L-type calcium channels<sup>75</sup> and PLB, the primary modulator of the SR-associated ATP-dependent calcium pump, SERCA II, and modulatory proteins associated with regulation of the contractile apparatus (e.g., troponin I [TnI]). More directly, however, PKA phosphorylates  $\beta$ -ARs,<sup>77</sup> and other G protein-coupled receptors, resulting in partial uncoupling and desensitization of receptors to further agonist stimulation. Changes in the phosphorylation state of L-type calcium channels and PLB uniformly results in increased  $[Ca^{++}]_i$  and enhanced rates of myocardial contractility and relaxation. However, the increases in intracellular calcium have a number of other effects beyond enhanced contractility including the activation of calcium sensitive enzymes (e.g.,  $Ca^{++}$ /calmodulin and calcineurin [phosphatase PP2B]).<sup>78</sup> On a more global level, changes in  $[Ca^{++}]_i$  can result in profound changes in gene expression patterns.

Various studies suggest that CaMKII may be involved in many of the detrimental effects of chronic  $\beta_1$ -AR stimulation. In support of this view, a transgenic mouse model of CaMKII inhibition was developed.<sup>79</sup> These mice express an inhibitory

**FIGURE 10-5** Signal transduction pathways stimulated by  $\beta$ -ARs. Canonically, both  $\beta_1$ - and  $\beta_2$ -ARs signal via the stimulatory G protein, G $\alpha_s$ , to stimulate adenylyl cyclase (AC) activity, increasing cAMP production and activating PKA. Downstream targets of PKA include L-type  $Ca^{++}$  channels, contractile proteins (e.g., TnI), and the regulator of sarcoplasmic reticulum calcium uptake, phospholamban (PLB). Increased  $[Ca^{++}]_i$  results in increased contractility and, if persistent, apoptosis. The  $\beta_1$ -AR activates at least two other pathways: CaMKII and the epidermal growth factor receptor (EGFR). Increased CaMKII activity results in increased  $[Ca^{++}]_i$  and calcineurin phosphatase activity, which activates pro-hypertrophic transcription factors causing the reexpression of the fetal gene program (FGP); it also accelerates the rate of myocyte apoptosis. In contrast,  $\beta_1$ -AR mediated stimulation of the EGFR is a cardio-protective, antiapoptotic pathway. The  $\beta_2$ -AR can also couple to the inhibitory G protein, Gi, resulting in a direct inhibition of AC activity and activation of pro-hypertrophic MAPKs and antiapoptotic pathways. (Adapted with permission from Port JD, Bristow MR. Altered  $\beta$ -adrenergic receptor gene regulation and signaling in chronic heart failure. *J Mol Cell Cardiol* 2001;33:887-905.)

peptide targeted to a conserved region of the CaMKII regulatory domain. Mice expressing the inhibitory peptide are resistant to pathological changes related to  $\beta$ -AR stimulation, and do not exhibit decreases in fractional shortening, increases in heart/body weight, or decreases in left ventricular (LV) internal diameter. Moreover, results in single cell experiments and *in vivo* models indicate that CaMKII can serve as a proarrhythmic signaling molecule.<sup>80</sup> These results suggest that the pathological effects of  $\beta_1$ -AR stimulation are mediated by CaMKII and not by PKA.

For some time,  $\beta_1$ - and  $\beta_2$ -ARs have been known to differ in the efficacy of coupling to adenylyl cyclase and to cAMP production, with the  $\beta_2$ -AR subtype being more efficiently coupled to cAMP production than is the  $\beta_1$ -AR.<sup>39</sup> In trabeculae isolated from the human heart, selective stimulation of contraction by either receptor pathway generally correlates well with receptor abundance.<sup>38,81</sup> Thus the fact that the  $\beta_2$ -AR produces more cAMP per unit of stimulus does not correlate with a greater inotropic potential for  $\beta_2$ -ARs. Overall, these data favor an argument that there is distinct intracellular compartmentalization of cAMP pools produced by  $\beta$ -ARs,<sup>82</sup> with the existence of discrete microdomains of high cAMP concentration in cardiomyocytes. Specifically, in neonatal cardiomyocytes, high concentrations of cAMP are found in the proximity of T tubules and the junctional SR. An argument is also made that diffusion of cAMP outside of these microdomains is quickly curtailed by the action of phosphodiesterases. Support for this notion is the finding that there appears to be close coordination between agonist-stimulated recruitment of phosphodiesterases to the  $\beta_2$ -AR, a process facilitated by interaction with  $\beta$ -arrestins, and the attenuation of signaling. Recent data indicates that the differential signaling and architecture of  $\beta_1$ - and  $\beta_2$ -ARs appears to be defined in part by a differential association with phosphodiesterases

(PDEs),<sup>83</sup> with PDE4 activity preferentially targeting cAMP produced by the  $\beta_1$ -AR, whereas cAMP produced by the  $\beta_2$ -AR is being targeted by multiple subtypes of PDEs.<sup>84</sup> Perhaps counterintuitive to the highly localized responses of  $\beta$ -ARs being dictated by scaffolding proteins is the recent study by Nikolaev et al<sup>84</sup> demonstrating in transgenic mice that isoproterenol-mediated increases in cAMP in cardiac tissues leads to “far-reaching” cAMP signals for the  $\beta_1$ -AR, whereas  $\beta_2$ -AR-generated cAMP appears to remain locally confined.

It is becoming increasingly clear that both the  $\beta_1$ -AR and the  $\beta_2$ -AR pathways couple to signaling pathways beyond the “traditional” *Gas*/adenylyl cyclase pathway.<sup>85</sup> Perhaps the best example of this diversity of signaling is the finding that the  $\beta_2$ -AR can interact with the inhibitory G protein, *G $\alpha$ i*. This is of interest in the setting of CHF for two reasons. As described earlier, increased circulating NE concentrations result in chronic activation of  $\beta$ -ARs. This, in turn, results in increased  $\beta$ -ARK activity and an increased phosphorylation state of  $\beta$ -ARs, resulting ultimately in the uncoupling of the receptor from the stimulatory *Gas* signaling pathway. It is this phosphorylated form of the  $\beta_2$ -AR that has an increased propensity to couple to the inhibitory *G $\alpha$ i* pathway<sup>86</sup> and its downstream effectors, including inhibition of AC and activation of MAPKs. Amplifying this effect is the finding that the abundance of *G $\alpha$ i* proteins is significantly elevated in the failing human heart.<sup>87</sup> Thus the increased phosphorylation state of the  $\beta_2$ -AR and the increased abundance of *G $\alpha$ i* protein both facilitate increased trafficking of  $\beta_2$ -AR signaling via *G $\alpha$ i*-associated pathways. The ramifications of this are potentially significant, particularly in regard to protective, antiapoptotic effects and to myocardial growth regulatory effects.

The  $\beta_1$ -AR, although currently thought to be less promiscuous than the  $\beta_2$ -AR in its ability to couple to pathways other than to *Gas*, nonetheless does exhibit signaling via additional pathways, in particular the CaMKII pathway. At least in part, this extra-*Gas* coupling, much like that of the  $\beta_2$ -AR, appears to be facilitated by the specificity of the carboxy-terminus PDZ (PSD-95/Dlg/ZO-1) domain of the receptor peptide, which drives the interaction with proteins containing specific PDZ recognition motifs. An excellent review on the general topic of regulation of  $\beta$ -AR signaling by scaffolding proteins has been published by Hall and Lefkowitz.<sup>88</sup> Examples of  $\beta_1$ -AR interacting proteins are PSD-95, MAGI-2, the endophilins (SH3p4/p8/p13), and CNrasGEF, all of which appear to have unique downstream roles. The association of the  $\beta_1$ -AR with PSD-95, which is a neuronal-associated protein, distinctly places the  $\beta_1$ -AR in the proximity of the synapse,<sup>89</sup> a location perhaps even driven by sympathetic innervation. Here, PSD-95 appears to inhibit the internalization of the  $\beta_1$ -AR,<sup>90</sup> an effect that is modulated by the kinase GRK5. Conversely, interaction of the  $\beta_1$ -AR with endophilins appears to negatively modulate *Gas* coupling and to promote  $\beta_1$ -AR internalization.<sup>91</sup> Recently, a more detailed picture of the  $\beta_1$ -AR SAP97-AKAP79 scaffold at its PSD-95/DLG/ZO1 motif has been demonstrated to be necessary for both PKA-mediated phosphorylation of the  $\beta_1$ -AR and for receptor recycling.<sup>76</sup> This is in contrast to the findings describing the association of the  $\beta_1$ -AR with CNrasGEF (PDZ-GEF1), an effector molecule that activates Ras, and thus growth pathways. In this case, the mechanism of Ras activation is rather unique given that it appears to be via *Gas* rather than the well-documented *G $\beta$  $\gamma$*  signaling pathway (see Figure 10-3).

Additional evidence for the importance of PDZ-mediated interactions has been described by Xiang et al.<sup>92</sup> Specifically, mutation of the PDZ motif by disruption of the carboxy-terminus renders the  $\beta_1$ -AR significantly more sensitive to agonist-mediated cell surface downregulation. Further, the deletion of C-terminal amino acids renders the  $\beta_1$ -AR more  $\beta_2$ -AR-like in that it becomes capable of interacting with *Gi*. Thus, even though the  $\beta_1$ -AR<sup>90</sup> and  $\beta_2$ -AR<sup>93</sup> both contain PDZ

motifs, the interacting proteins that each couple via these motifs are unique and are important basis of different regulatory and signaling properties. To expand this concept, the  $\beta_2$ -AR has been shown to modulate signaling independent of its interactions with G proteins. For example, the  $\beta_2$ -AR appears to couple to at least three other pathways: (1) NHERF, which in turn regulates the function of the  $\text{Na}^+/\text{H}^+$  exchanger; (2) to a non-PKA-dependent interaction with L-type calcium channels<sup>20,85</sup>; and (3) the phosphatidylinositol 3'-kinase pathway (PI3K), a pathway associated with the inhibition of apoptosis,<sup>94</sup> and to the PI3K-PTEN pathway, which is relevant to the regulation of both myocardial contractility and cell size and shape.<sup>95</sup>

As alluded to previously,  $\beta$ -AR stimulation results in the dissociation of the stimulatory G protein, *G $\alpha$ s*, into  $\alpha$  and  $\beta\gamma$  subunits, each of which are signaling entities. A major function of the  $\beta\gamma$  heterodimer is to recruit  $\beta$ -ARKs in proximity to the receptor. By virtue of the lipid-modified (isoprenylation) of the  $\gamma$  subunit, which promotes localization of the  $\beta\gamma$  subunit to the sarcolemmal membrane, the heterodimer is in position to orchestrate the colocalization of the  $\beta$ -AR with  $\beta$ -ARK. Protein/protein interaction of the  $\beta\gamma$  subunit with  $\beta$ -ARK occurs via a pleckstrin homology (PH) domain.<sup>96</sup> In this way, agonist-dependent  $\beta$ -ARK-mediated phosphorylation of  $\beta$ -ARs is the dominant mode of  $\beta$ -AR desensitization.<sup>48</sup> In addition to playing a scaffolding role,  $\beta\gamma$  subunits are also signaling molecules in their own right. Downstream targets of signaling include subsets of adenylyl cyclases, PI3K,  $\text{K}^+$  channels, and Ras/Raf/MEK/MAPK pathway(s) (see Figure 10-3).

Recently, significant attention has been paid to the specifics of  $\beta$ -AR localization and receptor trafficking. Differential targeting of  $\beta$ -AR subtypes to specific intracellular compartments has been described.<sup>97</sup> Of note is the apparent caveolar colocalization of the  $\beta_2$ -ARs with the inhibitory protein, *G $\alpha$ i*, and with PKA subunits and with GRK2. What is now becoming clear is that the localization of the  $\beta_2$ -AR to the caveolar compartment is an essential component of its signaling capabilities.<sup>98</sup> In contrast,  $\beta_1$ -ARs, and a number of other proteins including *Gas*, and ACs V and VI, are not specifically associated with caveolea; instead, these proteins have a more generalized distribution.

Although there is no doubt that constitutive stimulation of the  $\beta_1$ -AR can cause significant myocardial damage, an important and newly emergent concept of  $\beta$ -AR signaling is that of the connection between  $\beta_1$ -AR signaling with the cardioprotective effects of the epidermal growth factor receptor (EGFR) pathway. Work from Rockman et al<sup>50,51,99</sup> has shown that GRK5/6-mediated phosphorylation of the  $\beta_1$ -AR targets the association of  $\beta$ -arrestin to the receptor, which, in addition to activating MAP kinases, facilitates the activation of matrix metalloproteinases, causing the release of heparin-bound EGF which then activates the EGFR. Activation of the EGFR leads to activation of Ras/Raf/ERK/Akt and subsequent antiapoptotic, cardioprotective effects (see Figure 10-5).

## REGULATION OF $\beta$ -AR GENE EXPRESSION

Genes encoding  $\beta$ -ARs are regulated at virtually every level, including transcriptional and posttranscriptional regulation, as well as translational and posttranslational regulation. Much like protooncogenes and cytokines,  $\beta$ -ARs can profoundly affect a number of cellular functions affecting cell viability, thus the need for stringent, rapid, and redundant regulatory mechanisms.  $\beta$ -AR expression, at both the level of mRNA and protein, is the result of a number of independent regulated processes.

At the level of transcriptional regulation, both positive and negative transcriptional regulatory elements exist within the 5'-untranslated regions (UTRs) of  $\beta$ -ARs. Cell culture model

systems have provided significant evidence regarding the effects of a number of transcriptional regulatory pathways, starting with the most obvious, that of the direct effects of  $\beta$ -AR stimulation. Increases in cAMP can lead to a transient upregulation of  $\beta$ -AR mRNA via a cAMP-responsive element (CRE)-mediated transcriptional effect. However, it is recognized that in heart failure, at least for the  $\beta_1$ -AR, mRNA and protein are unequivocally downregulated.<sup>41</sup> Therefore, CRE-mediated upregulatory effects are unlikely to be important in the chronic setting. Conversely,  $\beta$ -AR genes have the potential to be negatively regulated by the transcriptional suppressor, ICER (inducible cAMP early repressor). Recent evidence points to a role for ICER in a pathophysiological feedback loop with its upregulation causing a persistent downregulation of PDE3A, a finding associated with increased isoproterenol-mediated cardiomyocyte apoptosis.<sup>100</sup>

In the cardiac context, a number of other transcriptional regulators of  $\beta$ -AR genes are also known to be important. Most notably, transcriptional regulation of  $\beta$ -AR genes by glucocorticoid- and thyroid hormone-responsive elements can have significant effects via their respective consensus DNA binding elements (e.g., GREs and TREs).<sup>101,102</sup> In general, glucocorticoids have been associated with causing an upregulation of  $\beta_2$ -ARs and a reciprocal downregulation of  $\beta_1$ -ARs,<sup>101,103</sup> whereas thyroid hormone has been uniformly associated with upregulation of  $\beta$ -AR expression.<sup>102</sup>

It is currently well recognized that like a number of protooncogenes, cytokines, and a number of other G protein-coupled receptors,  $\beta$ -ARs undergo posttranscription regulation at the level of mRNA stability. For  $\beta$ -ARs expressed in myocardial tissues, the relationship between mRNA and protein appears to be well preserved.<sup>104</sup> Thus mechanisms regulating  $\beta$ -AR mRNA abundance likely impacts  $\beta$ -AR protein expression. To this end, nucleic acid motifs known as A+U-rich elements (AREs), found within the 3'UTRs of several  $\beta$ -ARs, are known to be the target for a number of mRNA-binding proteins associated with changes in mRNA turnover. Previous evidence has confirmed a relationship between agonist-mediated stimulation of  $\beta$ -ARs, production of cAMP, and destabilization of  $\beta$ -AR mRNA, resulting in reduced mRNA and ultimately protein abundance.<sup>105</sup> Increasing evidence points to the role of MAPK pathways as critical regulators of the stability of ARE containing mRNAs including those encoding  $\beta$ -ARs.<sup>106</sup> In particular, several proteins associated with mRNA changes in mRNA turnover have been demonstrated to bind to  $\beta$ -AR AREs. These include AUF1/hnRNP D, which is associated with increased mRNA turnover<sup>107,108</sup>; HuR, which is associated with stabilization of numerous ARE containing mRNAs<sup>109</sup>; KSRP, which increases turnover of ARE containing mRNAs, drives muscle cell differentiation and modulates Wnt/ $\beta$ -catenin and PI3K/Akt signaling<sup>110</sup>; and tristetraprolin (TTP), which is associated with turnover of TNF- $\alpha$  mRNA.<sup>111</sup> How each of these proteins specifically affects  $\beta$ -AR mRNA turnover in the myocardial tissues remains to be explored. However, given the evidence that the homozygous deletion of TTP in transgenic mice results in a dramatic upregulation of TNF- $\alpha$  and a subsequent cardiomyopathy,<sup>112</sup> there is little doubt that these mechanisms are in play.

## MYOPATHIC POTENTIAL OF INDIVIDUAL COMPONENTS OF ADRENERGIC RECEPTOR PATHWAYS

The development and study of transgenic animal models has provided a wealth of information with regard to understanding the role of adrenergic receptor signaling in CHF. This section will summarize a few of the more relevant findings obtained from animal models containing cardiac-targeted overexpression or deletion of various components of adrenergic receptor

pathways. The impact of these changes on the development or prevention of cardiomyopathy is discussed.

## Adrenergic Receptors

The idea that significant differences exist between  $\beta_1$ - and  $\beta_2$ -AR signaling in the heart has been reinforced in recent years by data from a number of transgenic mouse models. One of the more notable initial observations was that overexpression of each receptor subtype can result in strikingly different cardiac phenotypes. As originally reported by Milano et al,<sup>113</sup> overexpression of the wild-type  $\beta_2$ -AR in mice, at relatively high abundance (~50- to 200-fold), was associated with increased basal AC activity, enhanced contractility, and elevated LV function. Interestingly, no pathology was apparent in animals up to 4 months of age. In a longer-term study, Liggett et al<sup>114</sup> reported comparable effects of increased  $\beta_2$ -AR on the myocardium (i.e., enhanced cardiac function from birth); however, this group also noted linear gene dose-dependence with regard to the development of cardiomyopathy. Animals expressing more than 60 times the background  $\beta$ -AR concentration maintained their hyperdynamic state for more than 1 year without an apparent increase in mortality. In contrast, overexpression of the  $\beta_2$ -AR at approximately 100-fold resulted in progressive cardiac enlargement, the development of heart failure, and premature death occurring at close to 1 year of age. At approximately 350 times the level of wild-type expression, the  $\beta_2$ -AR produced a cardiomyopathy, resulting in premature death in 50% of animals as early as week 25.<sup>114</sup>

Compared to the unusually high levels of  $\beta_2$ -AR expression required to produce myopathic results, wild-type  $\beta_1$ -AR overexpression at relatively low abundance (~twentyfold to fortyfold) can lead to markedly decreased contractility and LV function and increased hypertrophy and fibrosis, resulting in progressive myocardial failure and premature death.<sup>115,116</sup> The pathophysiological mechanism(s) responsible for the detrimental effects of  $\beta_1$ -AR overexpression in these animals are only partially understood. Chronic increases in PKA activity is likely to be a component of the pathology associated with  $\beta_1$ -AR overexpression as overexpression of the catalytic subunit of PKA is, in its own right, cardiomyopathic.<sup>117</sup> However, in the failing heart, cAMP abundance and, therefore, PKA activity is generally decreased.<sup>25</sup> Thus it is possible or perhaps even likely that  $\beta_1$ -AR-mediated CaMKII activity, which is increased in CHF, underlies the observed pathology.

Initial studies reported an increase in systolic function in young animals overexpressing the  $\beta_1$ -AR, with a progressive decline in LV function occurring with age.<sup>115,116</sup> Interestingly, this appears to occur before any structural alterations, such as fibrosis, which do not become apparent until at least 4 months, depending on the level of expression. In this same study, the mechanism of contractile dysfunction was found to involve impaired  $\text{Ca}^{2+}$  handling in cardiac myocytes, characterized by marked prolongation of intracellular  $\text{Ca}^{2+}$  transients. Subsequent examination of the expression levels of various sarcoplasmic reticulum (SR) proteins involved in  $\text{Ca}^{2+}$  release and uptake revealed a modest increase in the expression of SERCA protein in animals at 2 months of age, and increased phosphorylation of phospholamban at Ser16, a critical regulatory site, was also detected. Collectively, these results indicate that impaired  $\text{Ca}^{2+}$  handling is likely a major causal factor in producing early contractile dysfunction in  $\beta_1$ -AR overexpression, with these changes occurring before the appearance of mice interstitial fibrosis or other structural alterations.

It is worth noting that overexpression of genetic variants of the  $\beta_1$ -AR have different phenotypes. As described later, the gain-of-function Arg389 variant of the  $\beta_1$ -AR produced a much more marked and rapid cardiac pathology than does the Gly389 variant.<sup>118</sup>

Transgenic animal models that overexpress other adrenergic receptors have also been described. Overexpression of wild-type  $\alpha_1$ -AR subtypes has been observed to cause increases in cardiac contractility,<sup>119</sup> with variable effects of hypertrophy present in an  $\alpha_{1b}$ -AR model,<sup>120</sup> but not in an  $\alpha_{1a}$ -AR model.<sup>121</sup> However, overexpression of the wild-type  $\alpha_{1b}$ -AR, when coupled with chronic  $\alpha_1$ -AR stimulation by phenylephrine, results in severe myocardial hypertrophy in conjunction with high levels of  $\beta$ -ARK1 activity and increased mortality.<sup>122</sup> Similarly, overexpression of a constitutively active mutant of the  $\alpha_{1b}$ -AR has been shown to cause a mildly hypertrophic phenotype, with evidence of upregulation of hypertrophy-related genes and  $\beta$ -ARK1.<sup>113</sup> Thus overexpression of either  $\alpha_1$ - or  $\beta_2$ -ARs, mimicking increased adrenergic drive, generally recapitulates the hypertrophic phenotype, but not necessarily the heart failure phenotype, evoked by high catecholamine concentrations. This conclusion is of course gene-dose dependent.

## G Proteins and Adenylyl Cyclase

As described previously, the G proteins involved in adrenergic signaling are several, including Gs and Gi, which modulate AC activity, and Gq, which is linked to activation of PLC. Similar to that observed with the  $\beta$ -ARs, overexpression of each of these downstream signaling components results in a variety of cardiac phenotypes. Transgenic mice overexpressing wild-type Gas have been described as having a chronically increased heart rate, enhanced chronotropic and inotropic responses to an agonist, altered  $\beta$ -AR density, and an increased frequency of cardiac arrhythmias.<sup>123</sup> Over time, myocardial performance in Gas overexpressing animals declines, and LV dilation is observed. Likewise, myocyte hypertrophy, apoptosis, and fibrosis become evident with age, and animals die prematurely. In addition, there is evidence that overexpression of Gas is associated with an increase in L-type  $\text{Ca}^{2+}$  currents, an effect which appears to be independent of cAMP and AC activation. From these data, it has been suggested that Gas may directly regulate the activity of L-type calcium channels. Interestingly, much like transgenic models of  $\beta$ -AR overexpression,<sup>118</sup> the pathophysiological changes observed with Gas overexpression can be prevented and survival improved through treatment with  $\beta$ -blockers.<sup>124</sup>

Transgenic mice that overexpress G $\alpha_q$  also exhibit a myopathic phenotype characterized by marked myocyte hypertrophy, increased expression of hypertrophy-related genes, and increased fibrosis, ultimately resulting in decreased myocardial contractility.<sup>125</sup> The mechanism of cardiomyopathy appears to involve, at least in part, cross regulation to  $\beta$ -AR signaling pathways by G $\alpha_q$  or its downstream effectors.<sup>126</sup> Mice that overexpress G $\alpha_q$  exhibit decreased AC activity in response to an agonist, which is apparently due to impaired functional coupling of  $\beta$ -ARs to AC, since  $\beta$ -AR density is unchanged when compared with wild-type expression levels. In addition,  $\beta$ -AR stimulation of L-type  $\text{Ca}^{2+}$  channels is depressed in G $\alpha_q$  overexpressors, and expression levels of Gi are increased, as is PKC activity. In this model, inhibition of Gai unexpectedly caused sudden death, suggesting that the change in Gai expression may be a compensatory mechanism to counteract other detrimental signaling caused by the Gq pathway.

Cardiac-targeted overexpression of a modified Gi-coupled receptor has been reported.<sup>127</sup> Mice that contain this modified receptor reportedly exhibited significant ventricular conduction delays, which can be attenuated by treatment with pertussis toxin, suggesting strongly a Gi-dependent mechanism. Moreover, these animals developed a pronounced dilated cardiomyopathy, resulting in death by 15 weeks of age. These results were the first to suggest a potential causal role for

increased Gi signaling in the development and progression of heart failure,<sup>127</sup> and stand in distinction to the notion that the Gi pathway is simply protective, acting to abrogate the deleterious stimulatory effects of the Gas pathway. In fact, overexpression of the carboxy-terminus of Gai (GiCT), a peptide construct that inhibits Gi signaling, has been demonstrated to enhance apoptosis associated with ischemia.<sup>128</sup>

In contrast to the previous discussion, overexpression of more distal components of the Gs signaling pathways, specifically ACs V or VI, does not appear to cause any form of cardiomyopathy.<sup>129</sup> Agonist-stimulated AC activity is higher in this model, and basal and stimulated PKA activities are also increased; however, these effects translate into modestly enhanced inotropic, lusitropic, or chronotropic function. Further, no long-term histopathological sequelae or deleterious changes in cardiac function have been noted with AC overexpression.<sup>129</sup> Based on this profile, gene therapy trials using adenovirus-mediated gene transfer of adenylyl cyclases are under consideration.

## ADRENERGIC RECEPTOR POLYMORPHISMS IN HEART FAILURE

It has become an accepted paradigm that polymorphisms of many genes, including a number of components of adrenergic receptor signaling pathways and the renin-angiotensin system, can markedly influence the progression of cardiovascular disease and/or response to individual therapeutic agents (see Chapter 42). Depending on the genetic variant and the endpoint assessed, variable response may be generalized either to a class of agents (i.e.,  $\beta$ -blockers) or delimited to an individual agent.

In groundbreaking work performed in large part by Liggett et al, the polymorphic variants of  $\alpha$ - and  $\beta$ -ARs have been demonstrated to have profound effects on not only receptor signaling and sensitivity to pharmacological agents but also to clinical outcomes. For more detailed information on the subject, several overviews of adrenergic receptor polymorphisms have been published.<sup>130-132</sup> As with many genes, a number of haplotypes have been described.<sup>133,134</sup> Further, allele frequencies and combinations of complex haplotypes are not uniform across ethnic and geographical populations.<sup>130,133</sup>

Of particular importance, two major polymorphic loci have been identified for the human  $\beta_1$ -AR gene: variations at nucleotides 145 and 1165 encode either a serine (Ser) or glycine (Gly) variant amino acid position 49 or a Gly or arginine (Arg) variant at amino acid position 389. Data indicate that the Gly49 variant is significantly more susceptible to agonist-induced downregulation than is the Ser49 variant,<sup>135</sup> even though the two variants do not appear to be different in terms of their ability to couple to stimulation of adenylyl cyclase and production of cAMP. In contrast, the Arg389 variant of the  $\beta_1$ -AR is much more efficiently coupled to adenylyl cyclase stimulation than is the Gly389 variant.<sup>136</sup> For historical reasons, the Gly389 variant has been considered to be the “wild-type” allele as it was the first to be cloned<sup>29</sup>; however, its frequency in the Caucasian and African American populations being approximately 0.27 and 0.42, respectively,<sup>132,137</sup> establishes the fact that it is not the most common allele.

As a follow-up to cell-based studies, transgenic mouse studies where the  $\beta_1$ -AR Arg389Gly-receptor variants have been overexpressed clearly demonstrate that Arg389 is markedly more pathological.<sup>118</sup> Additionally, Arg389 mice are more responsive to  $\beta$ -blocker therapy, a notion that fits with the increased function receptor variant being able to be pharmacologically suppressed to a greater degree.

Over the past several years, a number of clinical studies, almost exclusively retrospective, have attempted to correlate

clinical outcome to the  $\beta_1$ -AR 389Arg/Gly genotype (see Chapter 42). An example of a study demonstrating differential efficacy for carvedilol in patients with  $\beta_1$ -AR 389Arg/Gly variants, the endpoint being increased ejection fraction, was recently published by Chen et al.<sup>138</sup> Conversely, Sehnert et al<sup>139</sup> recently demonstrated no effect of  $\beta_1$ -AR 389Arg/Gly variants on the clinical endpoint of transplant-free survival for heart failure patients receiving either carvedilol or metoprolol. However, Liggett et al demonstrated an effect of  $\beta_1$ -AR 389Arg/Gly variants on mortality and other endpoints for the investigational  $\beta$ -blocker, bucindolol.<sup>140</sup> Thus, for the mortality endpoint, a variable effect for the  $\beta_1$ -AR 389Arg/Gly polymorphism may be agent dependent. It is probably fair to say that the heterogeneity of outcome for this and other polymorphisms is due to a combination of variations in populations, including complex genetic traits, environmental factors, variable endpoints (e.g., EF% vs. mortality), cause of heart failure, and intent of the study (i.e., progression of disease vs. response to therapy).

Related to disease progression, a previous study by Small et al<sup>33</sup> investigated the potential synergism between  $\beta_1$ -AR and  $\alpha_{2c}$ -AR polymorphisms and uncovered a significant increased risk of progression to heart failure, particularly in African American subjects, when the gain-of-function (increased signaling) Arg398 allele  $\beta_1$ -AR is present in conjunction with the loss of function (decreased inhibition of prejunctional NE release)  $\alpha_{2c}$ -AR deletion allele.<sup>33</sup> What is of particular interest is that the  $\beta_1$ -AR Arg389 allele does not appear to be a risk factor in and of itself; however, its presence increases considerably the risk associated with the  $\alpha_{2c}$ -AR deletion allele.

A number of polymorphisms have also been described for the human  $\beta_2$ -AR, the best characterized of which is the presence of either a threonine (Thr) or isoleucine (Ile) at amino acid position 164.<sup>141</sup> The allele frequency of the 164 Ile, minor allele is quite low (<5%), and only 5% of the population is heterozygous Thr/Ile. Remarkably, no homozygous Ile/Ile subjects have been identified, possibly because of the myocardial dysfunction associated with this loss-of-function polymorphism. Similar to the  $\beta_1$ -AR Arg389 variant, the Thr164  $\beta_2$ -AR is much more efficiently coupled to adenylyl cyclase activation than is the Ile164 variant. The presence of the Ile164 allele is associated with reduced exercise capacity and reduced transplant-free survival. In a transgenic mouse model system, overexpression of the human  $\beta_2$ -AR Ile164 leads to impaired cardiac function,<sup>142</sup> a finding that recapitulates the observation that this allele is associated with reduced exercise capacity and reduced survival in patients with heart failure.<sup>143</sup>

As described previously, one of the major regulators of  $\beta$ -AR signaling are the GRKs. Interestingly, a Gln>Leu41 variant of GRK5 has been shown to be protective against heart failure-associated death or transplantation in an African American population<sup>144</sup> where the Leu allele is approximately 20 times more frequent than in Caucasian populations. The authors speculate that the increased agonist-mediated uncoupling of the  $\beta$ -AR by GRK5-Leu41 is, in essence, the equivalent of "genetic  $\beta$ -blockade."<sup>131,145</sup>

There would seem a high likelihood that beyond what has already been described,<sup>146</sup> other polymorphic variants of adrenergic receptors, other G protein-coupled receptors, and any number of downstream effectors will eventually be described. A significant question that remains to be addressed is whether or not the presence of specific polymorphisms, alone or in combination, are primary factors in the predisposition to, or in the rate of progression of, heart failure.

## SUMMARY

Adrenergic mechanisms are markedly altered in chronic heart failure, and these alterations exert major effects on the natural history of this clinical syndrome. Adrenergic

abnormalities can be classified into two major groups: those that produce a sustained increase in adrenergic drive and those that cause defects in  $\beta$ -AR signal transduction. Within each category there is the potential for benefit and harm, and successful therapeutic intervention involves interfering with the harmful components without compromising the beneficial aspects.

It should be clear from the scope of this review that adrenergic receptor signaling is far more complex than our naïve supposition that the binding of catecholamines to receptors simply increases the abundance of the second messengers, cAMP and  $\text{Ca}^{++}$ , thereby affecting an increase in myocardial contractility and heart rate. Although the importance of these functions has not been diminished, adrenergic receptors are now recognized to be important effectors in any number of cellular processes important to cardiomyocyte biology. Undoubtedly, the diversity and complexity of these signaling paradigms will continue to unfold. It is hoped that an increased appreciation of these processes, and the recognition that genetic variation is important to both disease progression and to therapeutic response, will lead to advances in heart failure therapeutics.

### The Biology of Proinflammatory Inflammatory Cytokines and Their Receptors, 163

Rationale for Studying Inflammatory Mediators in Heart Failure, 167  
Summary and Future Perspectives, 181

## Activation of Inflammatory Mediators in Heart Failure

Douglas L. Mann

Although clinicians have recognized the pathophysiological importance of inflammatory mediators in the heart as early as 1669,<sup>1</sup> the formal recognition that inflammatory mediators were activated in the setting of heart failure did not occur for another three centuries. Since the sentinel description of inflammatory cytokines in patients with heart failure in 1990,<sup>2</sup> there has been a growing interest in the role that these molecules play in regulating cardiac structure and function, particularly with regard to their potential role in disease progression in heart failure. Accordingly, in the present chapter we will summarize the recent growth of knowledge that has taken place in this field, with a particular emphasis on the potential role that proinflammatory cytokines play as mediators of disease progression in the failing human heart. We will also summarize the results of clinical trials that have employed antiinflammatory strategies in patients with heart failure.

### THE BIOLOGY OF PROINFLAMMATORY INFLAMMATORY CYTOKINES AND THEIR RECEPTORS

Cytokines are relatively small molecular weight protein molecules (generally 15 to 30 kDa) that are secreted by cells in response to a variety of different inducing stimuli. Whereas “proinflammatory cytokines” have traditionally been thought to be produced by the immune system, one of the more recent intriguing observations is that virtually all nucleated cell types within the myocardium, including cardiac myocytes themselves, are capable of synthesizing a portfolio of proinflammatory cytokines in response to various forms of cardiac injury (Box 11-1). Thus, from a conceptual standpoint, these molecules should be envisioned as proteins that are produced locally within the myocardium by “cardiocytes” (i.e., cells that reside within the myocardium), in response to one or more different forms of environmental stress. In the section that follows, we will review the biological properties of several important proinflammatory cytokines, including members of the tumor necrosis factor (TNF) family (including the recently described member TWEAK),<sup>3</sup> members of the IL-1 family (including the recently described members IL-18 and IL-33<sup>4,5</sup>), and the IL-6 family of cytokines.

#### Tumor Necrosis Factor (TNF) Superfamily

**Tumor Necrosis Factor.** Although TNF was originally defined by its anti-tumor activity *in vitro* and *in vivo*, TNF is now recognized as a cytokine with pleiotropic biological capacities. Besides its cytostatic and cytotoxic effects on certain tumor cells, it influences growth, differentiation, and/or function of virtually every cell type investigated, including cardiac myocytes.<sup>6</sup> In most cell types studied, TNF is initially synthesized as a nonglycosylated transmembrane protein of approximately 25 kDa. A 17-kDa fragment is proteolytically cleaved off the plasma membrane of the cell by a membrane-bound enzyme termed “TACE” (TNF- $\alpha$  convertase [ADAM17]) to produce the “secreted form,” which circulates as a stable 51-kDa TNF homotrimer (Figure 11-1).

The effects of TNF are initiated by binding to a lower affinity ( $K_d = 2 - 10 \times 10^{-10}$ ) 55-kDa “type 1 receptor” (also called TNFR1) and/or a higher affinity ( $K_d = 2 - 10 \times 10^{-11}$ ) 75-kDa “type 2 receptor” (also called TNFR2); intracellular signaling occurs as a result of TNF-induced oligomerization of the receptors. Both TNFR1 and TNFR2 share homology in their extracellular domains, which each contain a characteristic repeated cysteine consensus motif. In contrast, the intracellular domains of TNFR1 and TNFR2 differ, suggesting that each receptor has distinct modes of signaling and cellular function (see Figure 11-1).

Previous studies have identified the presence of both types of TNF receptors in nonfailing<sup>7</sup> and failing human myocardium.<sup>8</sup> Both TNF receptor subtypes have been immunolocalized to the adult human cardiac myocyte, thus providing a potential basis for beginning to understand the signaling pathways that are used by TNF. Although the exact functional significance of TNFR1 and TNFR2 in the heart is not known at present, the majority of the deleterious effects of TNF are coupled to activation of TNFR1,<sup>9</sup> whereas activation of TNFR2 appears to exert protective effects in the heart. One interesting aspect of the biology of TNF receptors is that mammalian cells appear to “shed” TNF receptors following a variety of different stimuli, including exposure to TNF, lipopolysaccharide, okadaic acid, or phorbol esters.<sup>10</sup> Previous studies have shown that once the type 1 (TNFR1) and type 2 (TNFR2) TNF receptors are proteolytically cleaved from the cell membrane, they exist in the circulation as circulating “soluble” receptors (referred to as sTNFR1 and sTNFR2, respectively). Both of these soluble receptors retain their ability to bind ligand and to inhibit the cytotoxic activities of TNF in cell culture. Of interest, elevated levels of sTNFR1 and sTNFR2 have been shown to be strong independent predictors of adverse clinical outcome in hospitalized heart failure patients (Figure 11-2).<sup>11</sup>

**Tumor Necrosis Factorlike Weak Inducer of Apoptosis (TWEAK).** TNF-like weak inducer of apoptosis (TWEAK), a member of the TNF superfamily of ligands, is first synthesized as a type II transmembrane protein that is cleaved from the membrane. TWEAK functions primarily as a soluble cytokine with diverse biological roles, including proinflammatory activity, angiogenesis, regulation of cell survival, and myoblast differentiation/proliferation.<sup>12</sup> TWEAK induces apoptosis indirectly through secondary activation of the TNF/TNFR1 pathway. The expression of TWEAK is relatively low in normal tissues, including the heart, but undergoes dramatic upregulation in the setting of tissue injury. For example, TWEAK is expressed in the border zone of infarcted myocardium, wherein increased

# BOX 11-1 Cardiac Pathophysiological Conditions Associated with Activation of Inflammatory Mediators

angiogenesis is observed, and in the nonischemic myocardium remote from the infarct area.<sup>12</sup> Recent studies have suggested that sustained elevated circulating levels of TWEAK, induced via transgenic or adenoviral-mediated overexpression of soluble TWEAK, were sufficient to provoke LV dilation, LV fibrosis, LV dysfunction, and increased mortality in mice.<sup>13</sup> Moreover, circulating levels of TWEAK are elevated in patients with nonischemic cardiomyopathy compared with patients with ischemic cardiomyopathy and/or normal controls.<sup>13</sup>

The receptor for TWEAK, Fn14 (fibroblast growth factor-inducible 14), is the smallest member of the TNF-receptor family. Fn14 is a type 1 transmembrane protein (102 aa) that is expressed both constitutively and in an inducible manner in many tissues including the brain, the kidney, the liver, and the heart.<sup>12</sup> Fn14 is highly upregulated in the border zone of the heart following LAD ligation.<sup>12</sup> Both norepinephrine and angiotensin II also strongly upregulate Fn14 in isolated neonatal cardiomyocytes.<sup>12</sup> Fn14 contains sequence motifs within the cytoplasmic domain that promote aggregation of a family of adaptor proteins termed “TRAF1, 2, and 3” (TNF-receptor-associated factor), which in turn activate intracellular signal transduction cascades, including nuclear factor  $\kappa$ B (NF  $\kappa$ B), and the mitogen-activated protein kinases JNK, p38, and ERK.

## The Interleukin-1 Superfamily

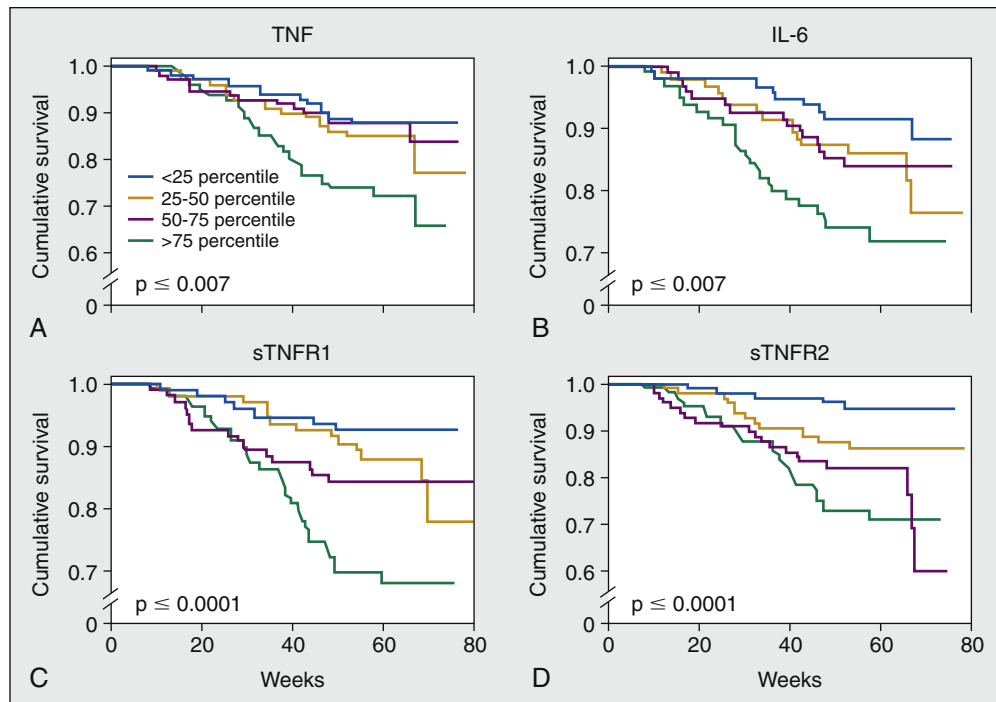

**Interleukin-1 (IL-1).** There are three members of the IL-1 gene family: IL-1 $\alpha$ , IL-1 $\beta$ , and IL-1 receptor antagonist (IL-1Ra).<sup>14</sup> As will be discussed later, IL-18 and IL-33 are related family members. IL-1 $\alpha$  and IL-1 $\beta$  are agonists, and IL-1Ra is a specific receptor antagonist. IL-1 $\alpha$  and IL-1 $\beta$  are synthesized within mammalian cells as precursors without leader sequences. The molecular weight of each precursor is 31 kDa. Processing of IL-1 $\alpha$  or IL-1 $\beta$  to “mature” forms of 17 kDa requires specific intracellular cellular proteases. In contrast, IL-1Ra has a signal peptide and is readily transported out of the cells and is then referred to as secreted IL-1Ra (sIL-1Ra). IL-1 $\alpha$  and IL-1 $\beta$  both bind to common receptors, which explains the similarity of effects of the two molecules. For the most part, IL-1 $\alpha$  remains intracellular or is retained on the cell membrane, and is therefore not detected in the circulation in most disease states. Unlike IL-1 $\alpha$ , the inactive or proform of IL-1 $\beta$  is only marginally active. However, once the proform of IL-1 $\beta$  is processed by an intracellular protease termed “ICE” (interleukin converting enzyme), mature IL-1 $\beta$  is rapidly secreted from the cell. The actions of IL-1 $\alpha$  and IL-1 $\beta$  can be competitively inhibited by IL-1Ra, which has a high degree of affinity for the type 1 IL-1 receptor, but lacks the ability to activate this receptor.<sup>14</sup> Similar to TNF, IL-1 $\beta$  appears to be synthesized

**FIGURE 11-1** Overview of TNF signaling. TNF is initially expressed as a functional 26-kDa homotrimeric transmembrane that may be cleaved by a metalloproteinase termed “TACE,” (TNF- $\alpha$ -converting enzyme [ADAM-17]). Once TNF is cleaved, it is released into the circulation as a 17-kDa protein that assembles as a functional 60-kDa homotrimer. The function of TNF is relayed by two structurally distinct receptors, termed “tumor necrosis factor receptor 1” (TNFR1; TNFRSF1A, p55, CD120a) and “tumor necrosis factor receptor 2” (TNFR2; TNFRSF1B, p75, CD120b). The TNFRs belong to the TNF receptor superfamily, a group of type I transmembrane glycoproteins that are characterized by a conserved homologous cysteine-rich domain in their extracellular region. Both TNFRs can be “shed” (cleaved) from the cell membrane, and are retained in the circulation as circulating “soluble” receptors (referred to as sTNFR1 and sTNFR2, respectively). Both of these soluble receptors retain their ability to bind ligand and to inhibit the biological activities of TNF. The main structural difference between TNFR1 and TNFR2 is the presence of a death domain (DD) in the cytoplasmic domain of TNFR1. The binding of TNF allows TRADD (TNF receptor-associated death domain protein) to interact with the DD. TRADD is an essential partner of TNFR1 for signal transduction that recruits the downstream adapter molecule FADD (fas-associated death domain), which initiates the caspase pathway responsible for apoptotic cell death. TRADD can also interact directly with RIP (receptor interacting protein) and TRAF2 (TNF receptor-associated factor 2 protein), which can activate downstream signaling pathways, such as NF  $\kappa$ B, AP-1, c-Jun N-terminal kinase stress kinases (JNK), and p38MAPK.

within the myocardium in response to stressful environmental stimuli.<sup>15</sup>

Early work on the IL-1 receptor (IL-1R) suggested that there was a single receptor; however, subsequent cross-linking studies have suggested the presence of a low affinity (80 kDa; IL-1RI) receptor and a higher affinity receptor (68 kDa, IL-1RII), each coded for by a single gene product.<sup>16</sup> Interestingly, the type I receptor (IL-1RI) transduces a signal, whereas the type II receptor (IL-1RII) binds IL-1 but does not transduce a signal. Indeed, IL-1RII acts as a sink for IL-1 and has been termed a “decoy” receptor. When IL-1 binds to IL-1RI, a complex is formed that then recruits an accessory protein,

**FIGURE 11-2** Kaplan-Meier survival analysis of inflammatory mediators in the VEST trial. The circulating levels of TNF (6A), IL-6 (6B), sTNFR1 (6C), and sTNFR2 (6D) were examined in relation to patient survival during follow-up (mean duration = 55 weeks; maximum duration = 78 weeks). For this analysis the circulating levels of cytokines and cytokine receptors were arbitrarily divided into quartiles. (From Deswal A, Petersen NJ, Feldman AM, et al. Cytokines and cytokine receptors in advanced heart failure: an analysis of the cytokine database from the vesnarinone trial (VEST). *Circulation* 2001;103:2055-2059.)

IL-1R-AcP. It is likely that the heterodimerization of the cytosolic domains of IL-1 RI and IL-1R-AcP trigger IL-1 signal transduction. Although IL-1Ra can bind to IL-1R1, it does not recruit IL-1R-AcP to the complex, and is thus incapable of signaling. The extracellular domains of the interleukin receptors or “soluble” portions of the IL-1RI (IL-1sRI) and IL-1RII (IL-1sRII) circulate in health and disease, and function as natural “buffers” that are capable of binding to IL-1 $\alpha$ , IL-1 $\beta$ , or to IL-1Ra.<sup>14</sup>

**Interleukin-18.** Interleukin-18 (IL-18) is a member of the IL-1 superfamily.<sup>17</sup> Similar to IL-1 $\beta$ , IL-18 is synthesized as an inactive precursor and is cleaved to its active form by caspase-1. Although IL-18 was initially recognized for its ability to induce interferon- $\gamma$  (IFN- $\gamma$ ) and its capacity to induce T-helper 1 (Th1) responses, IL-18 was subsequently found to play an important role in LPS-induced hepatotoxicity, which stimulated further study of the role of IL-18 in other settings. Relevant to the present discussion is the recent observation that IL-18 had been shown to be produced in the heart during ischemia reperfusion injury and endotoxemia.<sup>18</sup> Importantly, IL-18 activates NF- $\kappa$ B, which is a transcriptional regulator of many proinflammatory cytokines and cellular adhesion molecules in the heart. In vitro studies have shown that IL-18 increases the production of TNF and IL-1 $\beta$  in murine macrophages and human monocytes and also induces the expression of ICAM-1 and VCAM-1 on endothelial cells and monocytes.<sup>17</sup> In vivo studies have shown specific blockade of IL-18 using IL-18-binding protein improves contractile function in human atrial tissue following ischemia reperfusion injury,<sup>4</sup> and lipopolysaccharide-induced LV dysfunction in experimental animals.<sup>4</sup>

The IL-18 receptor (IL-18R) is related to the IL-1 family of receptors, and is composed of a ligand-binding subunit, IL-18R $\alpha$ , and an accessory subunit, IL-18R $\beta$ , both of which share sequence homology to the IL-1R family.<sup>19</sup> Moreover, the signal transduction pathways used by IL-1 $\beta$  and IL-18 are similar. In addition, there is a third receptor-like chain, the IL-18 binding protein (IL-18BP), that lacks a transmembrane

domain and thus does not signal. IL-18BP is produced constitutively and is secreted, and thus acts as a potent inhibitor of IL-18 activity.

**Interleukin-33 (IL-33).** As noted previously, IL-33 belongs to the IL-1 superfamily. IL-33 was identified in a search for the ligand for the ST2 receptor (see later discussion). IL-33 induces helper T cells, mast cells, eosinophils, and basophils to produce type 2 cytokines. The mode by which IL-33 exerts its effect has not been fully established but it probably acts similarly to other members of the IL-1 family. That is, precursor IL-33 is cleaved by caspases and is then released into the interstitium as an active cytokine, where it stimulates signaling in target cells.<sup>20</sup> In the heart, IL-33 is produced by cardiac fibroblasts in response to biomechanical strain. In vitro studies have shown that IL-33 markedly antagonizes angiotensin II and phenylephrine-induced cardiomyocyte hypertrophy; moreover, recombinant IL-33 reduced hypertrophy and fibrosis and improved survival after pressure overload in mice.<sup>5</sup> Thus IL-33 appears to activate a cardioprotective program in the heart.

ST2 is the cognate receptor for IL-33. There are four isoforms of ST2 (sST2 (soluble), ST2L (membrane bound), ST2V, and ST2LV). The overall structure of ST2L is similar to the structure of the type I IL-1 receptors, which consist of an extracellular domain of three linked immunoglobulin-like motifs, a transmembrane segment, and a TIR (Toll-like interleukin domain) cytoplasmic domain. sST2 lacks a transmembrane and cytoplasmic domains contained within the structure of ST2L and includes a unique 9-aminoacid C-terminal sequence.<sup>20</sup> Whereas ST2L is constitutively expressed primarily in hematopoietic cells, sST2 expression is largely inducible in a variety of cell types, including cells that reside in the heart. Interestingly, high baseline ST2 levels are a significant predictor of cardiovascular death and heart failure independent of baseline characteristics and NT-proBNP in patients with an ST-segment myocardial infarction.<sup>21</sup> The signaling pathways that are downstream from IL-33/ST2 signaling are still unclear, but may include phosphorylation of

extracellular signal-regulated kinase (ERK) 1/2, p38 MAPK, JNKs, and activation of NF- $\kappa$ B. However, the relationship between ST2L and NF- $\kappa$ B activation is a matter of ongoing debate.<sup>20</sup>

### Interleukin-6 (IL-6)

CH 11

IL-6 is another multifunctional cytokine that mediates inflammatory responses. Until IL-6 was cloned and sequenced, its diverse biological roles had led to a variety of different names for this molecule, including 26K factor, B-cell stimulatory factor 2, hepatocyte stimulating factor, and  $\beta_2$ -interferon.<sup>22</sup> Human IL-6 is produced as a 212-amino acid precursor and is processed to a 184-amino acid soluble form following cleavage of a signal sequence during secretion of the mature protein.<sup>22</sup> The mature protein is a 26-kDa glycoprotein<sup>23</sup> with a number of alternative N- and O-linked glycosylation sites. IL-6 can be detected in the circulation following gram-negative bacterial infection or TNF infusion, and following myocardial stunning<sup>24</sup> and appears to be secreted in direct response to TNF or IL-1, which are thought to induce IL-6 gene expression by releasing a nuclear-binding protein termed “NF- $\kappa$ B”.<sup>22</sup> Recently, IL-6 has been shown to exist in the circulation in “chaperoned” complexes of molecular mass 400 to 500, 150 to 200, and 25 to 35 kDa in association with binding proteins that can include soluble IL-6 receptor, anti-IL-6 antibodies, and anti-sIL-6R antibodies, and others. Sustained high levels of different particular IL-6 complexes are observed in the human circulation in cancer patients subjected to particular active anticancer immunotherapy regimens. However, “chaperoned” IL-6 complexes have not yet been reported in heart failure.<sup>25</sup> Recently two other cytokines that use the gp130 signaling pathway have been identified in heart failure: leukemia inhibitory factor and cardiotrophin-1.<sup>26,27</sup> However, the functional significance of these latter two cytokines in heart failure remains unknown at the time of this writing.

The human IL-6 receptor is a glycoprotein with a molecular mass of 80 kDa. In contrast to the receptors for IL-1 and TNF, the cytoplasmic domain of IL-6 is not necessary for intracellular signaling to occur. Moreover, when bound to its receptor, IL-6 is known to associate with a second membrane glycoprotein with a molecular mass of 130 kDa (gp130). Thus the current evidence suggests that the IL-6R system is composed of two functional chains: an 80-kDa IL-6 binding protein, termed “IL-6R,” and a 130-kDa “docking protein,” termed “gp130,” which transmits the intracellular signal.<sup>22</sup> Although the presence of IL-6 receptors has not yet been identified in the adult heart,<sup>28</sup> it is of considerable interest that genetic mice that are deficient in gp130 are embryonic lethal because their hearts do not develop.<sup>29</sup> Moreover, double transgenic mice that have been genetically engineered to overexpress both IL-6 and IL-6R develop substantial concentric hypertrophy.<sup>28</sup> Thus the gp130 family of receptors may play an important role in normal growth and development of the heart.

### Chemokines

Chemokines are a distinct family of cytokines that regulate biological processes such as chemotaxis, collagen turnover, angiogenesis, and apoptosis. The chemokine superfamily is divided into four groups (CXC, CX3C, CC, and C) according to the relative positioning of the first two closely paired cysteines of their amino acid sequence. Chemokines exert their effects by interacting with G protein-linked transmembrane receptors, referred to as “chemokine receptors”, which are found on the surfaces of their target cells. A major role of chemokines is the recruitment and activation of specific subpopulations of leukocytes that play a pivotal role in the immune response and inflammation. While chemokine-dependent functions are essential for the control of infection, wound healing, and hematopoiesis, excessive chemokine activation

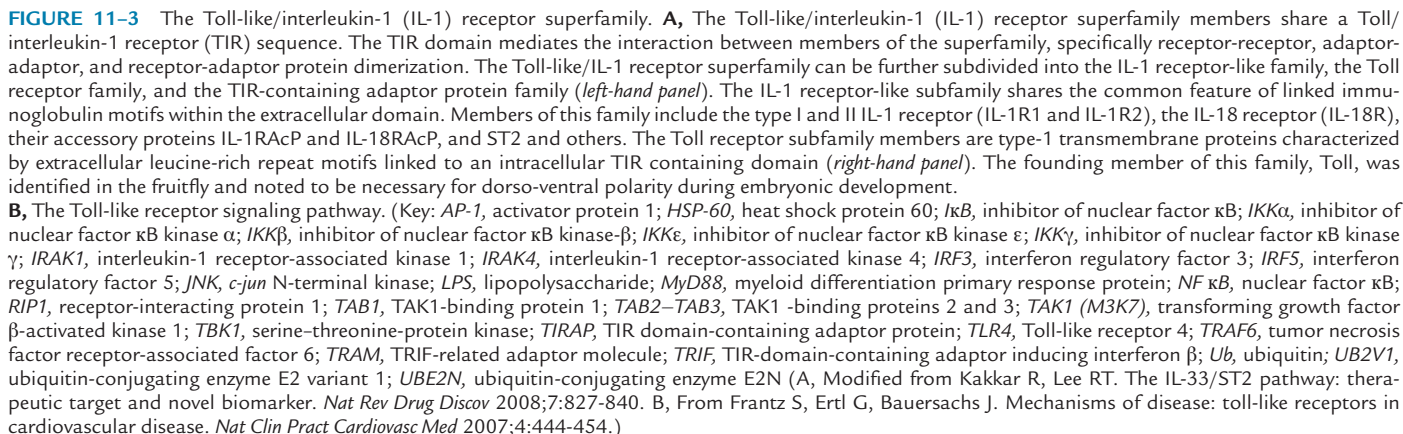

may result in inappropriate inflammation leading to cell death and tissue damage. Studies have shown that circulating levels of CC chemokines are elevated in patients with ischemic and nonischemic heart failure, including macrophage chemoattractant protein-1 (MCP-1), macrophage inflammatory protein-1 $\alpha$  (MIP-1 $\alpha$ ), and RANTES (regulated on activation normally T-cell expressed and secreted). The highest levels of these chemokines were noted in patients with NYHA class IV heart failure.<sup>30</sup> Given that these chemokines can attract inflammatory cells to the heart, they may contribute to disease progression in heart failure.

### Innate Immunity

Although a complete review of innate immunity in the heart is beyond the intended scope of this chapter, this topic will be reviewed briefly herein for the sake of completeness (please see references 31 and 32 for complete reviews of the subject). Traditionally, the immune system has been divided into innate and adaptive components, each of which has a different role in helping the host to differentiate self from nonself. The innate immune system is activated by a family of “pattern recognition receptors” that reside in a variety of cell types, including cardiac myocytes. These pattern recognition receptors recognize invariant patterns (so-called pathogen-associated molecular patterns) shared by groups of microorganisms but not by host tissues. Typical examples of pathogen-associated molecular patterns include the lipopolysaccharides (LPS) of gram-negative organisms, the teichoic acids of gram-positive organisms, the glycolipids of mycobacterium, the mannans of yeast, and the double-stranded RNAs of viruses. These pathogen-associated molecular patterns are unique to these pathogens and in some cases are required for their virulence. Thus one of the quintessential features of the innate immune system is that it serves as an “early warning system” that enables the host to accurately and rapidly discriminate self from nonself. Recent studies have shown that the heart possesses a functionally intact innate immune system, and that the cardiac innate immune system is activated nonspecifically in response to all forms of acute myocardial injury, especially during ischemia/reperfusion injury (reviewed in Mann<sup>33</sup>). Cardiac myocytes express at least five classical receptors that belong to the innate immune system (so-called pattern recognition receptors), including CD14, the soluble pattern recognition receptor for lipopolysaccharide,<sup>34</sup> and Toll-like receptors -2, 3, 4, and 6 (TLR-2, TLR-3, TLR-4, and TLR-6, respectively).<sup>35</sup>

As shown in Figure 11-3, A, the signaling pathway that is used by the TLR family of receptors is highly homologous to that of the IL-1 receptor (IL-1R) family. Both TLR and IL-1R interact with an adaptor protein termed “myeloid differentiation factor 88” (MyD88) via their Toll interleukin receptor (TIR) domains. When stimulated, MyD88 recruits IL-1 receptor-associated kinase (IRAK) to the receptor. IRAK is then activated by phosphorylation and associates with tumor necrosis receptor-associated factor 6 (TRAF6), leading to NF- $\kappa$ B activation through the classical NF- $\kappa$ B inducing kinase (NIK)  $\rightarrow$  IKK  $\rightarrow$  I $\kappa$ B $\alpha$  dependent pathway depicted in Figure 11-3, B.<sup>36</sup> Recent studies from this and other laboratories have shown that TLR-4 is critical for upregulating the expression of TNF, IL-1 $\beta$ , IL-6, and NOS2 in the heart following stimulation with lipopolysaccharide (LPS),<sup>37,38</sup> and that CD-14 and TLR-4 are essential for LPS-mediated LV dysfunction.<sup>39,40</sup> The role of TLR activation in heart disease is not confined to LPS-induced signaling, insofar as TLR2 and TLR4 knockout mice are protected from ischemia-reperfusion injury following reperfusion.<sup>41,42</sup> Moreover, both LV dilation and mortality are attenuated in TLR2 and TLR4 knockout mice following acute ligation of the left anterior descending artery.<sup>43,44</sup> Thus the extant literature suggests that TLR signaling may contribute to myocardial inflammation and LV remodeling following cardiac injury.

The interest in understanding the role of inflammatory mediators in heart failure arises from the observation that many aspects of the syndrome of heart failure can be explained by the known biological effects of proinflammatory cytokines (Box 11-2). That is, when expressed at sufficiently high concentrations, such as those that are observed in heart failure, cytokines are sufficient to mimic some aspects of the so-called heart failure phenotype, including (but not limited to) progressive left ventricular (LV) dysfunction, pulmonary edema, LV remodeling, fetal gene expression and cardiomyopathy.<sup>45</sup> Thus the “cytokine hypothesis<sup>46</sup>” for heart failure holds that heart failure progresses, at least in part, as a result of the

toxic effects exerted by endogenous cytokine cascades on the heart and the peripheral circulation. It bears emphasis that the cytokine hypothesis does not imply that cytokines cause "heart failure" per se, but rather that the overexpression of cytokine cascades contributes to disease progression of heart failure. Much like the elaboration of neurohormones, the elaboration of cytokines may represent a biological mechanism that is responsible for worsening heart failure. Although the deleterious effects of cytokines on myocardial function have received the most attention thus far, it bears emphasis that cytokines may also produce deleterious effects on LV structure (remodeling) and endothelial function. Accordingly, in the following section, we will discuss the studies that form the scientific basis for studying the role of proinflammatory mediators in the failing heart.

## BOX 11-2 Deleterious Effects of Inflammatory Mediators in Heart Failure

### Effects of Cytokines on Left Ventricular Function

One of the signatures of proinflammatory cytokines is their ability to depress LV function. The original observation that proinflammatory cytokines were capable of modulating LV function was reported in experimental studies that showed that direct injections of TNF produced hypotension, metabolic acidosis, hemoconcentration, and death within minutes, thus mimicking the cardiac/hemodynamic response seen during endotoxin-induced septic shock.<sup>47</sup> Studies in dogs showed that a single infusion of TNF resulted in systolic function within the first 24 hours of infusion.<sup>48</sup> Experimental studies in rats showed that circulating concentrations of TNF that overlap those observed in patients with heart failure were sufficient to produce persistent negative inotropic effects that are detectable at the level of the cardiac myocyte; moreover, the negative inotropic effects of TNF were completely reversible when the TNF infusion was stopped.<sup>45</sup> Subsequent studies in transgenic mice with targeted overexpression of TNF in the cardiac compartment demonstrated that targeted overexpression of TNF results in depressed LV ejection performance that is dependent on TNF “gene dosage.”<sup>49,50</sup> At the cellular level, studies in isolated contracting myocytes showed that the negative inotropic effects of TNF were the direct result of alterations in intracellular calcium homeostasis.<sup>51</sup> Treatment with more than 50 U/mL<sup>-1</sup> TNF produced a 20% to 30% decrease in the extent of cell shortening (Figure 11-4, A) and a 40% decrease in peak levels of intracellular calcium (see Figure 11-4, B). Moreover, whole cell patch-clamp studies suggested that the decrease in intracellular calcium was not the result of changes in the voltage-sensitive inward calcium current, suggesting that TNF-induced changes in intracellular calcium homeostasis were secondary to alterations in sarcoplasmic reticular handling of calcium.<sup>51</sup>

**Signaling Pathways for the Negative Inotropic Effects of Inflammatory Mediators.** With respect to the potential mechanisms for the deleterious effects of TNF on LV function, the literature suggests that TNF modulates myocardial function through at least two different pathways: that is, an immediate pathway that is manifest within minutes and is mediated by activation of the neutral sphingomyelinase pathway,<sup>52</sup> and a delayed pathway that requires hours to days to develop, and is mediated by nitric oxide.<sup>6,53</sup> It has also been suggested recently that TNF and IL-1 produce negative inotropic effects indirectly through activation and/or release of IL-18, which is a recently described member of the IL-1 family of cytokines.<sup>17</sup> Relevant to the present discussion is the observation that specific blockade of IL-18 using the neutralizing IL-18 antibody resulted in a decrease in infarct size in rats subjected to ischemia reperfusion injury.<sup>54</sup> Although the signaling pathways that are responsible for the IL-18-induced negative inotropic effects have not been delineated, it is likely that they will overlap those for IL-1, given that the IL-18 receptor complex uses components of the IL-1 signaling chain, including

**FIGURE 11-4** Effect of TNF on contractility of adult cardiac myocytes. **A**, Shows that in comparison with control (open bar) cells, cardiac myocytes treated with TNF (closed bars) developed a concentration-dependent decrease in cell shortening. Pretreatment with a neutralizing anti-TNF antibody (hatched bar) completely attenuated the effects of 200 U/mL TNF on cell shortening. When the cells were washed free of 200 U/mL TNF and allowed to recover for 45 minutes, the effects of TNF were completely reversible (hatched bar). **B**, Shows a typical time-intensity curve for fluorescence brightness in isolated cardiac myocytes treated with diluent (open circles) and 200 U/mL TNF-treated (closed triangles). As shown, the peak level of intracellular fluorescence brightness was reduced strikingly for the cells treated with 200 U/mL TNF. The inset of this figure, which depicts values obtained for group data, shows that there was an approximately 40% decrease in the percent change in peak intensity of fluorescence brightness for the TNF-treated cells. Taken together, panels A and B suggest that TNF produces negative inotropic effects in isolated cardiac myocytes by producing an alteration in intracellular calcium homeostasis. (Reproduced with permission from Yokoyama T, Vaca L, Rossen RD, et al. Cellular basis for the negative inotropic effects of tumor necrosis factor- $\alpha$  in the adult mammalian heart. *J Clin Invest* 1993;92:2303-2312.)

IL-1R-activating kinase (IRAK) and TNF receptor-associated factor-6 (TRAF-6).<sup>17</sup>

**Mechanism for the Delayed Negative Inotropic Effects of Cytokines.** The observation that proinflammatory cytokines increase the expression of nitric oxide (NO) through augmented transcription of nitric oxide synthase,<sup>55</sup> and that both the inducible (NOS2) and constitutive (NOS3) forms of NOS are expressed in rat cardiac myocytes<sup>53,56</sup> and in human myocardial tissue,<sup>57</sup> combined with the observation that NO is sufficient to depress myocardial function,<sup>53,56</sup> suggested that NOS/NO were responsible for the negative inotropic effects of cytokines. By way of review, NOS1 and NOS3 are calcium/calmodulin dependent, and release NO for short periods of time in direct response to changes in intracellular concentrations of calcium. Both NOS1 and NOS3 are expressed constitutively in a broad variety of cell types, and are activated by receptor and/or physical stimulation.<sup>58</sup> However, while combinations of cytokines may increase

NOS1/NOS3 activity indirectly over 24 hours by increasing the synthesis of NOS cofactors,<sup>59</sup> cytokine-induced calcium-dependent NOS activity has not been observed thus far.<sup>60</sup> In contrast to the constitutive isoforms of NOS, NOS2 is inducible and is calcium independent. Moreover, NOS2 levels are directly upregulated by cytokines.<sup>61</sup> What is perhaps less readily appreciated, however, is that the cytokine-mediated increase in NOS2 expression requires a lag period of hours to days before NO is produced and released. Thus although an increase in NOS2 expression may explain the delayed onset of cytokine-mediated functional effects, cytokine-mediated NOS2 expression does not readily explain the more immediate negative inotropic effects that have been reported for TNF, IL-2, and IL-6.<sup>51</sup> The signaling mechanisms that are responsible for the negative inotropic effects of NO are complex, and include guanylyl cyclase (cGMP)-mediated alterations in calcium homeostasis,<sup>62,63</sup> and NO-mediated blunting of  $\beta$ -adrenergic-stimulated generation of cAMP. Treatment of adult cardiac myocytes (>24 hr) with culture medium “conditioned” by activated macrophages produced an NO-mediated defect in isoproterenol-stimulated contractile function.<sup>53</sup> Although the mechanism for the NO-mediated defect in isoproterenol-stimulated contractile function is not known, it is interesting to note that earlier reports in neonatal cardiac myocytes suggested that TNF and IL-1 stimulation lead to a G protein-mediated defect in  $\beta$ -adrenergic signal transduction.<sup>6</sup>

**Mechanism for the Immediate Negative Inotropic Effects of Cytokines.** With respect to the mechanism for the immediate negative inotropic effects of TNF, IL-2, and IL-6, one study provided indirect evidence in support of the point of view that TNF-, IL-2-, and IL-6-induced contractile dysfunction resulted from “enhanced activity of a constitutive nitric oxide synthase (NOS2) in the myocardium.”<sup>64</sup> However, these findings with respect to induction of NOS2 activity by cytokines have not been confirmed by all laboratories.<sup>51</sup> There is, however, evidence that TNF-mediated activation of the neutral sphingomyelinase pathway may play an important role in mediating the immediate negative inotropic effects of cytokines.<sup>52</sup> Activation of the neutral sphingomyelinase pathway by a variety of ligands, including TNF and IL-1, has been shown to lead to hydrolysis of membrane-bound sphingomyelin, with the resultant generation of ceramide, which can then be deacylated to sphingosine by the enzyme ceramidase.<sup>65</sup> The importance of sphingosine, which is present in both skeletal and cardiac muscle,<sup>66</sup> is that at sufficiently high concentrations this molecule can block calcium release from the ryanodine receptor,<sup>67</sup> which might provide an explanation for a prior observation that TNF-induced alterations in intracellular calcium homeostasis are secondary to alterations in sarcoplasmic reticular handling of calcium.<sup>51</sup> Indeed, the concentrations of sphingosine that were induced by TNF in contracting cardiac myocytes were sufficient to produce negative inotropic effects and alterations of intracellular calcium homeostasis that were qualitatively and quantitatively similar to those observed with TNF alone.<sup>52</sup>

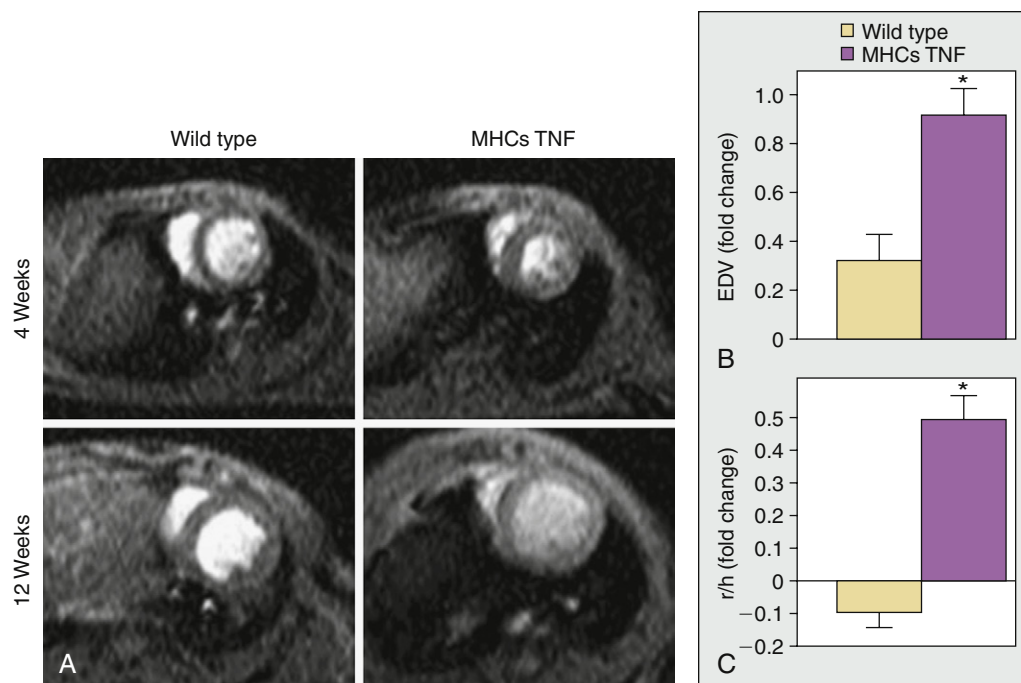

#### Effects of Cytokines on Left Ventricular Structure

Cardiac remodeling contributes to the development and progression of heart failure (see Chapters 8 and 15). However, the mechanisms that contribute to the structural changes that underlie progressive cardiac remodeling are only partially understood. As shown in Box 11-3, inflammatory mediators have a number of important effects that may play an important role in the process of LV remodeling, including myocyte hypertrophy,<sup>68</sup> alterations in fetal gene expression,<sup>49</sup> degradation of the extracellular matrix,<sup>45,69</sup> and progressive myocyte loss through apoptosis.<sup>70</sup> When concentrations of TNF that overlap those observed in patients with heart failure were infused continuously in rats, there was a time-dependent change in LV

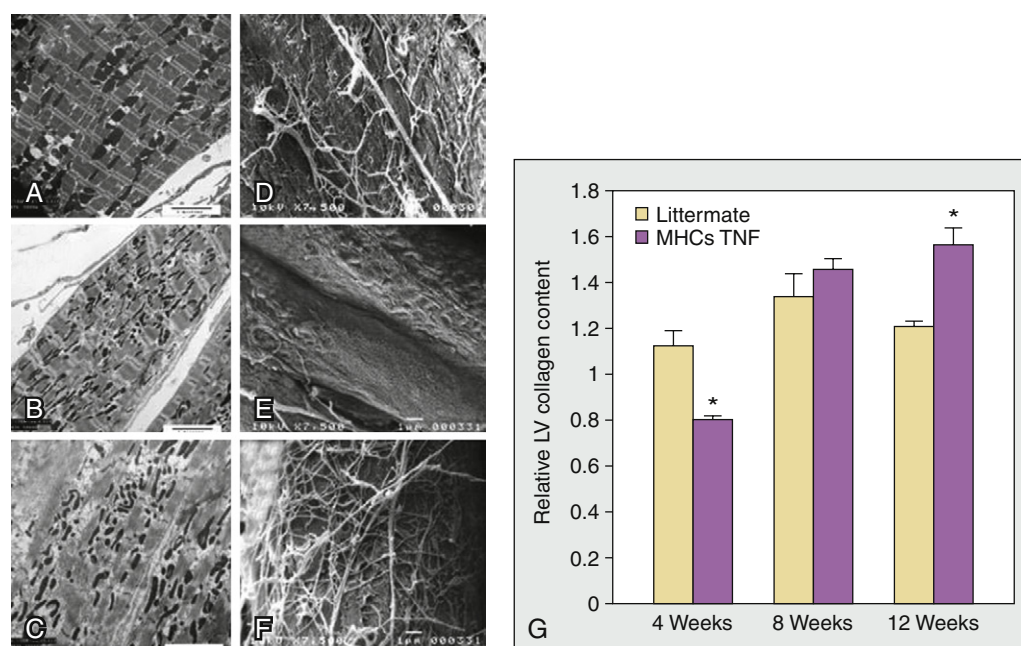

dimension that was accompanied by progressive degradation of the extracellular matrix.<sup>45</sup> Second, recent studies in transgenic mice with targeted overexpression of TNF have shown that these mice develop progressive LV dilation. For example, Sivasubramanian et al showed that a transgenic mouse line that overexpressed TNF in the cardiac compartment segued from a concentric LV hypertrophy phenotype to a dilated LV phenotype over a 12-week period of observation (Figure 11-5).<sup>69</sup> Similar findings have also been reported by Kubota et al<sup>49</sup> and Bryant et al,<sup>71</sup> who observed identical findings with respect to LV dysfunction and LV dilation in transgenic mice with targeted overexpression of TNF in the heart. With respect to the mechanisms that are involved in TNF-induced LV dilation, it has been suggested that TNF-induced activation of matrix metalloproteinases are responsible for this effect.<sup>69</sup> As shown in Figure 11-6 there was progressive loss of fibrillar collagen in the hearts of the transgenic mice overexpressing TNF in the cardiac compartment. Subsequent studies suggested that the loss of fibrillar collagen was secondary to increased activation of MMPs. The dissolution of the fibrillar collagen weave that surrounds the individual cardiac myocytes and links the myocytes together would be expected to allow for rearrangement (“slippage”) of myofibrillar bundles within the ventricular wall.<sup>72</sup> In addition to TNF, the related superfamily member TWEAK has been shown to have important effects of cardiac remodeling. In a recent study, elevated circulating levels of TWEAK induced via transgenic or adenoviral-mediated gene expression in mice resulted in progressive LV remodeling with subsequent severe cardiac dysfunction (Figure 11-7) that was independent of TNF signaling. Although the mechanisms for TWEAK-mediated LV dilation have not been fully elucidated, TWEAK was shown to activate NF  $\kappa$ B, activate the fetal gene program, and provoke cardiac myocyte hypertrophy through an FN14-dependent mechanism.

Cardiac-restricted overexpression of TNF has been shown to lead to progressive cardiac myocyte apoptosis (Figure 11-8) and LV wall thinning (see Figure 11-5, C).<sup>73</sup> Mechanistic studies showed that sustained TNF signaling resulted in activation of the intrinsic cell death pathway, leading to increased cytosolic levels of cytochrome *c*, Smac/DIABLO, and Omi/HtrA2, and activation of caspases 3 and 9. Targeted overexpression of Bcl-2 blunted activation of the intrinsic pathway and prevented LV wall thinning; however, Bcl-2 only partially attenuated cardiac myocyte apoptosis. Subsequent studies showed that caspase 8 was activated and that Bid was cleaved to tBid, suggesting that the extrinsic pathway was activated concurrently.<sup>74</sup> Thus sustained myocardial inflammation leads to activation of multiple cell death pathways that contribute to progressive cardiac myocyte apoptosis and adverse cardiac remodeling in mice with cardiac restricted overexpression of TNF.<sup>74</sup> Antagonism of IL-1 signaling by administering anakinra, a recombinant-human IL-1 receptor

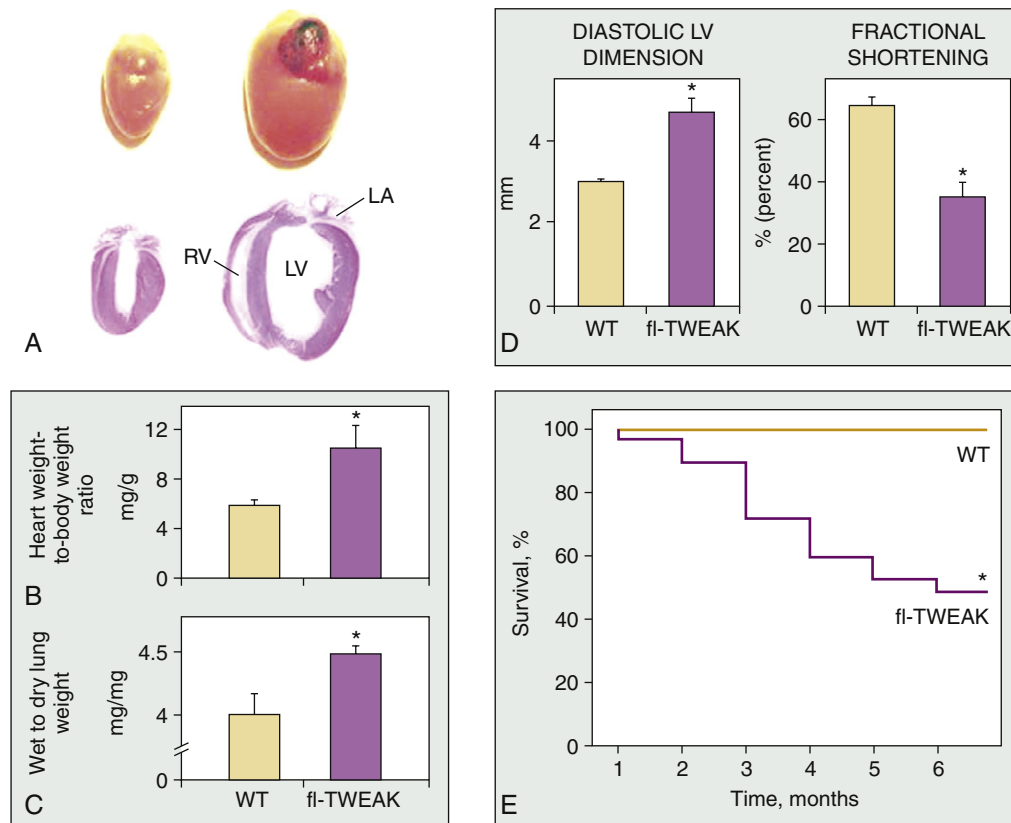

**FIGURE 11-5** LV remodeling in the littermate control and TNF transgenic mice. **A**, Representative short-axis MRI images of the littermate control and TNF transgenic mice at 4 and 12 weeks. **B**, Group data for fold-change in LV end-diastolic volume (EDV) from 4 to 12 weeks. **C**, Group data for the fold-change in the LV radius to LV wall at ages 4, 8, and 12 weeks (\* =  $P < 0.05$ ). (From Engel D, Peshock R, Armstrong RC, et al. Cardiac myocyte apoptosis provokes adverse cardiac remodeling in transgenic mice with targeted TNF overexpression. *Am J Physiol Heart Circ Physiol* 2004;287:H1303-H1311.)

**FIGURE 11-6** Effects of sustained proinflammatory cytokine expression on myocardial ultrastructure and collagen content. Panels A-C show representative transmission electron micrographs in littermate controls (**A**) and the TNF transgenic mice at 4 (**B**) and 8 weeks of age (**C**). The transmission electron micrographs from the littermate control mice at 4 weeks (**A**) revealed a characteristic linear array of sarcomere and myofibril. In contrast, the myofibril in the 4-week-old TNF transgenic mice were less organized, with loss of sarcomeric registration observed in many of the sections (Figure 11-3, **B**). The ultrastructural abnormalities in the TNF transgenic mice were further exaggerated in the 12-week-old TNF transgenic mice, which showed a significant loss of sarcomere registration and myofibril disarray (**C**). Panels D-F show representative scanning electron micrographs in littermate controls (**D**) and the TNF transgenic mice at 4 (**E**) and 8 weeks of age (**F**). Panel E shows that there was a significant loss of fibrillar collagen in the TNF transgenic mice at 4 weeks of age when compared with age-matched littermate controls (**D**). However, as the TNF transgenic mice aged (12 weeks), there was an obvious increase in myocardial fibrillar collagen content. **G**, illustrates the myocardial collagen content as determined by picro Sirius red staining. There was a loss of myocardial collagen content at 4 weeks of age in the TNF transgenic mice that was later followed by a progressive increase in myocardial collagen content at 8 and 12 weeks of age. (From Sivasubramanian N, Coker ML, Kurrelmeyer K, et al. Left ventricular remodeling in transgenic mice with cardiac restricted overexpression of tumor necrosis factor. *Circulation* 2001;104:826-831.)

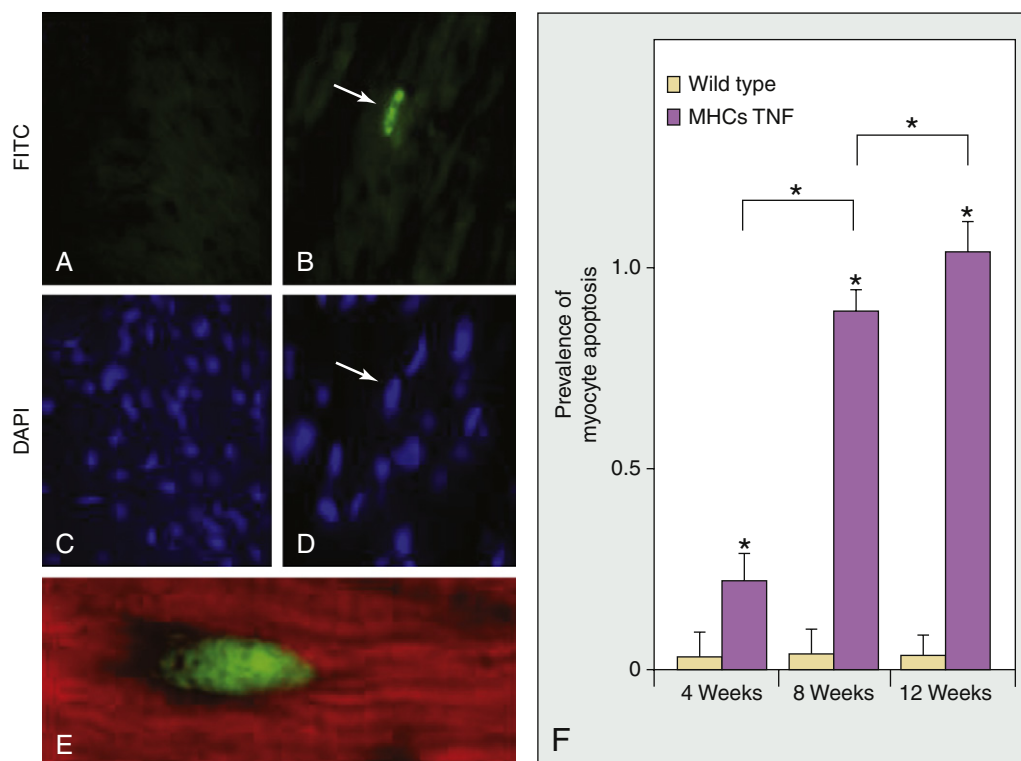

**FIGURE 11-7** Effects of TWEAK on LV structure and function. **A**, Representative whole hearts and trichrome-stained longitudinal sections from wild-type and transgenic mice overexpressing a full length TWEAK construct (fl-TWEAK) (Key: LV, left ventricle; RV, right ventricular; LA, left atrium). **B**, Increased heart weight-to-body weight ratios in fl-TWEAK mice compared with wild-type (WT) mice. **C**, Increased wet-to-dry lung weights in fl-TWEAK mice compared with WT mice. **D**, LV end-diastolic dimension and fractional shortening in WT and fl-TWEAK mice. **E**, Kaplan Meier survival curves for WT and fl-TWEAK mice demonstrating increased mortality in the fl-TWEAK mice. (\* =  $P < 0.01$ ) (Modified from Jain M, Jakubowski A, Cui L, et al. A novel role for tumor necrosis factor-like weak inducer of apoptosis (TWEAK) in the development of cardiac dysfunction and failure. *Circulation* 2009;119:2058-2068.)

antagonist has also resulted in decreased cardiac myocyte apoptosis, decreased LV remodeling, and improved LV function in a rat infarct model.<sup>75</sup> In vitro studies in rat cardiac myocytes demonstrated that anakinra inhibited caspase 1 and 9 activity, and prevented apoptosis in a simulated model of ischemia.<sup>75</sup> From a pathophysiological standpoint, the increase in LV wall thinning that attends progressive cardiac myocyte apoptosis would be expected to contribute to increased LV wall stress (i.e., afterload mismatch), and hence sustained unfavorable loading conditions of the heart, thereby contributing to progressive cardiac decompensation. Thus excessive activation of proinflammatory cytokines may contribute to LV remodeling through a variety of different mechanisms that involve both the myocyte and nonmyocyte components of the myocardium.

**Interactions Between the Renin-angiotensin System and Proinflammatory Cytokines in Adverse Cardiac Remodeling.** Although neurohormonal and cytokine systems have been regarded as functionally distinct biological systems, recent studies suggest that these two systems can cross regulate each other, with the result that neurohormonal and cytokine systems may participate in positive feed forward loops that contribute to adverse cardiac remodeling. Whereas angiotensin II was traditionally viewed as a circulating neurohormone that stimulated the constriction of vascular smooth muscle cells, aldosterone release from the adrenal gland, sodium reabsorption in the renal tubule, and/or as a stimulus for growth of cardiac myocytes or fibroblasts,<sup>76</sup> it is becoming increasingly apparent that angiotensin II provokes inflammatory responses in a variety of different cell and tissue types. For example, angiotensin II activates

NF  $\kappa$ B,<sup>77</sup> which is critical for initiating the coordinated expression of classical components of the myocardial inflammatory response, including increased expression of proinflammatory cytokines, nitric oxide, chemokines, and cell adhesion molecules.<sup>78</sup> Pathophysiologically relevant concentrations of angiotensin II are sufficient to provoke TNF mRNA and protein synthesis in the adult heart through a NF  $\kappa$ B dependent pathway.<sup>79</sup> Figure 11-10 shows that treatment with angiotensin II resulted in a rapid increase in TNF mRNA (see Figure 11-10, A) and protein synthesis (see Figure 11-10, B) in isolated buffer perfused hearts. Stimulation of isolated adult cardiac myocytes with angiotensin II resulted in an approximately threefold increase in TNF protein biosynthesis within 1 hour, and an approximately fifteenfold increase in TNF protein biosynthesis within 24 hours, suggesting that the increase in TNF biosynthesis in the intact heart was mediated, at least in part, at the level of the cardiac myocyte. The effects of angiotensin II on TNF mRNA and protein synthesis were mediated exclusively through the angiotensin type 1 receptor, insofar as pretreatment with the angiotensin type 1 receptor antagonist losartan completely abolished the effects of angiotensin II on TNF biosynthesis, whereas pretreatment with the angiotensin type 2 receptor antagonist PD123319 had no effect on angiotensin II-induced TNF biosynthesis (see Figure 11-10, B). This study further showed that the effects of angiotensin II on TNF myocardial biosynthesis were dependent upon protein kinase C-mediated activation of NF  $\kappa$ B.<sup>79</sup>

There is also increasing evidence that inflammatory mediators are capable of upregulating various components of the renin-angiotensin system in a variety of mammalian tissues,

**FIGURE 11-8** Cardiac myocyte apoptosis in littermate control and TNF transgenic mice. **A**, Representative myocardial sections (200 $\times$  magnification) showing DNA ligase staining in a littermate control and **(B)** TNF transgenic mice. Apoptotic nuclei are shown by the bright green nuclear fluorescence (arrow). DAPI staining was used to identify the total number of cell nuclei in littermate control **(C)** and TNF transgenic mice **(D)**. **E**, An apoptotic nucleus stained by the ligase technique in (600 $\times$  magnification) in the presence of antidesmin immunostaining. **F**, Prevalence cardiac myocyte apoptosis in littermate control and TNF transgenic mice at 4, 8, and 12 weeks (\* =  $P < .05$ ). (From Engel D, Peshock R, Armstrong RC, et al. Cardiac myocyte apoptosis provokes adverse cardiac remodeling in transgenic mice with targeted TNF overexpression. *Am J Physiol Heart Circ Physiol* 2004;287:H1303-H1311.)

including the heart. As one recent example, studies using transgenic mice with cardiac-restricted overexpression of TNF have shown that targeted overexpression of TNF leads to an increase in angiotensin II peptide levels in the heart.<sup>80</sup> This study serially examined several components of the renin-angiotensin system, including angiotensinogen, renin, angiotensin-converting enzyme (ACE), and angiotensin I and II peptide levels in a transgenic mouse line with cardiac-restricted overexpression of TNF. There was a significant increase in ACE mRNA levels (Figures 11-11, A, and 11-11, B) and ACE activity (see Figure 11-11, C), and increased angiotensin II peptide levels (see Figure 11-11, D) in the hearts of the TNF transgenic mice relative to littermate controls. Importantly, the expression of renin and angiotensinogen was not increased in the TNF transgenic mice compared with littermate controls. Thus this study suggested that the increased levels of angiotensin II peptide levels in the TNF transgenic mice was principally the result of increased ACE activity, as opposed to increased activation of the more proximal components of the renin-angiotensin system, namely renin and angiotensinogen. This study also showed that activation of the renin-angiotensin system was functionally significant in the TNF transgenic mice. That is, treatment of the TNF transgenic mice from 4 to 8 weeks of age with losartan significantly attenuated cardiac hypertrophy, myocardial fibrosis, and cardiac myocyte apoptosis in the TNF transgenic mice.<sup>80</sup> Taken together, these observations suggest that interactions between the renin-angiotensin system and inflammatory mediators may contribute to adverse cardiac remodeling.

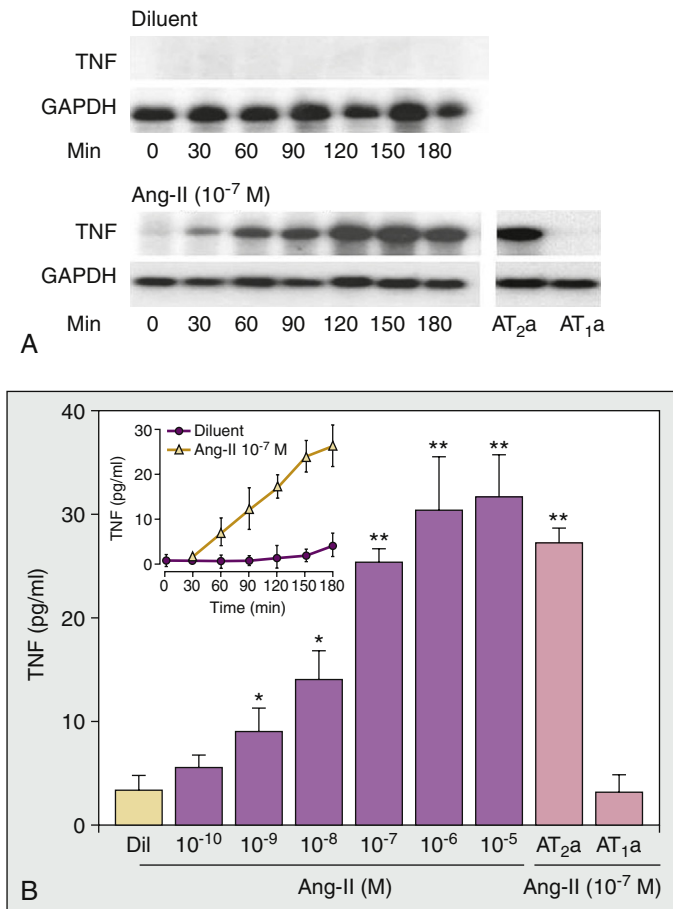

#### Effects of Proinflammatory Mediators on Endothelial Function

In addition to the effects of inflammatory mediators on cardiac structure and function, there is growing evidence that the concentrations of inflammatory mediators that exist in heart

failure are sufficient to contribute to endothelial dysfunction. The functional role of TNF in modulating endothelial function was suggested in studies by Agnoletti et al, who demonstrated that the serum of patients with heart failure induced apoptosis and downregulated endothelial constitutive nitric oxide synthase in human umbilical vein endothelial cells.<sup>81</sup> The importance of TNF in their studies was suggested by experiments in which an anti-TNF antibody partially antagonized the effects of heart failure sera on endothelial cell apoptosis.<sup>81</sup> The role of TNF-induced endothelial dysfunction is further supported by studies by Anker et al,<sup>82</sup> who showed that circulating TNF levels correlated inversely with peak blood flow in heart failure patients, independently of age, ejection fraction, peak oxygen consumption, and NYHA association class, thus suggesting that TNF might contribute to peripheral skeletal muscle weakness/fatigue in patients with heart failure. Finally, in a recent clinical study that used a soluble TNF antagonist (etanercept) to neutralize TNF, there was a short-term improvement in forearm-mediated blood flow that was fully reversible following the cessation of therapy.<sup>83</sup>

#### Clinical Trials Targeting Inflammatory Mediators in Heart Failure

Given that elevated levels of proinflammatory cytokines mimic many aspects of the heart failure phenotype and that the deleterious effects of inflammatory mediators are potentially reversible once inflammation subsides, investigators have used a variety of different approaches to antagonize inflammatory mediators in heart failure (Table 11-1). As shown in Figure 11-11, the biological effects of proinflammatory mediators can be antagonized through transcriptional or translational approaches, or by so-called biological response modifiers that bind and/or neutralize soluble mediators (e.g., TNF or IL-1 $\beta$ ). In addition, there are several novel “immunomodulatory strategies” that alter the levels of inflammatory

**FIGURE 11-9** Angiotensin II-induced myocardial TNF biosynthesis in the adult heart. **A**, TNF mRNA expression (RNase protection assay) was assessed ex vivo in diluent and angiotensin II ( $10^{-7}$  M)-treated (up to 180 min) buffer perfused Langendorff hearts, in the presence or absence of  $10^{-6}$  M PD123319, an AT<sub>2</sub> receptor antagonist (AT<sub>2</sub>a) or  $10^{-6}$  M losartan, an AT<sub>1</sub> receptor antagonist (AT<sub>1</sub>a). **B**, Myocardial TNF protein production was assessed in the superfusates of the angiotensin II-treated hearts using ELISA in the presence or absence of PD123319 ( $10^{-6}$  M) or losartan ( $10^{-6}$  M) pretreatment. The main panel of Figure 11-1, B, shows the dose-dependent effects of angiotensin II ( $10^{-10}$  M to  $10^{-5}$  M), whereas the inset shows the time course (up to 180 min) for TNF protein synthesis following stimulation with either diluent (solid circles) or  $10^{-7}$  M Ang-II (open triangles). (Key: AT<sub>1</sub>a = AT<sub>1</sub> receptor antagonist [losartan]; AT<sub>2</sub>a = AT<sub>2</sub> receptor antagonist [PD123319]) (\* =  $P < 0.05$  and \*\* =  $P < 0.01$  compared with diluent treated hearts). (From Kalra D, Sivasubramanian N, Mann DL. Angiotensin II induces tumor necrosis factor biosynthesis in the adult mammalian heart through a protein kinase C-dependent pathway. *Circulation* 2002;105:2198-2205.)

mediators through multiple mechanisms. In the section that follows, we will review the clinical trials that have targeted inflammatory mediators in heart failure.

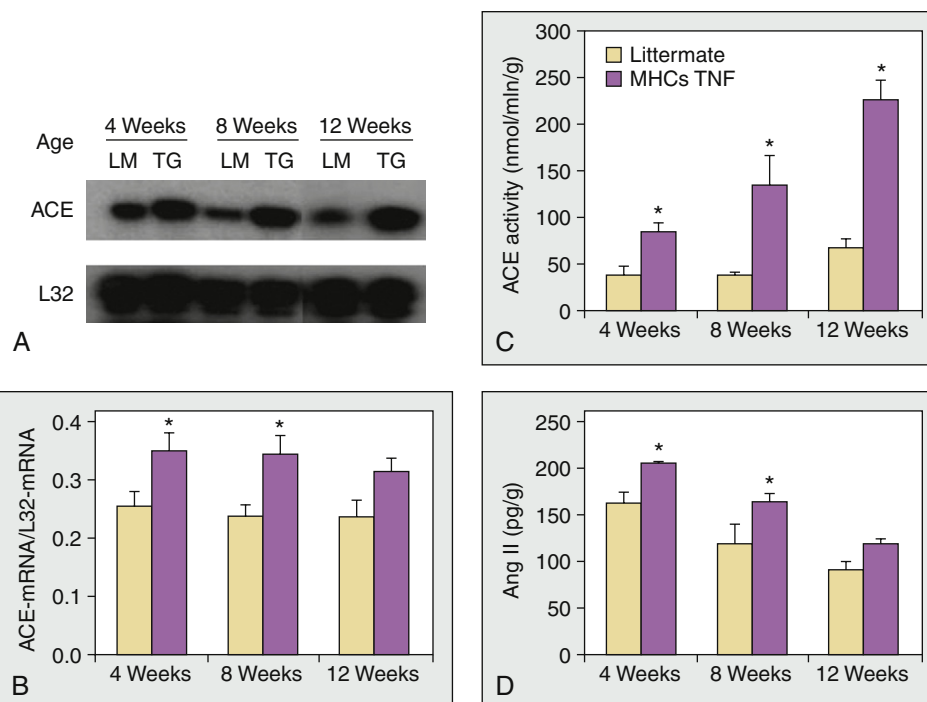

**Transcriptional Suppression of Proinflammatory Cytokines.** Experimental studies have shown that agents that raise cAMP levels prevent TNF mRNA accumulation, largely by blocking the transcriptional activation of TNF.<sup>84</sup> Pentoxifylline is a xanthine-derived agent that is known to inhibit TNF transcription and translation. Thus far, 144 heart failure patients have been treated with pentoxifylline in randomized clinical trials.<sup>85-88</sup> As shown in Table 11-1, two studies in patients with dilated cardiomyopathy examined patients with NYHA class II and III heart failure,<sup>85,86</sup> whereas a third study examined patients with NYHA class IV heart failure.<sup>88</sup> Pentoxifylline has also been used in NYHA class I-IV patients with ischemic heart disease.<sup>88</sup> The use of pentoxifylline was associated with significant improvement in NYHA functional class and/or LV ejection fraction in all studies.

Notably, the beneficial effects were seen in all NYHA classes of heart failure, in patients with ischemic and nonischemic cardiomyopathy, and in patients treated with ACE inhibitors and  $\beta$ -blockers. Relevant to the present discussion, the beneficial effects on cardiac function in some of the studies were accompanied by decreased circulating plasma levels of TNF.<sup>89</sup> However, it is important to recognize that pentoxifylline is a nonspecific inhibitor of phosphodiesterases and that the salutary effects of these agents might be unrelated to the immunomodulatory properties of this drug.

Thalidomide ( $\alpha$ -N-phthalimidoglutarimide) is another class of drug that may be useful in suppressing TNF production. Thalidomide selectively inhibits TNF production in monocytes,<sup>90</sup> but has no effect on the production of IL-1 $\beta$ , IL-6, or granulocyte/macrophage colony-stimulating factor (GM-CSF). Thalidomide appears to reduce TNF levels by enhancing mRNA degradation;<sup>91</sup> however, the mechanisms of action of thalidomide remain unclear, and contradictory results have been reported regarding its effects on cytokine levels in vivo. Based on its immunomodulatory properties, thalidomide has been studied in heart failure. In an open-label dose escalation study, thalidomide was safe and potentially effective when used at lower doses.<sup>92</sup> However, dose-limiting toxicity was observed in two patients (50 and 200 mg/day). There was a significant increase in the 6-minute walk distance and a trend ( $P = .16$ ) toward improvement in left ventricular ejection fraction and quality of life after 12 weeks of maintenance therapy with thalidomide.<sup>92</sup> In a larger placebo-controlled study of 56 patients with NYHA class II-III heart failure secondary to an ischemic or nonischemic cardiomyopathy with an LV ejection fraction less than 40%, treatment with up to 200 mg/day of thalidomide for 12 weeks resulted in an increase in LV ejection fraction and a decrease in LV end-diastolic volume.<sup>93</sup> These salutary changes were accompanied by a decrease in circulating levels of matrix metalloproteinase 2, but an increase in circulating levels of TNF. The effect of thalidomide on LV ejection fraction was observed to a greater degree in patients with dilated cardiomyopathy, who were able to tolerate higher doses of thalidomide.<sup>93</sup>

**Translational Suppression of Proinflammatory Cytokines.** Dexamethasone, which is thought to primarily suppress TNF biosynthesis at the translational level, may also block TNF biosynthesis at the transcriptional level.<sup>94</sup> One of the earliest studies to use this type of approach was performed by Parrillo et al,<sup>95</sup> who randomized 102 patients to treatment with prednisone (60 mg per day) or placebo. Following 3 months of therapy, they observed an increase in ejection fraction of more than 5% in 53% of the patients receiving prednisone, whereas only 27% of the controls had a significant improvement in ejection fraction ( $P = .005$ ). Overall, the mean ejection fraction increased  $4.3\% \pm 1.5\%$  in the prednisone group, as compared with  $2.1\% \pm 0.8\%$  in the control group ( $P = .054$ ). The patients were then categorized prospectively into two separately randomized subgroups. "Reactive" patients had fibroblastic or lymphocytic infiltration or immunoglobulin deposition on endomyocardial biopsy, a positive gallium scan, or an elevated erythrocyte sedimentation rate, and "nonreactive" patients, had none of these features. At 3 months, 67% of the reactive patients who received prednisone had improvement in LV function, as compared with 28% of the reactive controls ( $P = .004$ ). In contrast, nonreactive patients did not improve significantly with prednisone ( $P = .51$ ). Although specific cytokine levels were not measured in this study, their data suggest that patients with idiopathic dilated cardiomyopathy may have some improvement when given a high dose of prednisone daily.

**Targeted Anticytokine Approaches Using "Biological Response Modifiers."** Two different targeted approaches have been taken to selectively antagonize proinflammatory

**FIGURE 11-10** ACE mRNA, ACE activity, and angiotensin II peptide levels in mice with targeted overexpression of TNF and littermate control mice. **A**, Ribonuclease protection assay for ACE mRNA in the hearts of the 4-, 8-, and 12-week-old TNF transgenic mice and littermate control mice (LM) mice. **B**, Group data in hearts from 4-, 8-, and 12-week-old TNF transgenic mice ( $n = 7$  hearts/time) and 4-, 8-, and 12-week-old littermate control mice ( $n = 7$  hearts/time). **C**, ACE activity in the hearts from 4-, 8-, and 12-week-old TNF transgenic mice and the 4-, 8-, and 12-week-old littermate control mice. **D**, Group data for angiotensin II peptide levels in the hearts of the TNF transgenic mice and littermate control mice at 4, 8, and 12 weeks of age. (Key: LM, littermate control; TG, transgenic) (\* =  $P < .05$  vs. age-matched control group by Tukey test). (Reproduced with permission from Flesch M, Hoper A, Dell'Italia L, et al. Activation and functional significance of the renin-angiotensin system in mice with cardiac restricted overexpression of tumor necrosis factor. *Circulation* 2003;108:598-604.)

**FIGURE 11-11** Therapeutic strategies for antagonizing proinflammatory mediators. TNF gene transcription is mediated, in part, by activation of NF-κB. Agents that increase intracellular levels of cAMP (1) such as vesnarinone, pentoxifylline, milrinone, thalidomide, and thalidomide analogs (CelSids) decrease the level of inflammatory mediators through transcriptional blockade of inflammatory gene expression. Agents such as dexamethasone and prednisone and some p38 inhibitors suppress inflammation by blocking the translation of inflammatory mediators (2). Secreted TNF can be neutralized (3) by soluble TNF antagonists (etanercept) or by neutralizing antibodies (infliximab) that prevent TNF from binding to its cognate type 1 (p55) and type 2 (p75) TNF receptors. In addition to these targeted approaches, broad-based immunomodulatory strategies have been employed (4) using intravenous immunoglobulin (IVIg), statins, and irradiated (oxidized) whole blood (Celacade therapy). (Modified from Mann DL. Inflammatory mediators and the failing heart: past, present, and the foreseeable future. *Circ Res* 2002;91:988-998.)

cytokines in heart failure patients (Table 11-1). In the first approach, investigators used a recombinant human TNF receptor that acts as a “decoy” and prevents TNF from binding to its cognate receptors on target cells. The second approach that was employed was a chimeric monoclonal antibody that binds to and neutralizes circulating TNF.

**Soluble TNF Receptors.** Etanercept (Enbrel) is a genetically engineered, dimerized, fusion protein composed of two TNF p75 receptors and an IgG<sub>1</sub>Fc portion. Based on early preclinical studies that showed that etanercept was sufficient

to reverse the deleterious negative inotropic effects of TNF in vitro<sup>96</sup> and in vivo,<sup>45</sup> a series of phase I clinical studies were performed in patients with moderate to advanced heart failure. These early short-term studies in small numbers of patients showed improvements in quality of life, 6-minute walk distance, and LV ejection performance following treatment with etanercept for up to 3 months.<sup>97,98</sup> Following this, two multicenter clinical trials were initiated using etanercept in patients with NYHA class II-IV heart failure. The trial in North America, entitled *Randomized Etanercept North American Strategy*

to Study Antagonism of Cytokines (RENAISSANCE;  $n = 900$ ), and the trial in Europe and Australia entitled Research into Etanercept Cytokine Antagonism in Ventricular Dysfunction (RECOVER;  $n = 900$ ), were both quality of life trials that used a clinical composite assessed at 24 weeks as the primary endpoint. The clinical composite score classifies patients as better, worse, or the same after a clinical intervention based on the patient and the physician's assessment at the end of the study.<sup>99</sup> Both trials had parallel study designs, but differed in the doses of etanercept that were used in the two studies; that is, RENAISSANCE employed doses of 25 mg twice a week and 25 mg three times a week, whereas RECOVER employed doses of 25 mg once a week and 25 mg twice a week. A third trial, which used the pooled data from the RENAISSANCE (twice a week and three times a week dosing) and RECOVER (twice a week dosing only), termed Randomized Etanercept Worldwide Evaluation (RENEWAL;  $n = 1500$ ), had a composite primary endpoint of all cause mortality and hospitalization for heart failure. On the basis of prespecified stopping rules, both trials were terminated prematurely owing to a lack of benefit: There was no significant difference between placebo and etanercept with respect to change in the clinical composite score in both RENAISSANCE ( $P = .17$ ) and RECOVER ( $P = .34$ ) (Figure 11-12, A). Moreover, in the prespecified pooled analysis in RENEWAL, there was no effect of etanercept on the primary endpoint (see Figure 11-12, B) of death or chronic heart failure hospitalization (hazard ratio = 1.1, 95% CI 0.91 to 1.33,  $P = .33$ ).<sup>100</sup> However, in a posthoc analysis of hazard ratios for death/worsening heart failure, patients taking the twice a week dose of etanercept appeared to fare slightly better than patients taking the once a week dose of etanercept in RECOVER, with hazard ratios for death/heart failure hospitalization of 0.87 ( $P = .45$ ) and 1.01 ( $P = .97$ ), respectively. In contrast, RENAISSANCE patients receiving twice a week etanercept experienced an increased 1.21 ( $P = .17$ ) risk of death/heart failure hospitalization compared with placebo, while patients receiving the three times a week dose had a slightly worse hazard ratio of 1.23 ( $P = .13$ ). Analysis of the components of the clinical composite score in the RENAISSANCE trial showed that there was a significantly greater proportion of etanercept-treated patients (29%,  $P < .04$ ) who were in the worsened category at 24 weeks when compared with a placebo group (20%); however, this difference was not observed in the RECOVER trial. The disparity in clinical outcomes between RECOVER and RENAISSANCE may relate, at least in part, to the different length of follow-up in the two trials. Patients in RECOVER received etanercept for a median time of 5.7 months, whereas patients in RENAISSANCE received etanercept for 12.7 months. It bears emphasis that these studies were stopped prematurely; had they been allowed to continue to completion, the hazard ratios may have been worse. On the basis of these findings, the prescribing information for etanercept has been updated and now suggests that physicians exercise caution in the use of etanercept in patients with heart failure.

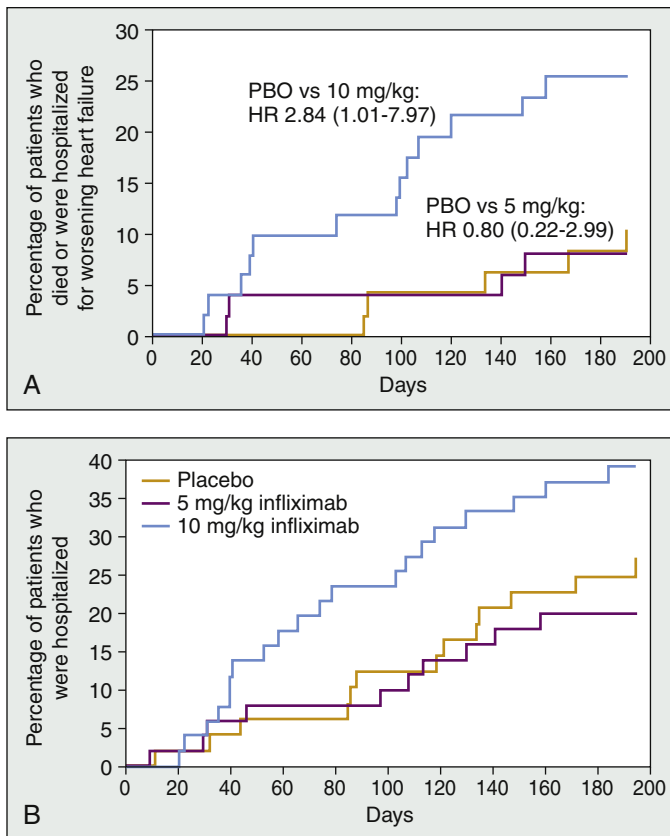

**Monoclonal Antibodies.** Infliximab (Remicade) is a chimeric monoclonal antibody consisting of a genetically engineered murine Fab fragment (that binds human TNF) fused to a human FC portion of human IgG<sub>1</sub>. Although infliximab had been shown to be effective in Crohn disease and rheumatoid arthritis, there were no preclinical, nor early phase I clinical studies to support the use of this agent in heart failure. The Anti-TNF- $\alpha$  Therapy Against CHF (ATTACH) trial was a phase II study in 150 patients with moderate to advanced heart failure (NYHA class III, IV).<sup>101</sup> The primary endpoint of the ATTACH trial was the clinical composite score described previously.<sup>99</sup> Patients were randomized to receive three separate intravenous infusions of infliximab (5 mg/kg or 10 mg/kg) at baseline and at 2 and 4 weeks, followed by an assessment of the clinical composite at 14 and 28 weeks. Although this trial went to completion, analysis of the aggregate data revealed

**FIGURE 11-12** Results of the RENAISSANCE, RECOVER, and RENEWAL trials. **A**, Analysis of the “clinical status” composite score for the RECOVER and RENAISSANCE trials in the placebo and etanercept groups. **B**, Kaplan-Meier analysis of the time to death or heart failure hospitalizations in the placebo and etanercept group (twice a week and three times a week) in the RENEWAL analysis. (From Mann DL, McMurray JJV, Packer M, et al. Targeted anti-cytokine therapy in patients with chronic heart failure: results of the randomized etanercept worldwide evaluation (RENEWAL). *Circulation* 2004;109:1594-1602.)

increased rates of mortality and heart failure hospitalization, particularly in the group who was receiving the highest dose of infliximab (Figure 11-13). By 38 weeks of follow-up, nine infliximab patients had died (two in the 5-mg/kg group and seven in the 10-mg/kg group) compared with just one death in the placebo group. On the basis of these findings, the prescribing information for infliximab has been changed and it is now recommended that treatment with infliximab be discontinued in patients with worsening heart failure and that treatment with infliximab should not be initiated in patients with heart failure.

**Why Have Targeted Anti-TNF Therapies Failed in Heart Failure Trials?** Given the wealth of preclinical data and early clinical studies that suggested a role for TNF antagonism in heart failure, the negative results of the clinical trials have been discouraging. This statement notwithstanding, analysis of the aggregate clinical trial data permits some insight into the potential reasons for why these studies have been negative. It is important to recognize that neither the trials with etanercept nor the trial with infliximab was neutral (i.e., no effect); that is, in both trials there was evidence for dose- and time-dependent worsening of heart failure and/or worsening outcomes. This in turn suggests that the biological agents used in the trials either had intrinsic effects themselves, or alternatively that TNF antagonism has untoward effects in the setting of heart failure. With respect to the

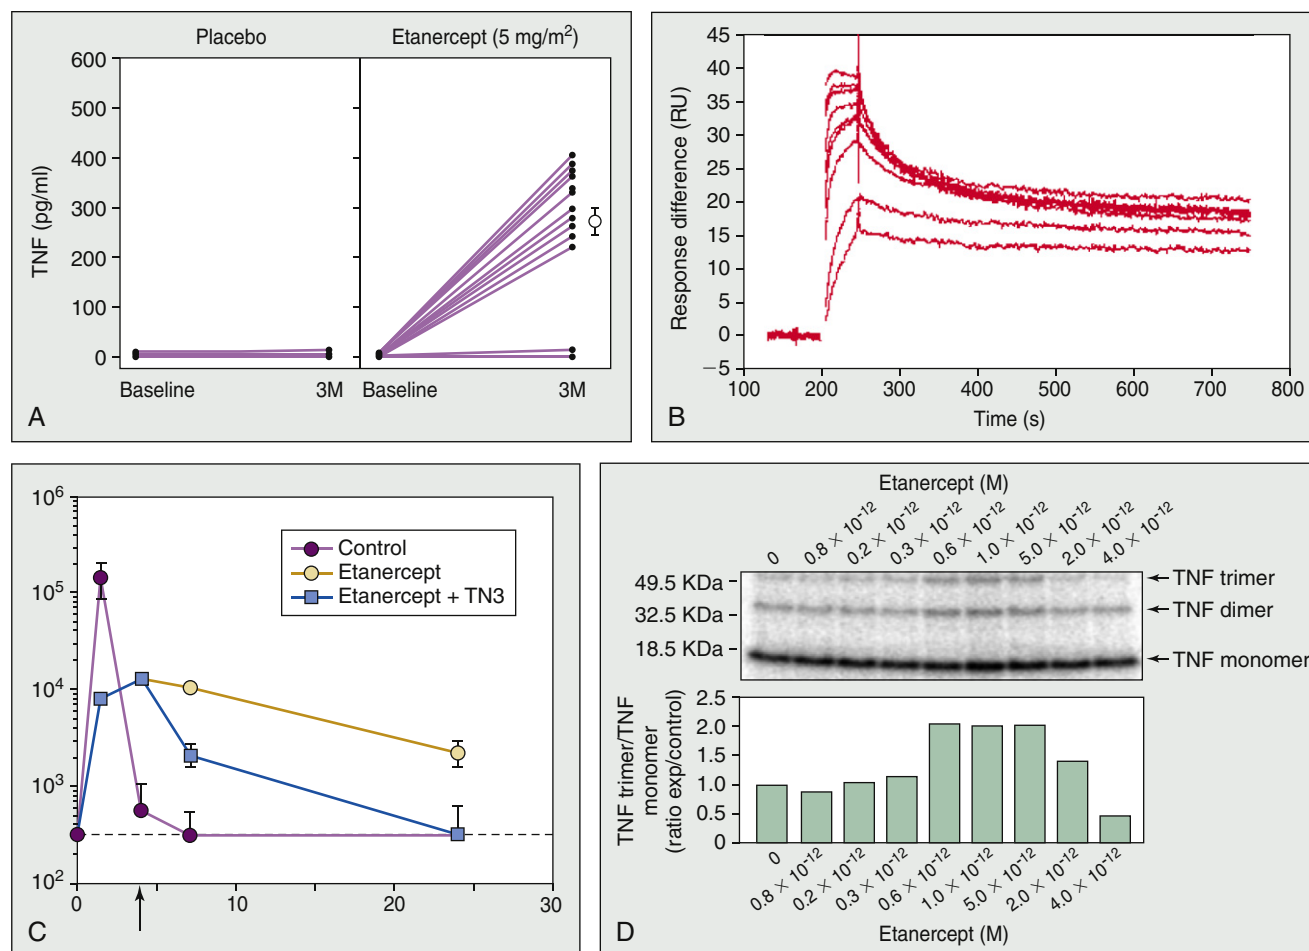

**FIGURE 11-13** Results of the ATTACH trial. **A**, Kaplan-Meier rates of death and hospitalization for heart failure. **B**, Kaplan-Meier rates of hospitalization for any reason. (Key: PBO, placebo; HR, hazard ratio). (From Chung ES, Packer M, Lo KH, et al. Randomized, double-blind, placebo-controlled, pilot trial of infliximab, a chimeric monoclonal antibody to tumor necrosis factor- $\alpha$ , in patients with moderate-to-severe heart failure: results of the anti-TNF therapy against congestive heart failure (ATTACH) trial. *Circulation* 2003;107:3133-3140.)

first explanation, it bears emphasis that infliximab exerts its effects, at least in part, by fixing the complement in cells that express TNF on the membrane. As shown in Figure 11-14, **A**, infliximab is directly cytotoxic to cells expressing TNF on the membrane. Whereas this type of biological action may be beneficial in eliminating activated T cells in Crohn disease, it is likely to be overtly deleterious in the setting of heart failure, wherein failing myocytes express TNF on cell membranes.<sup>8</sup> Indeed complement fixation in the heart leads to sustained myocarditis, and cardiac myocyte lysis mediated by the complement membrane attack complex.<sup>102</sup> Analysis of the data presented in the ATTACH trial supports the point of view that infliximab was overtly deleterious. As shown in Figure 11-14, **B**, there was an increase in the plasma levels of immunoreactive TNF at the time of treatment with infliximab at 2 and 6 weeks, and after the last dose in infliximab at 6 weeks. Although the investigators attributed the increase in TNF levels to infliximab binding to TNF in the circulation, this explanation does not explain the striking twenty-fivefold increase in TNF levels from 10 to 28 weeks, when the infliximab levels were declining below detectable levels. An alternative explanation for the increase in TNF levels after infliximab was that there was ongoing tissue injury secondary to complement activation in the heart, and that the twenty-fivefold increase in TNF levels was in response to increased cardiac injury and that the increase in TNF levels and/or increased tissue damage were responsible for the increase in heart failure hospitalizations and deaths in the infliximab-treated group.

**FIGURE 11-14** Biological properties of infliximab. **A**, Infliximab (cA2 G1) is cytotoxic for cells that express TNF on their cell membranes (TNF+), whereas it is not cytotoxic for cells that do not express TNF on their membranes (SP2/O). The mechanism for the cytotoxic effects of infliximab was demonstrated using F(ab)2 fragments of infliximab, which lack the Fc domain and therefore cannot fix complement. As shown the F(ab)2 fragment of infliximab was not cytotoxic for TNF+ cells. **B**, Levels of immunoreactive TNF in patients who received a placebo and infliximab (10 mg/kg) are displayed in relation to the circulating levels of infliximab (data are redrawn from Figures 2 and 4<sup>101</sup>). The dotted horizontal lines depict the upper and lower limits of the therapeutic window for infliximab. (A, Modified from Scallion BJ, Moore MA, Trinh H, et al. Chimeric anti-TNF- $\alpha$  monoclonal antibody cA2 binds recombinant transmembrane TNF- $\alpha$  and activates immune effector functions. *Cytokine* 1995;7:251-259. B, Modified from Chung ES, Packer M, Lo KH, et al. Randomized, double-blind, placebo-controlled, pilot trial of infliximab, a chimeric monoclonal antibody to tumor necrosis factor- $\alpha$ , in patients with moderate-to-severe heart failure: results of the anti-TNF therapy against congestive heart failure (ATTACH) trial. *Circulation* 2003;107:3133-3140.)

Cytokine binding proteins such as etanercept also have intrinsic biological activity and, in certain settings, can act as agonists for the cytokine that they bind.<sup>103</sup> As a case in point, in human studies etanercept acts as a carrier protein that stabilizes TNF and results in the accumulation of high concentrations of immunoreactive TNF in the peripheral circulation of etanercept-treated patients with heart failure (Figure 11-15, **A**).<sup>104</sup> As shown in Figure 11-15, **B**, TNF complexed to etanercept does not remain tightly bound, but rather dissociates with an extremely fast off-rate (~620 msec).<sup>105</sup> The increase in circulating levels of TNF bound to etanercept combined with the rapid off-rates of TNF from etanercept can lead to an increase in TNF bioactivity, as depicted in Figure 11-15, **C**.<sup>104</sup> This increase in TNF bioactivity that has been observed experimentally and may be secondary to a shift in the equilibrium between TNF monomers, dimers, and trimers in favor of more biologically active TNF homotrimers by virtue of the ability of etanercept to stabilize TNF in its functionally active

**FIGURE 11-15** Biological properties of etanercept. **A**, Etanercept (5 mg/m<sup>2</sup>) increases the circulating levels of immunoreactive TNF in heart failure patients. **B**, Kinetic analysis of TNF binding to etanercept using surface plasmon resonance biosensor technology (BIAcore assay<sup>124</sup>). Etanercept was exposed to 1000, 500, 250, 125, 62.5, 31.25, 16.63, 3.90, and 1.95 nM of TNF, and the kinetics of TNF binding was determined by the decay of the light signal after peak binding to etanercept. The off-rate of TNF from etanercept was determined to be 620 msec. **C**, Etanercept increases TNF bioactivity. Animals were inoculated with bacteria and levels of TNF bioactivity measured at the indicated time points. TNF bioactivity peaked at 90 min after bacterial inoculation, but was undetectable at later time points. Mice treated with etanercept after bacterial inoculation showed a significant reduction in the level of peak TNF bioactivity; however, as shown TNF bioactivity was significantly prolonged by etanercept. Mice that received etanercept after bacterial inoculation followed by an anti-TNF neutralizing antibody (TN3), had a shorter duration of TNF bioactivity. The arrow indicates the timing of the administration of the neutralizing anti-TNF antibody. **D**, Effects of etanercept on TNF stability. *Upper panel:* a fixed concentration of <sup>125</sup>I-TNF was incubated with increasing concentrations of etanercept ( $8 \times 10^{-14}$  M –  $6.25 \times 10^{-10}$  M) or diluent, followed by cross-linking and autoradiography. The arrows depict TNF monomers, dimers, and trimers. Note that etanercept increases the mass of homotrimeric TNF. *Lower panel:* Group data were expressed as the ratio of trimeric to monomeric TNF, and the results displayed as the fold-change in this ratio relative to diluent treated cells. Effect of the soluble TNF-antagonist etanercept on tumor necrosis factor bioactivity and stability. *Clin Transl Sci* 2008;1:142-145.)

homotrimeric form (Figure 11-15, D). Thus panels A to D in Figure 11-15 show that etanercept can, in certain settings, act as a “stimulating antagonist.”<sup>103</sup> While the aforementioned biological effects of etanercept might not be problematic in rheumatoid arthritis, wherein TNF is encapsulated within a joint space and peripheral circulating TNF levels are relatively low (compared with heart failure) or are nonexistent,<sup>106</sup> an increase in the circulating levels of biologically active TNF in a patient with heart failure might be expected to produce worsening heart failure, for all of the reasons articulated at the outset of this chapter (see Box 11-2).

**Immunomodulatory Strategies.** An alternative approach to targeting specific components of the inflammatory cascade is to employ strategies that dampen the various components’ systemic inflammatory response. Thus far, two different approaches have been employed in heart failure studies: intravenous immunoglobulin and immune modulation

therapy (IMT). The topic of immunoadsorption is reviewed in Chapter 24 (see Aukrust et al<sup>107</sup> for a recent review).

**Intravenous Immunoglobulin.** Therapy with intravenous immunoglobulin (IVIG) has been tried in a wide range of immune-mediated disorders, such as Kawasaki syndrome, dermatomyositis, multiple sclerosis, and most recently dilated cardiomyopathy (Chapter 24), wherein the initial results have been encouraging. In a double-blind, placebo-controlled study of 20 ischemic and nonischemic NYHA class II-IV heart failure patients with an LV ejection fraction less than 40%, monthly IVIG treatment for 6 months resulted in a significant increase in LV ejection fraction from 26% to 31%, independent of heart failure cause.<sup>108</sup> These improvements in functional class and LV function were accompanied by an increase in the antiinflammatory mediators IL-10, IL-1 receptor antagonist (IL-1Ra), and soluble TNF receptors, and a slight decrease in plasma TNF, suggesting that IVIG evoked

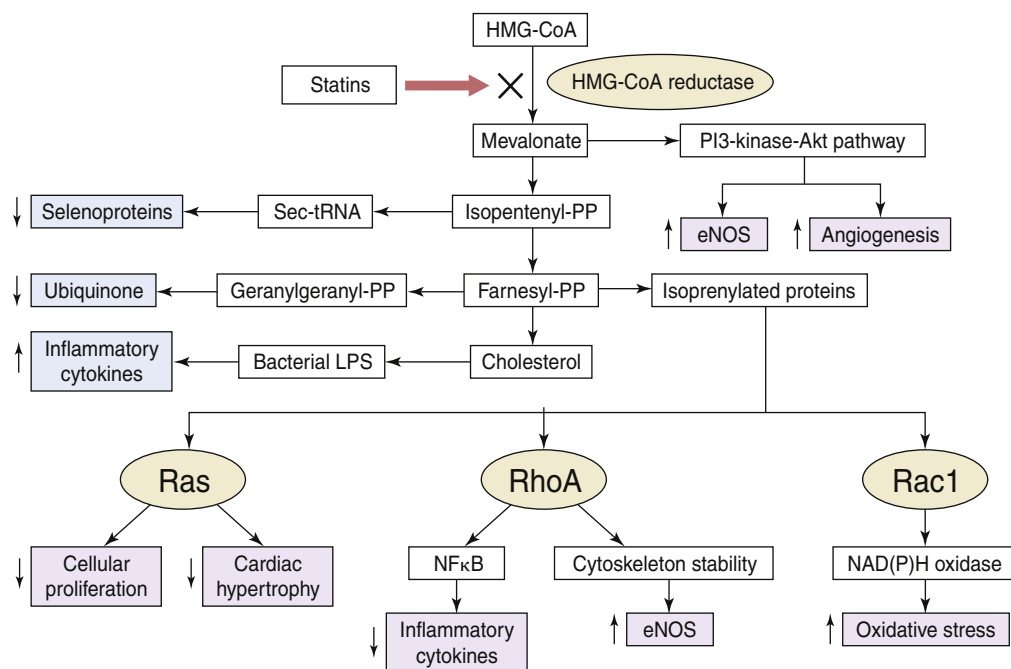

a net antiinflammatory effect. In contrast to these encouraging results, induction therapy with IVIG in the IMAC (Intravenous in Myocarditis and Acute Cardiomyopathy) trial in patients with recent-onset cardiomyopathy (<6 months) and an LV ejection fraction less than 40% demonstrated no significant effect on LV ejection fraction when compared with a placebo.<sup>109</sup> However, it bears emphasis that there was also an increase in LV ejection fraction from 23% to 42% in the placebo arm, which would have made it difficult to show a statistically significant increase in LV ejection fraction in the treatment arm. Moreover, there were important differences in the IVIG dosing strategies in IMAC and the study by Gullestad et al. That is, while both studies used induction therapy (a total of 2 g/kg IVIG), in the study by Gullestad et al maintenance therapy (monthly infusions [0.4 g/kg] for a total of 5 months) was also given. Thus one possible reason for the different outcomes in these two studies is that IVIG maintenance therapy is required for an extended period of time, as has been observed in other chronic inflammatory disorders.

**Immune Modulation Therapy (IMT).** Immune modulation therapy (IMT; Celacade; Vasogen, Inc.) uses a medical device (the VC7000 Blood Treatment System) to expose a sample of blood to a combination of physiochemical stressors ex vivo. The treated blood sample is then administered intramuscularly along with local anesthetic into the same patient from whom the sample is obtained. The physiochemical stresses to which the autologous blood sample is subjected are known to initiate or facilitate apoptotic cell death. The uptake of apoptotic cells by macrophages results in a down-regulation of proinflammatory cytokines, including TNF, IL-1 $\beta$ , and IL-8, and an increase in production of the antiinflammatory cytokines, including TGF- $\beta$  and IL-10.<sup>110</sup> Recent studies have shown that IMT leads to a decrease in the production of proinflammatory cytokines and a corresponding increase in antiinflammatory cytokines in human subjects.<sup>111</sup> Given that an imbalance exists between proinflammatory and antiinflammatory cytokines in patients with heart failure,<sup>112</sup> IMT may restore this balance more towards normal. In a recent trial employing Celacade in 73 patients with moderate heart failure, the investigators noted that, compared with the placebo group, the group receiving Celacade experienced significantly fewer hospitalizations or deaths. The decrease in the event rate in the treatment arm was also supported by improvements in quality of life and NYHA clinical classification.<sup>113</sup> Based on the encouraging results of the early studies, the ACCLAIM (*Advance Chronic Heart Failure Clinical Assessment of Immune Modification*) pivotal study was conducted in 2426 patients with NYHA class II-IV heart failure patients with ischemic and nonischemic dilated cardiomyopathy.<sup>114</sup> Patients were randomly assigned to receive Celacade ( $n = 1213$ ) or placebo ( $n = 1213$ ) by intragluteal injection on days 1, 2, 14, and every 28 days thereafter. The primary endpoint in this event-driven trial was the composite of time to death from any cause or first hospitalization for cardiovascular reasons. As shown in Figure 11-16, A, there was no significant difference between the Celacade- and placebo- treated patients with respect to the primary endpoint of the trial, which was death from any cause or cardiovascular hospitalization (hazard ratio 0.92; 95% CI 0.80 to 1.05;  $P = .22$ ). However, in a prespecified subgroup of patients with NYHA II heart failure (see Figure 11-16, B), and in those without a history of previous myocardial infarction (see Figure 11-16, C) Celacade was associated with a 39% (0.61; 95% CI 0.46 to 0.80;  $P = .0003$ ) and 26% (0.74; 0.57 to 0.95;  $P = .02$ ) reduction in the risk of primary endpoint events, respectively, suggesting that IMT may have a role as a potential treatment for selected patients without a history of myocardial infarction (NYHA class II-IV) and/or patients with milder heart failure (NYHA class II).

**FIGURE 11-16** Results of the ACCLAIM trial. **A**, Kaplan-Meier estimates of time to primary endpoint of time to death from any cause or first hospitalization for cardiovascular reasons in all patients. **B**, Kaplan-Meier estimates of time to death from any cause or first hospitalization for cardiovascular reasons in patients with NYHA class II heart failure. **C**, Kaplan-Meier estimates of time to death from any cause or first hospitalization for cardiovascular reasons in patients with nonischemic cardiomyopathy. (Modified from Torre-Amione G, Anker SD, Bourge RC, et al. Results of a nonspecific immunomodulation therapy in chronic heart failure (ACCLAIM trial): a placebo-controlled randomized trial. *Lancet* 2008;371:228-236.)

**FIGURE 11-17** Cholesterol biosynthesis and the beneficial (gray background) and adverse (checked background) downstream effects of statin treatment. *eNOS*, endothelial nitric oxide synthase; *HMG-CoA*, 3-hydroxy-3-methylglutaryl coenzyme A; *LPS*, lipopolysaccharide; *PI3*, phosphatidylinositol-3; *PP*, pyrophosphate. (From Ramasubbu K, Estep J, White DL, Deswal A, Mann DL. Experimental and clinical basis for the use of statins in patients with ischemic and nonischemic cardiomyopathy. *J Am Coll Cardiol* 2008;51:415-426.)

**Statins.** Statins have a variety of pleiotropic effects, including inhibition of inflammatory responses, increased nitric oxide bioavailability, improved endothelial function, and antioxidant properties. In addition to inhibiting cholesterol synthesis, statins also lower intermediate products in the mevalonate pathway including isoprenoids such as farnesyl pyrophosphate (farnesyl-PP) and geranylgeranyl pyrophosphate (geranylgeranyl-PP), which have been linked to activation of downstream signaling pathways mediated by Ras and Rho, respectively (Figure 11-17). The Ras family of proteins is responsible for cell proliferation and hypertrophy, whereas the Rho family of proteins is important for superoxide generation, inflammation, and cytoskeletal formation. Rho inhibition has also been linked to increased expression of endothelial nitric oxide synthase, which has a beneficial effect on endothelial function through increased nitric oxide production. Although the mechanism is less clear, statins also activate the phosphatidylinositol 3-kinase/Akt pathway, which is coupled to cytoprotective signaling pathways.<sup>115</sup> In experimental models, statins attenuated LV remodeling and improved LV ejection performance without directly affecting infarct size. The attenuation in LV remodeling was attributed to decreased cardiac myocyte hypertrophy, decreased activation of matrix metalloproteinases, and decreased fibrosis.<sup>115</sup> Importantly, statins have also been shown to promote angiogenesis, mobilize bone-marrow endothelial progenitor cells, and lead to downregulation of angiotensin type 1 receptor, any or all of which may have an additional beneficial effect(s) on cardiac remodeling.<sup>115</sup>

Several retrospective analyses of clinical trials or observational databases have suggested that the use of statins in patients with coronary artery disease has either decreased the incidence of heart failure or reduced mortality in patients with known heart failure. Given the known salutary effects of statins on outcomes in coronary artery disease, and the high prevalence of ischemic heart disease in heart failure trials, these findings are perhaps not that surprising. Nonetheless, a prespecified posthoc analysis of the TNT (Treating to New Targets), in which patients with coronary heart disease were randomized to 10 mg/day or 80 mg/day of atorvastatin and then followed for a mean of 4.9 years for traditional coronary events (death, nonfatal myocardial infarction, or stroke),

showed that heart failure hospitalization rates were significantly lower in patients with a prior history of heart failure who were treated with 80 mg/day of atorvastatin when compared with the group treated with 10 mg/day (hazard ratio, 0.87; 95% confidence interval, 0.64 to 1.16;  $P = .34$ ). The decrease in heart failure hospitalizations was unlikely secondary to a reduction in interim coronary events, insofar as one third of patients hospitalized for heart failure had evidence of preceding angina or myocardial infarction during the study period.<sup>116</sup> In addition to these retrospective trials, several small prospective trials assessing the effects of statins on nonmortality clinical endpoints and other surrogate endpoints (echocardiographic parameters and biomarkers of inflammation) also support the beneficial effects of statins in heart failure (reviewed in Ramasubbu et al<sup>117</sup>).

Based on the results of these promising studies, several large clinical trials were performed with rosuvastatin in patients with heart failure. The *Rosuvastatin Impact on Ventricular Remodeling Cytokines and Neurohormones* (UNIVERSE) trial examined the effects of rosuvastatin (40 mg/day) on LV remodeling in patients with ischemic and nonischemic dilated cardiomyopathy.<sup>118</sup> Compared with a placebo, rosuvastatin was associated with significant reduction of low-density lipoprotein cholesterol, but had no effects on LV dimension, LV ejection fraction, or neurohormones. Similar findings were reported in the *Controlled Rosuvastatin Multinational Trial in Heart Failure* (CORONA) trial, in which 5011 patients (>60 years of age) with NYHA functional class II-IV heart failure of ischemic cause were randomized to 10 mg/day of rosuvastatin versus placebo.<sup>119</sup> In CORONA, treatment with rosuvastatin did not confer a significant benefit with respect to the primary endpoint (Figure 11-18, A), which was a composite of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke (HR 0.92, 95% CI 0.83 to 1.02;  $P = .12$ ). Further, there were no significant differences in several of the secondary endpoints including all-cause mortality (HR 0.95; 95% CI 0.86 to 1.05;  $P = .31$ ) and coronary events (HR 0.92; 95% CI 0.82 to 1.04;  $P = .18$ ), despite a significant decrease in circulating levels of low-density lipoprotein cholesterol and C-reactive protein (CRP). These results were surprising considering the known salutary effects of statins on coronary events in patients with coronary artery disease. However, it

**FIGURE 11-18** Results of the CORONA and GISSI-HF trials. **A**, Kaplan-Meier estimates of a composite of death from cardiovascular causes, nonfatal myocardial infarction, or nonfatal stroke in the CORONA trial. **B**, Kaplan-Meier estimates of all causes of death in the GISSI-HF trial. (A, From Kjekshus J, Apetrei E, Barrios V, et al. Rosuvastatin in older patients with systolic heart failure. *N Engl J Med* 2007;357:2248-2261. B, From Gissi-HF Investigators. Effect of rosuvastatin in patients with chronic heart failure (the GISSI-HF trial): a randomized, double-blind, placebo-controlled trial. *Lancet* 2008;372:1231-1239.)

is worth noting that the rate of atherothrombotic events was relatively low in the CORONA study, and that the majority of deaths were caused by sudden death or worsening heart failure, which reflects the fact that the patient population consisted of patients with symptomatic heart failure rather than symptomatic coronary artery disease. Thus the primary composite endpoint of the CORONA study may not have captured the beneficial effects of rosuvastatin in this elderly group of patients with advanced heart failure. And indeed, treatment with rosuvastatin resulted in a significant decrease in heart failure hospitalizations, which was a prespecified secondary endpoint in the CORONA study, thus ending speculation that treatment with statins might lead to worsening heart failure. The Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza cardiaca-Heart Failure (GISSI-HF) investigated the efficacy and safety of rosuvastatin in patients with NYHA class II-IV heart failure, irrespective of cause and/or

LV ejection fraction.<sup>120</sup> Patients were randomly assigned to rosuvastatin 10 mg daily ( $n = 2285$ ) or a placebo ( $n = 2289$ ), and followed up for a median of 3.9 years. The primary end-points of the trial were time to death or admission to hospital for cardiovascular reasons. As shown in **Figure 11-18, B**, there was no significant difference in the probability of all-cause death in patients who were treated with rosuvastatin when compared with the placebo group (adjusted HR 1.00, 95.5% CI 0.898 to 1.122,  $P = .943$ ). Further, there was no significant difference in the composite endpoint of death or admission to the hospital for cardiovascular reasons (adjusted HR 1.01, 99% CI 0.908 to 1.112,  $P = .903$ ). Of note, 10% of the total population in GISSI-HF had an LV ejection fraction greater than 40%. Although this subgroup was too small to draw definite conclusions about the effects of statins in heart failure with a preserved EF, there were no differences in outcomes between this subgroup when compared with the results for the overall group. In a parallel arm of the GISSI-HF study, randomized NYHA class II-IV heart failure patients received n-3 polyunsaturated fatty acids (PUFA) or a placebo (see Chapter 24). This arm of GISSI-HF showed that there was a small but statistically significant decrease in all-cause death in the n-3 PUFA-treated group when compared with the placebo group (adjusted HR 0.91, 95.5% CI 0.833 to 0.998],  $P = .041$ ). There was also a reduction in the number of hospitalizations for cardiovascular reasons (adjusted HR 0.92, 99% CI 0.849 to 0.999,  $P = .009$ ), raising the possibility that dietary supplementation with polyunsaturated fatty acids may benefit patients with heart failure.<sup>121</sup> Thus, taken together, the results of the randomized trials with rosuvastatin do not support a primary role for treating heart failure patients with statins. Whether the negative results of these studies are secondary to the hydrophilic properties of rosuvastatin or a true lack of treatment benefit of statins in heart failure patients cannot be addressed at present. Accordingly, statins should not be used as a primary treatment for patients with heart failure outside of the current practice guidelines for the treatment of coronary artery disease.

## Summary and Future Perspectives

In the present review we have focused on recent clinical and experimental evidence that suggests that inflammatory mediators play a role in disease progression in heart failure by virtue of the deleterious effects that these molecules exert on the heart and the peripheral circulation. As discussed, pathophysiologically relevant concentrations of these molecules mimic many aspects of the so-called heart failure phenotype in experimental animals, including LV dysfunction, LV dilation, activation of fetal gene expression, cardiac myocyte hypertrophy, and cardiac myocyte apoptosis (see **Box 11-2**). Thus analogous to the proposed role for neurohormones, proinflammatory cytokines would appear to represent another distinct class of biologically active molecules that can contribute to heart failure progression. Nonetheless, the early attempts to translate this information to the bedside have not only been disappointing, but have in many instances led to worsening heart failure. While one interpretation of these findings is that inflammatory mediators are not viable targets in heart failure, based on the arguments delineated previously, the countervailing point of view is that we simply have not targeted proinflammatory mediators with agents that can be used safely in the context of heart failure, or alternatively, that targeting a single component of the inflammatory cascade is not sufficient in a disease as complex as heart failure. Moreover, it is important to recognize that all currently approved therapies for chronic heart failure, including cardiac resynchronization therapy (see Chapter 47), have a net beneficial effect on the elaboration of inflammatory mediators.<sup>122</sup> Accordingly, in future studies it may be necessary to use biomarkers to select

heart failure patients who have ongoing inflammation despite optimal medical therapy. Indeed a recent consensus statement from the Translation Research Committee of the Heart Failure Association of the European Society of Cardiology suggested that there may not be a common inflammatory pathway that characterizes all of the different forms of heart failure, and that going forward it would be important to design specific antiinflammatory approaches for different types and stages of heart failure, and to determine the specific inflammatory pathways that are activated in different forms of heart failure.<sup>123</sup> Thus despite the inauspicious beginning with targeted antiinflammatory approaches, strategies that use small molecules that have a broad spectrum of antiinflammatory properties and/or immunomodulatory strategies that restore the balance of proinflammatory and antiinflammatory gene networks are currently being evaluated (e.g., pentraxins, PI3K $\gamma$  inhibitors, mannose binding lectins [reviewed in Heymans et al<sup>123</sup>]). As with all therapeutic approaches in heart failure, the only way to really answer the question of whether these types of antiinflammatory strategies will have any added value in heart failure is through well-designed clinical trials.

Summary, 194

There is now evidence that oxidative stress is increased in heart failure, and experimental studies suggest that this may contribute to the structural and functional changes leading to disease progression. Our understanding of the role of oxidative stress in myocardial dysfunction, though largely incomplete, continues to grow. In this chapter, we will review the evidence for increased oxidative stress in heart failure, *in vivo* evidence suggesting a role for oxidative stress in the pathogenesis of heart failure, and recent *in vitro* studies that suggest potential mechanisms by which reactive oxygen species (ROS) (see Chapter 15) might mediate myocardial remodeling and contractile dysfunction (see Chapter 13).

## REACTIVE OXYGEN SPECIES, ANTIOXIDANT SYSTEMS, AND OXIDATIVE STRESS

Reactive oxygen species (ROS) are a by-product of aerobic metabolism, and so the highly metabolically active myocardium is rich in ROS. As in all tissues, ROS are handled in the myocardium by both soluble and enzymatic antioxidant systems. "Oxidative stress" occurs when the production of ROS exceeds the capacity of antioxidant defense systems. ROS cascades begin with the formation of superoxide anion ( $O_2^-$ ) by either enzymatic or nonenzymatic one electron reduction of molecular oxygen (Figure 12-1). The unpaired electron in  $O_2^-$  is an unstable free radical that reacts with itself and other oxygen-containing species, and directly or indirectly with organic molecules including lipids, nucleic acids, and proteins, ultimately leading to disruption of cellular functions. All aerobic organisms, from bacteria to man, have evolved a complex antioxidant defense system of enzymatic and non-enzymatic components to defend against the unavoidable formation of ROS.<sup>1</sup> In parallel there has been the evolution of specific ROS-generating systems that are used both in the immune system, where the toxicity of ROS is exploited to fight infectious organisms<sup>2</sup> and in all cell types where ROS act as signaling intermediates for the purpose of triggering specific intracellular changes in cell biology.

Primary antioxidant enzymes (defined here as those that directly interact with ROS) including superoxide dismutases (SOD), catalase, and peroxidases work in parallel with nonenzymatic antioxidants to protect cells and tissues from ROS. The mitochondrial enzymes manganese superoxide dismutase (MnSOD) and glutathione peroxidase (GPx) appear to be the most important in controlling myocardial levels of  $O_2^-$  and  $H_2O_2$ . Approximately 70% of the SOD activity in the heart, and 90% of that in the cardiac myocyte, is attributable to MnSOD (SOD2).<sup>3</sup> The remainder consists of cytosolic Cu/ZnSOD (SOD1), with less than 1% contributed by extracellular-SOD (ECSOD, SOD3).<sup>4</sup> This is in contrast to other organs, where Cu/ZnSOD plays a greater role. The relative importance of MnSOD in the regulation of oxidative stress in the myocardium is highlighted by the demonstration that homozygous knockout mice deficient in MnSOD develop normally *in utero*, but die soon after birth with dilated cardiomyopathy.<sup>5</sup> In contrast, mice deficient in CuZnSOD or ECSOD grow normally

and have no overt myocardial phenotype.<sup>4</sup> As the only SOD located in the mitochondria, MnSOD plays a critical role in the control of mitochondrial ROS generated during normal oxidative phosphorylation (see later discussion). The phenotype of the MnSOD knockout mouse therefore also underscores the importance of the mitochondria as a source of ROS in the myocardium.

$H_2O_2$ , the product of SOD, is handled by one of several glutathione peroxidases (GPx) and/or catalase. GPx are selenium-containing enzymes that catalyze the removal of  $H_2O_2$  through oxidation of reduced glutathione (GSH), which is recycled from oxidized glutathione (GSSG) by the NADPH-dependent glutathione reductase (GRed). The activity of GPx requires stoichiometric quantities of GSH, and therefore low levels of GSH reduce the activity of GPx. GRed requires NAD(P)H as a reductant to recycle GSSG to GSH. In this context, enzymes in the pentose phosphate pathway and glucose-6-phosphate dehydrogenase (G6PD), the rate-limiting enzyme in this pathway, can be thought of as ancillary antioxidant enzymes that are critical to cellular antioxidant defenses.<sup>6</sup> Other ancillary antioxidant enzymes are emerging that work through distinct mechanisms, such as heme oxygenase-1, which is induced by oxidative stress and serves a cytoprotective function through the breakdown of pro-oxidant heme into equimolar amounts of carbon monoxide, biliverdin/bilirubin, and free ferrous iron. Carbon monoxide<sup>7</sup> and bilirubin<sup>8</sup> have been shown to exert direct cardioprotective effects via their respective antiinflammatory and antioxidant actions. Cardiospecific overexpression of heme oxygenase-1 also has been shown to reduce infarct size, and inflammatory and oxidative damage, and attenuate postinfarct cardiac remodeling in animals after coronary artery occlusion and reperfusion injury.<sup>9,10</sup>

GPx-1, like MnSOD, is encoded on the nuclear genome but localizes to the mitochondria. Mice deficient in GPx-1 have no overt abnormality in myocardial function. GPx are selenium-containing enzymes,<sup>11</sup> and dietary deficiency of selenium, as occurs in some areas of China, is associated with a dilated cardiomyopathy and heart failure. There is evidence of increased oxidative stress in selenium-deficient people

**FIGURE 12-1** Reactive oxygen species (ROS) and antioxidant enzyme systems: Enzymatic or nonenzymatic formation of superoxide anion leads to the formation of other ROS (shown in bold). Potentially toxic ROS are removed by the enzymes superoxide dismutase (SOD), glutathione peroxidase (GPx), and catalase. The presence of  $\text{Fe}^{2+}$  or nitric oxide (NO) can allow the formation of hydroxyl radical ( $\text{OH}^\cdot$ ) and peroxynitrate ( $\text{ONOO}^-$ ), respectively. These latter reactions are favored when the activity of SOD is decreased.  $\text{O}_2^-$  can increase the formation of  $\text{OH}^\cdot$  by reducing  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ . Glutathione plays a central role in cellular antioxidant defenses not only as a reducing agent for the action of GPx, but also through direct reactions with ROS. Glutathione is recycled by the enzyme glutathione reductase, which requires NAD(P)H. Thus indirectly, the pentose phosphate pathway, by supplying NAD(P)H, also plays an important role in antioxidant defenses.

and animals.<sup>12</sup> However, it appears that the effect of selenium deficiency on the heart are not due to direct effects of this oxidative stress, but perhaps due to cardiotoxic viral infections evolving rapidly toward virulent strains in a selenium-deficient heart.<sup>13</sup> A similar phenomenon may occur in people suffering from AIDS, where selenium deficiency is a risk factor for the development of heart failure.<sup>14</sup>

Glutathione is an important cellular antioxidant (see Figure 12-1), both as a cofactor for GPx and a direct scavenger of reactive oxygen and nitrogen species. Cells replenish GSH both through the action of glutathione reductase on GSSG and by de novo GSH synthesis. Increased oxidative stress lowers the GSH/GSSG ratio, which may thus be used as a measure of myocardial oxidative stress.<sup>15</sup> Unlike the levels of lipid peroxidation products, which can reflect oxidative stress inside and/or outside of the cell, the GSH/GSSG ratio specifically measures intracellular oxidative stress. Other thiol-containing proteins, such as the metal binding metallothionein, also have significant antioxidant functions through direct scavenging of ROS, and may also play a role in the control of oxidative stress in the failing heart.<sup>16</sup> Overexpression of metallothionein also has been shown to suppress mitochondrial oxidative stress, cardiac apoptosis, and the development of diabetic cardiomyopathy.<sup>17</sup>

Thioredoxin is also a thio-containing protein. It belongs to the thioredoxin system, which consists of thioredoxin reductase, thioredoxin, peroxiredoxin, and NADPH.<sup>18</sup> Like glutathione *S* transferase, heme oxygenase-1, and NAD(P)H oxidoreductase, this system is inducible by a variety of oxidative stresses and thioredoxin levels are increased in the myocardium of patients with cardiomyopathies,<sup>19</sup> and in the circulating blood of congestive heart failure (CHF) patients.<sup>20</sup> Thioredoxin is multifunctional. It not only exerts an antioxidant effect through thioredoxin peroxidase by scavenging ROS, but also interacts with multiple cellular signal transduction pathways, including downregulation of p38 mitogen-activated protein kinase and apoptosis signal-regulating kinase (ASK)-1, to exert an antiapoptotic effect. Part of its cardioprotective action is also mediated via activation of heme oxygenase-1 and the antiapoptotic Bcl-2 pathway.<sup>21</sup> Like metallothionein, induction of thioredoxin has been shown to

exert a cardioprotective effect in animals after chronic myocardial infarction<sup>21</sup> or Adriamycin-induced cardiomyopathy.<sup>18</sup>

Vitamin antioxidants also play a major role in the control of ROS cascades and the prevention of free radical chain reactions. In particular,  $\alpha$ -tocopherol and ascorbic acid, vitamins E and C, respectively, can act synergistically to prevent lipid peroxidation and membrane breakdown.  $\alpha$ -Tocopherol is a fat-soluble vitamin that concentrates in cellular membranes. Through the aromatic ring headgroup attached to its hydrocarbon chain,  $\alpha$ -tocopherol is able to form a “stable” tocopheryl radical when it reacts with ROS and lipid peroxyl radicals. Ascorbic acid reacts with tocopheryl radicals, thereby converting them back to tocopherol. Circulating and tissue levels of  $\alpha$ -tocopherol have been used as measures of both antioxidant capacity and oxidative stress.<sup>15</sup> In addition,  $\alpha$ -tocopherol has been used as a therapeutic intervention in animal models of heart failure.<sup>22,23</sup>

## OXIDATIVE STRESS IN HUMAN HEART FAILURE

Oxidation products of several organic molecules including lipids, proteins, and nucleic acids have been used to demonstrate oxidative stress in many diseases including heart failure (Table 12-1). While these methods can individually be criticized for their relative nonspecificity, collectively the data support the conclusion that there is increased systemic and myocardial oxidative stress in patients with heart failure. Several studies have shown that the lipid peroxidation products such as malondialdehyde (MDA)<sup>24</sup> and 4-hydroxynonenal<sup>25</sup> are increased and total thiol levels are decreased in patients with ischemic and nonischemic cardiomyopathy compared with subjects without heart failure.<sup>26</sup> Myeloperoxidase, a peroxidase enzyme present abundantly in granulocytes, is increased in the circulating blood of patients with heart failure (HF). Increased plasma myeloperoxidase is associated with a higher likelihood of more advanced HF patients.<sup>27</sup> Moreover, oxidative stress markers may have some prognostic value, as they correlate with worsening NYHA functional class, chronicity of disease,<sup>24</sup> cardiac dysfunction,<sup>27</sup> and circulating levels of other markers with prognostic value such as the soluble tumor necrosis factor  $\alpha$  receptor.<sup>28</sup> Plasma myeloperoxidase also appears to be an independent predictor of death, heart transplantation, or HF hospitalization.<sup>27</sup> Levels of exhaled pentane, a volatile lipid peroxidation product, are also increased in patients with heart failure.<sup>29</sup> However, while pentane levels normalized in patients taking captopril, they did not normalize with other angiotensin-converting enzyme inhibitors (ACEI) that lack a thiol moiety. Given the apparent class benefit of ACE inhibitors in heart failure, it is hard to argue that this antioxidant effect is important therapeutically. Along a similar line, Ghatak et al showed that circulating markers of oxidative stress normalized in patients with heart failure after 4 weeks of vitamin E therapy,<sup>30</sup> although to date there has been no demonstrable benefit of therapy with vitamin E for up to 12 weeks.<sup>31</sup> Thus the prognostic value of these measures of oxidative stress remains unclear at this time.

Increased myocardial oxidative stress in heart failure has been demonstrated by measurements of 8-iso-prostaglandin  $\text{F}_{2\alpha}$  (8-isoprostanes). 8-Isoprostanes are a family of prostaglandin  $\text{F}_{2\alpha}$  isomers formed by the peroxidation of arachidonic acid through a noncyclooxygenase-mediated reaction catalyzed by free radicals.<sup>32</sup> In contrast to reactive aldehydes, lipid hydroperoxides, and conjugated dienes, 8-isoprostanes are more stable products of lipid peroxidation and thus have been proposed to be a more accurate indicator of oxidative stress *in vivo*.<sup>33</sup> 8-Isoprostanes are elevated in tissue subjected to increased oxidative stress, and can be extracted and measured quantitatively using several methods including

**TABLE 12–1 Studies of Oxidative Stress Markers in Human Heart Failure**

Markers	Studies	Findings
MDA, Thiols, SOD, GPx	McMurray et al <sup>143</sup>	Increased plasma MDA, decreased plasma thiols in patients with CAD and LV dysfunction.
	Belch et al <sup>144</sup>	Increased plasma MDA, decreased plasma thiols in patients with CHF. Weak correlation between decreasing thiols and worsening LV function.
	McMurray et al <sup>126</sup>	Increased MDA, decreased plasma thiols in both CAD and non-CAD patients with HF.
	Ghatak et al <sup>30</sup>	Increased MDA, and reduced erythrocyte SOD and GPx activities in CHF. Weak correlation with LV function. Improved by vitamin E administration.
	Diaz-Velez et al <sup>24</sup>	Increased MDA in CHF. No correlation with LV function. Some correlation between MDA and chronicity of illness.
	Keith et al <sup>145</sup>	Correlated oxidative stress with NYHA clinical class and levels of soluble TNF receptor levels as marker of prognosis.
	Maks et al <sup>25</sup>	Plasma unsaturated aldehydes including 4-OH-nonenal were elevated in association with impaired LV contractile function in HF patients.
	Polidori et al <sup>146</sup>	Plasma MDA was higher in patients with severe CHF than those with moderate disease.
	Campolo et al <sup>147</sup>	Reduced cysteine and MDA were increased in CHF patients.
Myeloperoxidase	Tang et al <sup>27</sup>	Associated with an increased likelihood of more advanced HF, and predictive of worse long-term clinical outcomes.
Breath pentane	Sobotka et al <sup>29</sup>	Increased exhaled pentane in CHF compared with controls. Pentane levels reduced by captopril therapy.
8-isoprostanes	Mallat et al <sup>34</sup>	Pericardial 8-isoprostanes in patients undergoing open-heart surgery correlated with preoperative NYHA functional class.
	Kameda et al <sup>35</sup>	Pericardial 8-isoprostanes correlated with LV end-diastolic volume, and activities of MMP-2 and MMP-9 and gelatinolysis in CAD patients.
	Polidori et al <sup>36</sup>	Plasma F2 isoprostanes correlated with antioxidant status and NYHA class.
	Nonaka-Sakukawa et al <sup>148</sup>	Urinary 15-Ft-isoprostanes increased in proportion to the severity of CHF, and correlated with plasma BNP and serum IL-6.
Pentosidine	Koyama et al <sup>37</sup>	Serum pentosidine was an independent risk factor for cardiac events in patients with HF.
Plasma carboxyls	Amir et al <sup>38</sup>	Serum oxidative stress levels increased with NYHA functional class and were associated with higher CRP and BNP.
8-hydroxy-2'-deoxyguanosine	Watanabe et al <sup>42</sup>	Correlated with NYHA functional class, left atrial diameter, LV end-diastolic diameters, LV end-systolic diameters, and plasma BNP.
	Kono et al <sup>41</sup>	Increased in both the serum and myocardium of patients with HF. Reduced with carvedilol therapy.
	Pignatelli et al <sup>149</sup>	Serum levels increased in CHF, progressively from Class I-II to Class III-IV. Correlated with TNF- $\alpha$ and sCD40L.
Uric acid	Cicoira et al <sup>150</sup>	Elevated serum uric acid levels correlated with parameters of diastolic dysfunction in HF.
	Anker et al <sup>47</sup>	Uric acid predicted mortality in patients with moderate to severe CHF.
	Kojima et al <sup>45</sup>	Correlated with Killip's classification and mortality in patients with acute MI.
	Sakai et al <sup>43</sup>	Positive transcardiac gradient of uric acid increased with the severity of HF and inversely correlated with LVEF.
	Kittleson et al <sup>44</sup>	High uric acid was associated with increased cardiac filling pressures and reduced cardiac index. Correlated with NT-proBNP.
	Ioachimescu et al <sup>48</sup>	An independent predictor of death in patients at high risk of cardiovascular disease.
Biopyrrins	Hokamaki et al <sup>50</sup>	Urinary biopyrrin levels were elevated and correlated with blood BNP and severity of HF.

Abbreviations: BNP, brain-natriuretic peptide; CAD, coronary artery disease; CHF, congestive heart failure; CRP, C-reactive peptide; IL-6, interleukin-6; GPx, glutathione peroxidase; LV, left ventricle; MDA, malonyldialdehyde; NYHA, New York Heart Association; SOD, superoxide dismutase; TNF, tumor necrosis factor.

an enzyme-linked immunoassay. Mallat et al measured 8-isoprostanes in the pericardial fluid of patients with NYHA functional Class I-III HF undergoing open heart surgery for ischemic or valvular disease.<sup>34</sup> They found that the level of 8-isoprostanes correlated with increasing NYHA functional class in patients preoperatively, consistent with the concept that worsening heart failure is associated with increased myocardial oxidative stress. Elevated pericardial 8-isoprostanes also correlate with left ventricular (LV) end-diastolic volume, and activities of matrix metalloproteinases and gelatinolysis<sup>35</sup> in CAD patients. Plasma and urinary isoprostanes also correlate with the severity of clinical HF, antioxidant status, and blood BNP and IL-6.<sup>36</sup>

In addition to the lipid peroxidation products, oxidation products of glycoproteins, proteins, and nuclear DNAs are increased in HF, indicative of increased oxidative stress. Serum pentosidine, an advanced glycation end product, is an independent risk factor for cardiac events in patients with

HF.<sup>37</sup> Plasma carboxyls are also increased in patients with more symptomatic HF, and associated with higher C-reactive protein (CRP) and Brain Natriuretic Peptide (BNP).<sup>38</sup> More recently, 8-hydroxy-2'-deoxyguanosine (8-OHdG), which is formed when DNA is oxidatively damaged by ROS, has been found to be one of the most sensitive biomarkers for oxidative stress, and can be measured in plasma, urine, and tissue. Myocardial 8-OHdG is increased in animals with cardiac hypertrophy<sup>39</sup> and tachycardia-induced cardiomyopathy.<sup>40</sup> 8-OHdG is increased in both the serum and myocardium of patients with HF.<sup>41</sup> Plasma levels of 8-OHdG correlate with NYHA functional class, cardiac function, and several HF biochemical markers such as plasma BNP, TNF- $\alpha$ , and sCD40L.<sup>42</sup>

Uric acid, produced by the ubiquitous ROS-generating xanthine oxidase (see later discussion), has been considered as a marker for oxidative stress in the cardiovascular system. It is released from the failing human heart, with an inverse correlation between the positive transcardiac gradient of uric

acid and LV ejection fraction.<sup>43</sup> Increased serum uric acid levels are associated with increased cardiac filling pressure and reduced cardiac index in HF,<sup>44</sup> and correlates with Kilip's classification in acute MI,<sup>45</sup> plasma NT-proBNP in HF,<sup>44</sup> and parameters of diastolic dysfunction.<sup>46</sup> Uric acid is also a strong independent predictor of mortality in patients with moderate to severe HF<sup>47</sup> and patients at high risk of cardiovascular disease.<sup>48</sup> This association, however, is only significant when hyperuricemia is a marker of increased xanthine oxidase activity but not when hyperuricemia is caused by impaired renal elimination of uric acid.<sup>49</sup>

Biopyrrins are oxidized metabolites of bilirubin, which are increased in HF, probably secondary to hepatic dysfunction due to venous congestion and/or increased heme oxygenase-1 activity. Urinary biopyrrin levels are elevated and correlate with blood BNP and severity of HF.<sup>50</sup>

## OXIDATIVE STRESS AND ANTIOXIDANT THERAPY IN ANIMAL MODELS OF HEART FAILURE

Although there are no positive large-scale clinical trials of antioxidant therapy in heart failure to date, there are multiple studies of oxidative stress and antioxidant therapy in animal models of heart failure. Singal et al, working with several animal models of heart failure, have characterized changes in myocardial oxidative stress and antioxidant capacity in both myocardial hypertrophy and the transition to failure. In a model of stable myocardial hypertrophy after abdominal aortic banding they found an increase in the activity of SOD and GPx.<sup>51</sup> However, in a model of pressure-overload leading to failure in the guinea pig, both SOD and GPx activity fell during the failure stage in association with a decreased ratio of GSH/GSSG, consistent with an increase in myocardial oxidative stress.<sup>52</sup>

Singal et al have also found similar changes in antioxidant capacity and oxidative stress in the rat late after myocardial infarction (MI).<sup>15</sup> As in the setting of pressure overload, there was a small increase in antioxidant enzyme activity early after MI. However, also like the banding model, late after MI there was evidence for increased oxidative stress. During the period from 4 to 16 weeks after MI there was a progressive decrease in LV systolic function and an increase in end-diastolic pressure. These changes in ventricular function were accompanied by (1) a progressive decline in GPx and catalase activities, (2) an increase in myocardial lipid peroxidation, (3) a decrease in the GSH/GSSG ratio, and (4) decreased levels of vitamin E. SOD activity was decreased only at the latest time point examined. Thus in both the pressure overload and post-MI models of myocardial remodeling leading to heart failure in rodents, there is evidence for increased oxidative stress and a maladaptive decrease in antioxidant enzyme capacity that correlates in time with declining ventricular function. Similar observations were made in a large animal model of volume overload-induced heart failure secondary to mitral regurgitation in which there was also evidence of increased myocardial levels of lipid peroxidation products, decreased antioxidant enzyme capacity, and depletion of vitamin E.<sup>53</sup>

The extent to which changes in antioxidant enzyme activity occur in the failing human heart is controversial. Two studies have reported no decrease in SOD or GPx activity in pathological samples from explanted human hearts at the time of cardiac transplant as compared with nonfailing controls.<sup>54,55</sup> In contrast, MnSOD activity has been found to be reduced in the failing human heart.<sup>56</sup> This appears to occur at a posttranscriptional level, as mRNA expression of MnSOD is increased in the same failing samples when compared with the nonfailing specimens. The discrepancy among these studies in failing human heart tissue may reflect differences in the "control"

hearts, where variable degrees of pathological and pharmacological stress may be important confounding factors. Nevertheless, it remains unclear whether the decreased expression of antioxidant enzymes seen in rodent models of heart failure (i.e., decreases in SOD and GPx) contributes to the oxidative stress in the end-stage failing human heart. In the face of increased ROS production, however, the lack of an increase in antioxidant capacity in the failing human heart does most likely reflect a state of relative inadequate antioxidant capacity.

Several animal studies have now demonstrated benefits of pharmacological antioxidants with regard to the development of heart failure in the setting of hemodynamic overload (Table 12-2). Interestingly, the benefits vary depending on the model and the antioxidant used. In dogs with surgically induced mitral regurgitation, administration of vitamin E prevented in part the decline in ventricular function over a 4-month study.<sup>53</sup> While the administration of vitamin E partially prevented the downregulation of GPx and catalase activity and the increase in MDA, the decrease in SOD activity was not prevented. Vitamin E administration also has beneficial effects in the aortic banding model of pressure overload in the guinea pig.<sup>22</sup> In animals treated with implanted tablets of  $\alpha$ -tocopherol, there was a measurable increase in myocardial  $\alpha$ -tocopherol levels. There was no difference in the compensatory hypertrophy that occurs at early time points after banding. However at late time points,  $\alpha$ -tocopherol administration prevented the transition to heart failure, as evidenced by improved LV peak developed pressure.

In pacing-induced rabbit cardiomyopathy, antioxidant vitamins reduced the tissue GSSG/GSH and 8-OHdG levels, and attenuated the associated cardiac dysfunction and  $\beta$ -receptor downregulation.<sup>40</sup> Vitamin E supplement also improved LV function and significantly reduced myocardial 8-isoprostanes and oxidized glutathione accumulation in rodents with diabetes and cardiac dysfunction.<sup>23</sup> However, vitamin E supplementation has not been shown to have any significant effects in human heart failure. In a 12-week placebo-controlled study, vitamin E supplement did not reduce plasma MDA or isoprostane levels.<sup>31</sup> Nor did it reduce

**TABLE 12-2** Antioxidants with Therapeutic Effects in the Failing Heart

Antioxidant	Cardiomyopathy Setting	Observations (Species)
Antioxidant vitamins	Surgical mitral insufficiency	Vitamin E improved left ventricular (LV) function (dog). <sup>53</sup> Vitamin E improved contractile function. Reduced dilation (rat). <sup>22</sup> Vitamin E, C, and beta carotene increased cardiac oxidative stress and attenuated the associated systolic dysfunction, and $\beta$ -AR downregulation (rabbit). <sup>40</sup> Vitamin E supplementation improved LV function and significantly attenuated myocardial 8-iso-prostaness and oxidized glutathione accumulation (rat). <sup>23</sup>
	Pressure overload	
	Tachy-pacing cardiomyopathy	
	Diabetic cardiomyopathy	
Probucol	Myocardial infarction	Improved survival and LV function; reduced cytokine expression and myocyte death (rat). <sup>151</sup>
Dimethylthiourea (DMTU)	Myocardial infarction	DMTU reduced LV dilation; improved systolic function (mouse). <sup>59</sup>

blood BNP, TNF- $\alpha$ , or norepinephrine, or improve the quality of life questionnaire scores in the subjects. Long-term vitamin E supplementation also produced no effects on primary prevention of cardiovascular events in humans.<sup>57</sup>

In a study of post-MI remodeling in the rat, administration of probucol decreased the levels of myocardial oxidative stress, preserved myocardial systolic function, and improved animal survival.<sup>58</sup> While the probucol-treated animals had increased wall thickness of the scarred myocardium, there was no effect of probucol on ventricular dilation. In contrast, the ROS scavenger DMTU prevented chamber dilation and pump dysfunction in the mouse post-MI.<sup>59</sup> The reason for the differences between the effects of probucol and DMTU in the post-MI setting remains to be determined, but is likely due to their relative abilities to reach intracellular compartments and scavenge specific ROS. In any case, it appears that chronically elevated oxidative stress in the myocardium may play a central role in the process of myocardial remodeling leading to heart failure. Collectively these and other studies (see Table 12-2) suggest that deficits in antioxidant capacity in the remodeling myocardium contribute to increased oxidative stress and the progression to heart failure.

## THE CELLULAR SOURCES OF OXIDATIVE STRESS IN HEART FAILURE

There are many potential sources of  $O_2^-$  and other ROS in all eukaryotic cells, and several of these appear to be important in the failing myocardium (Figure 12-2). Several enzyme systems that generate  $O_2^-$  are present in the myocardium and some of these may produce pathophysiological amounts of  $O_2^-$  in the failing heart. Xanthine oxidoreductase, a member of the molybdoenzyme family, is a major source of ROS in human cardiovascular diseases. This enzyme system consists

of two interconvertible forms: xanthine dehydrogenase and xanthine oxidase; both are involved in the conversion of hypoxanthine and xanthine to uric acid. The constitutive xanthine dehydrogenase uses  $NAD^+$  primarily as an electron acceptor, whereas the inducible xanthine oxidase transfers electrons to molecular oxygen, yielding 4 units of ROS per unit of transformed substrate. In addition, xanthine oxidoreductase can generate superoxide via NADH oxidase activity and produce nitric acid via nitrate and nitric reductase activities.<sup>60</sup> Thus activation of xanthine oxidoreductase is expected to cause both oxidative and nitrosative stresses. The gene expression of xanthine oxidase is regulated by oxygen tension, cytokines, and glucocorticoids, and it is increased in the failing heart of dilated cardiomyopathic patients<sup>61</sup> and in rats with heart failure produced by either monocrotaline or coronary artery occlusion.<sup>62,63</sup>

To study the functional importance of xanthine oxidase-induced production of ROS in heart failure, xanthine oxidase inhibitors (allopurinol, oxypurinol, and febuxostat) have been studied extensively in experimental cardiomyopathies. These agents uniformly reduce myocardial xanthine oxidase expression and activity, and attenuate the production of ROS in the failing heart. They also improve cardiac function, LV size,  $\beta$ -adrenergic receptor sensitivity, and myocardial mechanoenergetic coupling (e.g., see Ekelund et al.<sup>64,65</sup>). Also, alterations in fetal gene expression (see Chapter 2) and  $Ca^{2+}$  handling pathway (see Chapter 3) seen in hypertrophied and failing heart are reduced by oxypurinol.<sup>66</sup> The improvements in cardiac structure and function by xanthine oxidase inhibitors are consistent with attenuation of cardiac remodeling in HF. In small mechanistic studies in human heart failure, allopurinol reduced plasma MDA, improved endothelium-dependent flow-mediated response,<sup>67,68</sup> reduced myocardial oxygen consumption, and improved myocardial efficiency.<sup>61</sup> Also, in acute and short-term studies, oxypurinol increased LV ejection fraction and

**FIGURE 12-2** Cellular sources of reactive oxygen species (ROS) and ROS signaling in cardiac hypertrophy. ROS-generating systems are shown on the left and include xanthine oxidase, NADPH oxidases (NOX2, NOX4), nitric oxide synthase (NOS), and mitochondrial complexes. ROS activation has protean effects on calcium handling, myofilament function, matrix activation, kinase and phosphatase stimulation, and transcriptional regulation. Metalloproteinases (Key: NFκB, nuclear factor-kappaB; PKC, protein kinase C; PI3K, phosphatidylinositol 3 kinase; PLB, phospholamban; RyR, ryanodine receptor; SERCA2, sarcoplasmic reticular ATPase 2) (Modified from McKinsey TA, Kass DA. Small-molecule therapies for cardiac hypertrophy: moving beneath the cell surface. *Nat Rev Drug Discov* 2007;6:617-635.)

reduced LV end-diastolic volume.<sup>69</sup> However, the xanthine oxidase inhibitor did not improve a primary composite OPT-CHF, endpoint (mortality, HF morbidity, or quality of life) in a long-term study of symptomatic systolic HF patients.<sup>70</sup> In subgroup analysis, the authors noted that clinical improvements were seen in patients with elevated uric acid, and that degree of serum uric acid reduction over the course of study correlated with clinical outcomes. The magnitude of improvement in cardiac function by oxypurinol in pressure-overload heart failure also depends on the initial level of xanthine oxidase activity.<sup>71</sup> Thus it is possible that xanthine oxidase inhibitors may exert a beneficial effect in patients with elevated serum uric acid or if larger doses of xanthine oxidase inhibitors are employed to produce greater xanthine oxidase inhibition. Additional studies are needed.

NAD(P)H oxidase is a plasmalemmal enzyme that mediates the ROS-dependent effects of angiotensin in vascular smooth muscle cells.<sup>72</sup> The activation of NAD(P)H oxidase results in increased generation of  $O_2^-$  in the cytosol. This enzyme complex was first described in the neutrophil, where it is responsible for the oxidative burst which produces large amounts of cytotoxic ROS. However, NAD(P)H oxidases in other cell types appear to be capable of producing much lower levels of ROS that can act as signaling intermediates in growth pathways.<sup>73</sup> Recent studies have implicated this oxidase in the hypertrophic response of ventricular myocytes (see later discussion).<sup>74,75</sup>

Nonenzymatic autooxidation reactions of several organic molecules, including neurohormones, may also contribute to the formation of ROS in vivo. Oxidation of norepinephrine and epinephrine to adrenochrome and  $O_2^-$  has been proposed as a mechanism for myocardial injury in the presence of chronic adrenergic stimulation.<sup>76</sup> As small amounts of ascorbic acid can completely prevent this reaction, and there are clearly direct adrenergic receptor-mediated deleterious effects of adrenergic stimulation,<sup>77</sup> it is unclear whether adrenochrome-mediated injury contributes to heart failure. In addition, thiol compounds including cysteine and GSH can autooxidize to form  $O_2^-$ , particularly in the presence of transition metals such as iron. The cardiotoxicity of iron overload is likely a combination of this plus the catalysis of Fenton chemistry to generate hydroxyl radicals. Myoglobin can also autooxidize from oxymyoglobin to metmyoglobin with the release of  $O_2^-$ , and this may be another source of ROS given the high concentration of myoglobin in the ventricular myocyte.<sup>78</sup>

Growing evidence supports the mitochondria as an important source of myocardial ROS in the failing heart (for review see Tsutsui, 79). Some small fraction of electrons entering the mitochondrial electron transport chain “leak” to molecular oxygen to form  $O_2^-$  (Figure 12-3). Because of the density of mitochondria in cardiac myocytes this can result in a high flux of  $O_2^-$ . Ide et al have found convincing evidence of increased mitochondrial formation of ROS in the myocardium of dogs with rapid-pacing-induced heart failure.<sup>80</sup> As in other models of heart failure, lipid peroxidation levels were increased in the myocardium of the failing animals compared with controls. In a mitochondrial fraction form, they examined the formation of  $O_2^-$  using electroparamagnetic resonance (EPR) with the  $O_2^-$  spin-trap 5,5'-dimethyl-1-pyrroline-N-oxide (DMPO). The DMPO spin signal, which is directly proportional to the rate of formation of ROS, was 2.8-fold higher in mitochondria from failing hearts compared with nonfailing controls. This was associated with an approximately 50% decrease in the activity of mitochondrial electron transport complex I, suggesting a functional uncoupling of the mitochondria that may have contributed to the increase in ROS formation. Thus at least in this heart failure model there is evidence of oxidative stress which is due, at least in part, to increased mitochondrial formation of  $O_2^-$ .

**FIGURE 12-3** NAD(P)H oxidases and mitochondria as sources of ROS in the heart. An NAD(P)H oxidase is expressed in cardiac myocytes similar to that found in neutrophils and vascular cells. The oxidase is composed of at least five subunits, with two membrane proteins that comprise the oxidase activity and three cytoplasmic proteins that serve regulatory functions. The complex catalyzes the one electron reduction of  $O_2$  to  $O_2^-$  with NADPH or NADH as a reducing cofactor. The mitochondrial electron transport chain creates a proton-motive force through the transfer of electrons from NADH dehydrogenase (complex I) and succinate dehydrogenase (complex II) to ubiquinone (Q), thereby forming reduced ubiquinone ( $QH_2$ ). Partially reduced ubiquinone ( $Q^-$ ) is a radical that can reduce  $O_2$  to  $O_2^-$ . This oxygen “leakage” is a potentially large source of ROS, and has been implicated in the increased oxidative stress in heart failure (see text).

## EFFECTS OF OXIDATIVE STRESS ON MYOCARDIAL STRUCTURE AND FUNCTION

### Role of ROS in Myocardial Remodeling

One consequence of myocardial oxidative stress may be the promotion of myocardial remodeling (see chapter 15). Following an injury such as myocardial infarction there is progressive “remodeling” of the remaining, viable myocardium, a process characterized by chamber enlargement, myocardial thinning and pump dysfunction. Multiple mechanisms contribute to myocardial remodeling including myocyte hypertrophy, myocyte slippage, myocyte apoptosis and/or alterations in the turnover and properties of the extracellular matrix (see Chapter 5). The stimuli for ventricular remodeling includes increased wall stress, inflammatory cytokines (see Chapter 11), and neurohormones including catecholamines and angiotensin II. In vitro and in vivo experimental studies have shown that oxidative stress can cause myocardial remodeling, and mediate many of the effects of remodeling stimuli, raising the possibility that ROS may play a central role in the process of ventricular remodeling.

ROS regulate growth pathways in many cell types, including the cardiovascular system (see Figure 12-2). As discussed previously, the effect of angiotensin II on vascular smooth muscle cell hypertrophy depends on increased production

of  $O_2^-$  via NADPH oxidase.<sup>81</sup> Likewise, the growth effects of stimuli that act via the small GTP-binding protein *ras* appear to be mediated by increases in  $O_2^-$ .<sup>82</sup> ROS appear to mediate similar growth responses in ventricular myocytes. For example, small alterations in cellular oxidative stress in cardiac myocytes in vitro can lead to changes in myocyte hypertrophy. The copper chelator diethyldithiocarbamic acid (DDC) inhibits the activity of CuZnSOD in a concentration-dependent manner leading to measurable increases in cellular  $O_2^-$  levels as assessed by lucigenin chemiluminescence or nitro-blue tetrazolium (NBT) reduction.<sup>83</sup> Exposure to low concentrations of DDC (1 to 10  $\mu$ M) for 24 hours caused myocyte growth with increases in protein synthesis and cell size, and associated with increased expression of ANF mRNA and decreased expression of SERCA2 mRNA. All of the effects of DDC were inhibited by antioxidants, and thus support the conclusion that small increases in intracellular oxidative stress can cause typical myocyte hypertrophy.

ROS appear to mediate the hypertrophic effect of mechanical strain,<sup>84</sup> a well-known stimulus for myocyte hypertrophy. Low- (5%) and high- (25%) amplitude strain of cardiac myocytes causes amplitude-dependent increases in both ROS formation and myocyte hypertrophy, and the hypertrophic effect was inhibited by an SOD-mimetic. Unlike high-amplitude strain (as discussed later), there was no effect of low-amplitude strain on the frequency of apoptosis as measured by TUNEL or DNA laddering. Similarly, myocyte hypertrophy stimulated by angiotensin II or TNF- $\alpha$  is mediated by ROS.<sup>85</sup> Both TNF- $\alpha$  and angiotensin II increase the formation of ROS, and the hypertrophic effects of these stimuli are inhibited by concomitant treatment with soluble antioxidants including vitamin E. As formation of both angiotensin II and TNF- $\alpha$  have been demonstrated in myocytes subjected to mechanical strain,<sup>86</sup> these observations may be related to the similar observations made with mechanical strain (see previous discussion).  $\alpha$ -Adrenergic receptor stimulation also induces myocyte ROS formation and stimulates myocyte hypertrophy through an ROS-dependent pathways.<sup>74</sup> Likewise, endothelin modulates myocyte early response gene expression through ROS-dependent activation of *ras*<sup>87</sup> and ouabain causes hypertrophy via ROS-dependent activation of a pathway involving both *ras* and mitogen-activated protein kinases (MAPK).<sup>88</sup>

While the details of how these agonists increase myocyte ROS formation remains to be elucidated, a growing literature suggests that a NAD(P)H oxidase is involved (see Figures 12-3 and 12-4). For example, in isolated adult rat ventricular myocytes the NAD(P)H oxidase inhibitor diphenylene iodonium completely prevents  $\alpha_1$ -adrenergic- and endothelin-stimulated activation of the MAPKs extracellular-signal regulated kinase 1 and 2 (ERK1/2).<sup>74</sup> In contrast, inhibition of the mitochondrial respiratory chain with rotenone had no effect on the  $\alpha_1$ -adrenergic receptor-stimulated activation of ERK1/2.

The neutrophil NAD(P)H oxidase is a complex consisting of at least four major subunits, including two membrane-spanning components (p22phox and gp91phox), and two cytosolic components (p67phox and p47phox) (for review see Griendling<sup>81</sup>). A similar oxidase system has been identified in many cell types in the cardiovascular system.<sup>89</sup> Although the cardiovascular NAD(P)H oxidases retain a similar enzyme complex structure to neutrophil oxidase with four subunits, their component structures and biochemical characteristics are considerably different. Using reverse transcriptase-polymerase chain reactions (RT-PCR) and Northern blot analysis, expression of the four major subunits of NAD(P)H oxidase (p22phox, gp91phox, p67phox, and p47phox) has been identified in rat cardiac myocytes.<sup>74</sup> The gp91phox knockout mouse has been studied in the setting of angiotensin II infusion, with results supporting a role for an NAD(P)H oxidase in both vascular and myocardial hypertrophy.<sup>75,90</sup>

**FIGURE 12-4** Schematic presentation of the effects of ROS on myocyte phenotype. Through activation of kinase cascades such as MAPK, ROS can induce myocyte hypertrophy. ROS can also alter the activity and expression of  $Ca^{2+}$  handling proteins, including SERCA2 and the  $Na^+/Ca^{2+}$  exchanger, to alter myocardial contractility. Mitochondrial ROS may be particularly prone to induce apoptosis by stimulating the mitochondrial release of cytochrome *c*, which is necessary for the activation of caspase cascades. The endoplasmic reticulum (ER) is also a source of ROS production. Under stress, the ER-resident molecular chaperone, glucose-regulated protein-78, is upregulated and leads to the transcriptional induction of ER stress response genes and the activation of caspase 12. Translational arrest decreases the workload on the ER, essential for cell recovery and survival. However, when the ER is overwhelmed by the stress, caspase 12 is released and activates caspase 3 and the final programmed cell death pathway.

Suppressor doses of angiotensin II administered subcutaneously for 2 weeks caused cardiac hypertrophy that was associated with increased myocardial expression of a fetal gene program, increased myocyte cross-sectional area, and increased myocardial collagen content in wild-type, but not gp91phox, knockout mice. Thus NADPH oxidase appears to play a central role in the cardiac hypertrophic response to several neurohormones and peptides (see Figure 12-4).

In contrast to the growth effects of low levels of ROS generated by specific oxidases and acting via specific signaling systems, higher levels of ROS-induced myocyte cell death, which may also be important in the pathophysiology of heart failure. For example, high concentrations of DDC leading to approximately 50% inhibition of SOD activity in neonatal rat ventricular myocytes induce myocyte apoptosis as assessed by nuclear morphology and TUNEL staining for DNA fragmentation.<sup>83</sup> At apoptotic concentrations, but not at hypertrophic concentrations, DDC increased myocyte expression of Bax, a pro-apoptotic member of the Bcl-2 family. Like the hypertrophic effect of low concentrations of DDC, the apoptotic effect of higher concentrations of DDC was prevented by antioxidants. Thus higher levels of intracellular oxidative stress cause ROS-dependent apoptosis in myocytes.

Direct addition of ROS to cardiac myocytes in culture also causes apoptosis.<sup>91</sup> Similarly, the cardiotoxic anthracyclines

are well known to generate intracellular ROS<sup>92</sup> and induce both myocyte apoptosis and necrosis in a dose-dependent manner (see Chapter 58). The apoptosis, but not necrosis, could be inhibited by the addition of the iron chelator dexrazoxane, which is used clinically in the prevention of anthracycline cardiotoxicity.<sup>93</sup> These results implicate hydroxyl radicals formed via the Fenton reaction in anthracycline-induced apoptosis. Although not specifically examined, hydroxyl radicals may also account for the apoptotic effect of extracellular  $O_2^-$  or  $H_2O_2$  in isolated ventricular myocytes. Thus multiple studies have shown that oxidative stress can cause myocyte apoptosis in vitro.

ROS appear to mediate the apoptotic effect of high-level mechanical strain on cardiac myocytes. Cheng et al showed that ROS formation increases in papillary muscles subjected to oxidative stress in vitro, and is associated with increased myocyte apoptosis.<sup>94</sup> Application of a static mechanical load (approximately sixfold the estimated normal end-diastolic wall stress) for 4 hours increased both the production of  $O_2^-$  and the frequency of apoptosis. Addition of an NO donor decreased the level of ROS formation and the frequency of apoptosis, thus suggesting a mechanistic role for ROS in strain apoptosis. More direct evidence for ROS-dependent apoptosis in the setting of increased mechanical load comes from studies in isolated ventricular myocytes. Cyclic mechanical stretch in isolated cardiac myocytes increases ROS production,<sup>84</sup> and when cells are stretched at a high amplitude there is an increase in the number of apoptotic myocytes, associated with an increase in Bax expression. Treatment of myocytes with an SOD-mimetic prevents stretch-induced apoptosis. Thus ROS appear to mediate both growth and death responses in cardiac myocytes.

### Mechanisms of ROS-induced Phenotype in Cardiac Myocytes

The mechanism by which increases in ROS lead to myocyte hypertrophy and apoptosis appear to involve activation of one or more stress-responsive protein kinases of the MAPK superfamily,<sup>95</sup> which is known to respond to ROS, and activate both hypertrophy and apoptosis in myocytes in vitro (see Chapter 2). This family of protein kinases includes ERKs and two stress-responsive MAPK subfamilies (SR-MAPKs), the p38-kinases and the c-Jun N-terminal kinases (JNKs). The ERKs consist of p42 (ERK-1) and p44 (ERK-2). The p38-kinases consist of at least six isoforms ( $\alpha_1$ ,  $\alpha_2$ ,  $\beta_1$ ,  $\beta_2$ ,  $\gamma$ , and  $\delta$ ), with the  $\alpha$  and  $\beta$  isoforms appearing to predominate in cardiac myocytes. The JNKs consist of 46-kDa or 54-kDa proteins.

ROS activate SR-MAPKs in the cardiovascular system.  $H_2O_2$  activates p38-kinase, JNKs, and ERKs in neonatal rat ventricular myocytes.<sup>96</sup> In perfused rat hearts,  $H_2O_2$  activated SR-MAPKs, with minimal activation of ERKs. Ischemia and ischemia/reperfusion selectively activated SR-MAPKs: p38-kinase was activated by both ischemia and ischemia/reperfusion, whereas JNKs were activated by ischemia/reperfusion, and neither stimulus activated ERKs.<sup>97</sup> An  $O_2^-$  scavenger inhibited p38-kinase activation, whereas a  $OH^\cdot$  scavenger prevented activation of both p38-kinases and JNKs during ischemia/reperfusion, raising the possibility that specific ROS differentially activate specific SR-MAPKs.

The possibility that SR-MAPKs mediate the effects of oxidative stress on myocyte growth is supported by in vitro and in vivo overexpression studies using molecular constructs of specific kinases or activators, and examining the effect on myocyte growth. For example, in neonatal rat ventricular myocytes, overexpression of constitutively active p38 kinase( $\beta$ ) or JNKs causes a hypertrophic response, whereas constitutively active p38-kinase( $\alpha$ ) causes apoptosis.<sup>98</sup> Other studies have used pharmacological inhibitors. For example, an inhibitor of ERK activation decreases the hypertrophic response

of ventricular myocytes to  $\alpha$ -adrenergic stimulation,<sup>99</sup> and this pathway appears to be activated by ROS generated by an NAD(P)H oxidase (see previous discussion). Inhibition of ERK activation also increases the apoptotic response to ROS, suggesting that ERKs may also exert a prosurvival effect.<sup>91</sup>

Apoptosis induced by oxidative stress appears to involve the activation of JNKs (see Chapter 6). In the H9C2 cardiac cell line, oxidative stress-induced apoptosis is associated with activation of JNKs, and transfection of a dominant negative JNK markedly diminishes the extent of apoptosis.<sup>100</sup> Similarly, ischemia/reperfusion-induced myocardial injury is associated with JNK activation and myocyte apoptosis is inhibited by the antioxidant/ $\beta$ -blocker carvedilol,<sup>101</sup> again supporting a role for JNK in ROS-induced myocyte injury. Similar mechanisms have been proposed for the beneficial effects of  $\beta$ -receptor blockade in chronic heart failure, although these speculations remain unproven.

Mitochondria are involved at an early step in the regulation of apoptosis in general, and appear to be involved in oxidative stress-induced apoptosis in the heart through the release of cytochrome *c* from the intermembrane space (see Chapter 6). Cytochrome *c* release activates caspase 9 and caspase 3 and appears to potentiate mitochondrial generation of ROS, possibly through effects on electron transport.<sup>102</sup> The process of cytochrome *c* release is modulated by the Bcl-2 family of proteins (for review see Reed<sup>103</sup>). Proapoptotic members of the Bcl-2 family (Bax, Bad, and Bak) interact with the outer mitochondrial membrane and allow for cytochrome *c* release and dissipation of the membrane potential through what has been termed the "mitochondrial permeability pore transition". Antiapoptotic members of the family (e.g., Bcl-2 and Bcl-xL) inhibit Bax-mediated cytochrome *c* release, caspase 3 activation, and the generation of ROS. In myocytes treated with direct addition of ROS, p53 activity increases in association with translocation of Bax and Bad from the cytosol to the mitochondrial fraction, with associated release of cytochrome *c*.<sup>104</sup> Interestingly, it appears that exogenous  $O_2^-$  induces apoptosis by a pathway distinct from  $H_2O_2$ . While treatment with  $H_2O_2$  induced mitochondrial release of cytochrome *c* and activation of caspase 3, treatment with xanthine and xanthine oxidase (in the presence of catalase) as a source of  $O_2^-$  induced apoptosis without either cytochrome *c* release or activation of caspase 3. In contrast,  $O_2^-$ -induced apoptosis involved activation of the laminase Mch2 $\alpha$ , and was inhibited by the pancaspase inhibitor Z-VAD-fmk. In contrast, increasing intracellular  $O_2^-$  by inhibition of superoxide dismutase does increase Bax expression, suggesting that a mitochondrial pathway may be involved. Together these data suggest that extracellular and intracellular  $O_2^-$  may trigger apoptosis via distinct pathways. This would not be surprising, as extracellular  $O_2^-$  should enter the cell minimally given its negative charge and the negative resting membrane potential. Extracellular  $O_2^-$  might trigger apoptosis via changes in matrix/integrin interactions. The effect of extracellular xanthine/xanthine oxidase on myocyte detachment in tissue culture suggests such a mechanism.<sup>83</sup>

In addition to actions on the cell membrane death receptors (extrinsic pathway) and release of proapoptotic factors from the mitochondria (intrinsic pathway), ROS may exert its apoptotic effects via stress at the endoplasmic reticulum (ER) (for review see Lee<sup>105</sup>). The ER is a multifunctional cellular organelle responsible for posttranslational processing of newly synthesized secretory and membrane proteins, maintenance of calcium homeostasis, and production and storage of glycogen, steroids, and other macromolecules. When the cell is exposed to obnoxious stimuli, such as hypoxia, ischemia, gene mutation, oxidative insult, or unglycosylation that increase misfolded proteins or perturb intracellular  $Ca^{2+}$  homeostasis in the ER, an adaptive process that couples the ER protein load with the ER protein folding capacity occurs.<sup>106</sup>

This process, known as unfolded protein response (UPR), is characterized by upregulation of ER chaperones such as glucose-regulated protein 78 (GRP78), release and activation of three key transmembrane proteins (protein kinase R-like ER kinase, inositol-requiring enzyme-1, and activating transcription factor 6) to promote the transcription of UPR genes, and removal of the unfolded proteins to the ubiquitin proteasome for degradation, aiming at restoring cellular homeostasis.<sup>107</sup> However, if ER stimuli overwhelm the capacity of UPR to remove the unfolded proteins from the ER, a maladaptive ER overload response (EOR) occurs. EOR is associated with transcriptional induction of C/EBP homologous protein (CHOP), cleavage of the ER-resident procaspase 12 to active caspase 12, and eventual programmed cell death through the activation of caspase 9 and 3. It has now been demonstrated that UPR and EOR are activated not only in acute myocardial ischemia/reperfusion but also in cardiac hypertrophy and failure.<sup>107-109</sup> Dilated cardiomyopathy also has been shown to occur in transgenic mice overexpressing a mutant KDEL receptor for ER chaperones that sensitizes the cells to ER stress.<sup>110</sup> The ER stress is functionally linked to  $\beta$ -adrenergic receptor-mediated activation of  $\text{Ca}^{++}$ /calmodulin-dependent protein kinase II and p-38 MAPK.<sup>109</sup> It has been shown to be activated by norepinephrine and an anti- $\beta_1$ -adrenoceptor antibody in an autoimmune cardiomyopathy.<sup>111</sup> Evidence has now accumulated that UPR and ROS production are closely linked,<sup>112</sup> and that ROS generation may occur both upstream and downstream to UPR signaling targets, including depolarization of the inner mitochondrial membrane following  $\text{Ca}^{2+}$  release.<sup>113</sup> It is also recognized that the phosphatidylinositol-3 kinase/Akt pathway and Bcl-2 family proteins are involved in the control of ER stress-induced apoptosis. Cardiac overexpression of metallothionein prevented both the inactivation of Akt and induction of ER stress in alcoholic cardiomyopathy.<sup>114</sup> Likewise, darbepoetin alfa treatment enhanced the activation of the phosphatidylinositol-3-kinase/Akt pathway, and reduced ER stress-related apoptosis in  $\beta$ -receptor peptide-induced autoimmune cardiomyopathy.<sup>109</sup> Akt phosphorylation is antiapoptotic; its inactivation is associated with reduction of prosurvival Bcl proteins. It is known that the Bcl-2 homolog domain-3-only protein bimakalim (Bim), which is sequestered by the prosurvival Bcl protein in healthy cells, may be freed when the level of Bcl protein is reduced, and translocates to the ER membrane to activate caspase 12<sup>115</sup> and ER stress-induced apoptosis by both protein phosphatase 2A-mediated dephosphorylation and CHOP-mediated direct transcription induction.<sup>116</sup> In contrast, in animals overexpressing Bcl-xL, ER stress is reduced as the antiapoptotic protein binds to Bim and inhibits its translocation to the ER. PUMA (p53-upregulated modulator of apoptosis) is another proapoptotic homolog domain-3-only member of the Bcl-2 protein family, which has been demonstrated to be critical for cardiomyocyte apoptosis induced by ER stress.<sup>117</sup>

### ROS-induced Changes in Calcium Handling

Myocytes isolated from the failing heart show markedly abnormal intracellular  $\text{Ca}^{2+}$  transients along with alterations in the expression and/or activity of  $\text{Ca}^{2+}$  handling proteins,<sup>118</sup> and these changes may be due in part to oxidative stress. The contribution of the  $\text{Ca}^{2+}$  handling proteins to contractile dysfunction in the failing heart are discussed in detail in Chapter 3. Of note, the downregulation of sarcoplasmic reticulum  $\text{Ca}^{2+}$  ATPase (SERCA2) expression and activity in the failing heart appear to contribute to contractile dysfunction in heart failure. The mechanism by which ROS leads to decreased SERCA2 activity may involve decreases in protein expression, as in primary cultures of cardiac myocytes exposed to increased levels of ROS<sup>83</sup> and/or alterations in protein function due to oxidative posttranslational modifications (OPTM). In

vascular smooth muscle, peroxynitrite (ONOO) causes OPTM of SERCA.<sup>119</sup> Low ONOO levels increase enzyme activity via a reversible glutathiolation at cysteine 674, whereas higher levels of ONOO decrease enzyme activity via irreversible sulfenylation at the same site.

There are other effects of ROS on myocyte  $\text{Ca}^{2+}$  handling that can result in changes in contractile function. ROS alter  $\text{Ca}^{2+}$  transients and excitation-contraction coupling in isolated myocytes by increasing the activity of the  $\text{Na}^{+}/\text{Ca}^{2+}$  exchanger, which in some situations may lead to  $\text{Ca}^{2+}$  overload.<sup>120</sup> A similar increase in  $\text{Na}^{+}/\text{Ca}^{2+}$  exchanger activity can be seen in some models of heart failure. For example, late after MI in the rabbit heart there is increased  $\text{Na}^{+}/\text{Ca}^{2+}$  exchanger activity together with a depressed force-frequency relationship.<sup>121</sup> Electrophysiological studies in isolated myocytes have also shown direct effects of reactive oxygen and nitrogen species on the voltage-dependent  $\text{Ca}^{2+}$  channel and the calcium release channel.<sup>122,123</sup> It remains to be seen whether these direct effects of ROS on  $\text{Ca}^{2+}$  handling proteins in vitro contribute to abnormal excitation-contraction coupling and contractility in the chronically failing heart.

### ROS Regulation of Interstitial Matrix Turnover by Cardiac Fibroblasts

As discussed in Chapter 5, one mechanism for ventricular chamber dilation is via alterations in the interstitial matrix of the myocardium. Individual ventricular myocytes are mechanically coupled to other cells via interstitial matrix proteins that connect to the sarcomere via integrins and intermediate filaments. Like intracellular proteins, there is a regular turnover of interstitial matrix proteins that is regulated by proteases and the protein synthetic machinery of the cardiac cells. Collagen is the major component of the interstitium that contributes to the structural integrity of the myocardium. Myocardial collagen content is regulated by the balance between synthesis and degradation, the latter primarily due to the action of matrix metalloproteinases (MMPs).<sup>124</sup>

Both cardiac fibroblast collagen synthesis and MMP activity are regulated in part by oxidative stress.<sup>125</sup> Fibroblasts from adult or neonatal rats grown in primary culture respond to both intracellular and extracellular oxidative stress with decreases in procollagen mRNA expression and collagen synthesis. Moreover, oxidative stress increases fibroblast MMP activity as measured by in-gel zymography. It is possible that such actions would result in myocyte slippage and chamber dilation, and impaired cell-cell mechanical coupling, and thereby contribute to abnormalities in both systolic and diastolic function. A role for oxidative stress in the regulation of interstitial matrix was recently defined in the mouse heart. Early after MI there was increased expression and activity of MMPs, and treatment with an antioxidant (DMTU) reduced the extent of ventricular dilation and suppressed MMP activity.<sup>59</sup> These results were similar to the effect of a pharmacological inhibitor of MMPs, and suggest that antioxidant strategies may be useful in preventing ventricular dilation in heart failure.

### NITRIC OXIDE AND ITS INTERACTION WITH ROS

Nitric oxide (NO) is also a free radical and can modify the myocardial response to oxidative stress both directly and indirectly. NO is synthesized in the conversion of L-arginine to L-citrulline by a family of nitric oxide synthases (NOS). NO, a free radical gas, is buffered in the cell by reactions with glutathione and reacts reversibly with sulfhydryl groups of proteins forming S-nitrosothiols leading to alterations in protein function.<sup>126</sup> Through chemical reactions with ROS, NO

can either *decrease* or *increase* the oxidative stress in a cell or tissue. Under normal circumstances, myocardial NO is produced at low levels by NOS3. NOS3 is present in virtually all cell types in the myocardium including myocytes, fibroblasts, and endothelial cells, and is regulated by a calcium-sensitive interaction with calmodulin.<sup>127</sup> Inducible nitric oxide synthase (NOS2) is not regulated by  $\text{Ca}^{+2}$ , and when expressed is capable of producing high levels of cellular NO. Though NOS2 is expressed minimally in the normal myocardium, it is induced by exposure to cytokines, hypoxia, and other stimuli in both myocytes and nonmyocytes because of activation of specific transcription factors and leads to a marked increase in the production of NO.<sup>128</sup> Of note, there is evidence for increased expression and activity of the NOS2 in the myocardium of patients with both idiopathic and ischemic dilated cardiomyopathies.<sup>129</sup>

Low levels of NO, as are formed by NOS3, may reduce the level of oxidative stress by decreasing the production of  $\text{O}_2^-$  through inhibition of oxidative enzymes.<sup>130</sup> Indirectly, low levels of NO may also exert beneficial effects on myocardial remodeling. NO through the activation of guanylate cyclase can inhibit signaling and transcription factors that regulate cardiac hypertrophy. NO may also be able to promote cell survival by regulating steps in the apoptotic cascade including proteases.<sup>131</sup> Mice lacking NOS3 have worse ventricular function late after MI,<sup>132</sup> consistent with the notion that NOS3-derived NO is beneficial for the failing result in nitrosative heart.

Higher levels of NO may increase oxidative stress by reacting with  $\text{O}_2^-$  to generate peroxynitrite ( $\text{ONOO}^-$ ), a free radical which is toxic and longer-lived than either NO or  $\text{O}_2^-$ .<sup>133</sup>  $\text{ONOO}^-$  can react with many cell constituents including tyrosine residues of susceptible proteins such as MnSOD, causing irreversible inactivation.<sup>134</sup> Based on the relative rate constants for the reaction of  $\text{O}_2^-$  with superoxide dismutase (SOD) and NO, the formation of  $\text{ONOO}^-$  is favored when the levels of  $\text{O}_2^-$  or NO are high, or the level of SOD is low. Interestingly, Xia and associates have shown that NOS2 is also capable of catalyzing the formation of  $\text{O}_2^-$ ,<sup>135</sup> particularly in the setting of arginine depletion. Thus expression of NOS2 may contribute directly to the formation of ROS (for review see Zimmet<sup>136</sup>).

Multiple experimental studies have shown that high concentrations of NO can have direct toxic effects on cardiac myocytes in vitro. The cytotoxic effect of cytokines on adult rat ventricular myocytes in culture is inhibited by the NOS inhibitor L-NMMA.<sup>137</sup> Similarly, in neonatal rat ventricular myocytes, cytokines induce cell death via NO-dependent apoptosis.<sup>138</sup> Cytokine-induced apoptosis can be prevented by either an inhibitor of NOS2 or an SOD-mimetic, thus implicating  $\text{ONOO}^-$ . Moreover, NOS2 appears to contribute to the myocyte apoptosis that occurs in the setting of myocardial failure in vivo. In the failing mouse heart, late after MI, NOS2 expression is increased in the remote myocardium and in NOS2 knockout mice there is less myocyte apoptosis, improved contractile function, and increased animal survival, as compared with wild-type mice with MI of identical size.<sup>139</sup>

Animal models of autoimmune and viral myocarditis (see chapter 31) have also implicated a direct toxic effect of NO and  $\text{ONOO}^-$  in vivo. In these models there is massive inflammation in the myocardium that results in overt myocyte necrosis. The amount of necrotic myocardium and the elevation of serum CK in rats with experimental autoimmune myocarditis was reduced by aminoguanidine, an inhibitor of NOS2.<sup>140</sup> Interestingly, treatment with aminoguanidine also decreased the amount of  $\text{O}_2^-$  anion formed. This latter effect could occur either through NOS2-dependent  $\text{O}_2^-$  production in this system or the inactivation of MnSOD by  $\text{ONOO}^-$ .<sup>141</sup>

Both good and bad aspects of NO were revealed in a model of viral myocarditis when L-NAME was used to treat mice with viral myocarditis.<sup>142</sup> Mice were infected with coxsackievirus

B3 in the presence of increasing doses of L-NAME. At the highest dose of L-NAME, there was decreased mouse survival. At a low dose, however, L-NAME improved survival, and the severity of heart failure and extent of myocardial necrosis. The exact mechanism that determines the “optimal” NO concentration remains to be determined. Interestingly, as discussed previously, stretch-induced myocyte apoptosis was inhibited by the addition of an NO donor.<sup>94</sup> Coincident with the decrease in apoptosis was a decrease in the level of  $\text{O}_2^-$ . There are several potential mechanisms for this beneficial effect of NO. At low levels, NO can reduce apoptosis by inhibiting specific enzymes in the programmed cell death pathway.<sup>131</sup> Another possibility is that the NO donor decreased production of mitochondrial ROS production. As mentioned previously, NO decreases mitochondrial respiration and myocardial oxygen consumption and thus indirectly controls the rate of ROS production.<sup>130</sup>

## SUMMARY

Oxidative and nitrosative stress are elevated systemically and in the myocardium of patients with chronic myocardial failure. The cause of increased ROS in this setting is still incompletely understood, but is clearly multifactorial including increased production of ROS due to increased metabolic activity, stimulated production by mechanical strain, neurohormonal activation, inflammatory cytokines, and decreased antioxidant activity. Based on both in vitro and in vivo studies, it appears likely that increases in oxidative and nitrosative stress contribute to the ventricular remodeling and contractile dysfunction in the failing heart.

Oxidative stress has many effects on myocardial structure and function. It is clear that oxidative stress can trigger a range of responses in myocytes in vitro, and that similar responses may occur in vivo in situations leading to myocardial dysfunction. As in other tissues, oxidative stress can stimulate both growth and death of cells. The mechanism by which various ROS activate cell signaling pathways remains an area of active investigation and promises to offer new therapeutic targets for pharmacological antioxidants.

There remain many unanswered questions about the role of oxidative stress in myocardial failure. In addition, the results of applying preclinical observations to develop therapeutic strategies for patients with heart failure have been disappointing. Further work is clearly needed. In developing therapeutic strategies targeted specifically at oxidative stress, we will need to understand in more detail (1) the relative contributions of decreased antioxidant activity versus increased formation of ROS; (2) the situations in which oxidative and/or nitrosative stress contribute to the pathogenesis of myocardial dysfunction in vivo; (3) the precise ROS involved; and (4) the optimal place in ROS cascades to intervene to prevent adverse effects of ROS on myocardial structure and function. Advances in our understanding of antioxidant enzymes and the technology for manipulation of these genes, and the development of animal models for acute and chronic myocardial injury, are likely to provide new insight into the potential therapeutic value of antioxidants in the treatment and prevention of myocardial dysfunction.

## Alterations in Ventricular Function: Systolic Heart Failure

David A. Kass

Systolic cardiac depression is a hallmark of many patients with heart failure. It reflects a fundamental weakness of the pump and thus its inability to deliver sufficient cardiac output at an adequate mean arterial pressure. The failing heart often exhibits both major decrements in resting systolic function and also limitations of systolic reserve required for individuals to perform normal activities of daily living and exercise. The underlying mechanisms for systolic dysfunction are numerous, ranging from posttranslational changes in myofilament proteins depressing force development and calcium interaction, depressed calcium cycling (see Chapter 3) into and out of the sarcoplasmic reticulum, altered ion channel function, mitochondrial and metabolism abnormalities,

molecular and structural remodeling including cell death (see Chapter 6) and loss, and altered membrane receptor signaling<sup>1-3</sup> (Figure 13-1). In addition, interactions between the myocytes and the vasculature are providing sufficient nutrients and matching angiogenesis to organomegaly is considered important for maintaining function.<sup>4,5</sup> Lastly, there is tight communication between the myocyte and the matrix environment, involving key signaling in both directions that alters the collagen weave and activates molecular cascades in the muscle cells.<sup>6</sup>

Direct demonstration of abnormal myocyte function in failing hearts has been achieved using isolated myocytes where sarcomere shortening is generally measured in unloaded cells, and muscle preparations where developed force and length are both measured. Intact and chemically membrane-disrupted (skinned) preparations are used, the latter to assess changes in myofilament calcium dependence. Results of these studies obtained in a variety of experimental models of heart failure and human disease are discussed elsewhere in Chapter 3. In intact hearts, the quantitation and analysis of systolic dysfunction is more complex, given the dependence of most measures on the complex structure of the chamber, and on ambient loading conditions that are imposed on the heart and often abnormal themselves in the heart failure state. For example, the most common measure—ejection fraction—is determined not only by the properties of the muscle wall, but also by chamber remodeling, and by the stresses imposed by the arterial system and volume loading from the venous circuit.

The ambiguities associated with many common assessments of chamber systolic function are not solely of academic interest because they may themselves have contributed to a disappointing history of efforts to improve systolic function in the failing heart. Ejection fraction is neither very specific nor particularly sensitive to changes in underlying contractile function.<sup>7</sup> Thus dosing pharmaceuticals to achieve a given change in EF may risk biasing trials toward testing higher doses of medications that ultimately prove disappointing. Furthermore, classification of heart failure based on a parameter such as EF may introduce ambiguities. The interpretation of an EF less than 30% in an NYHA class I patient following a myocardial infarction is quite different from that of an individual with class III symptoms associated with dilated cardiomyopathy. Both EF declines largely reflect chamber remodeling dilation that increases the end-diastolic volume despite a relatively preserved stroke volume. However, in one instance, infarct remodeling dominates this decline and the residual myocardium could be quite normal and capable of providing adequate cardiac reserve. In the other example, the myopathy is diffuse, and there is little

reserve capacity. These two situations may look similar when assessed by conventional parameters such as blood pressure, cardiac output, or EF, yet be very different when viewed by alternative approaches such as pressure-volume relations.<sup>8</sup>

The purpose of this chapter is to review the current understanding of the mechanisms underlying systolic depression in cardiac failure, the relationship between properties determined by the muscle and dysfunction assessed in the intact chamber, methods to assess systolic function and the impact of various loading influences on these measures, the interaction of systolic function with the arterial loading system or ventricular/arterial interaction, new approaches to therapeutic targeting of systolic dysfunction, and the contribution of contractile synchrony and effects of artificial resynchronization on systolic function.

### CELLULAR AND MOLECULAR DETERMINANTS: A VIEW FROM 30,000 FEET

The greatest advances in understanding of heart failure over the past decade have come from new understandings of the molecular signaling involved and its impact on cellular and organ level pathobiology. Full justice to this topic is a book in its own right, but the reader is referred to Chapter 2 for a more comprehensive review in the current volume. Here, I want to provide a brief overview of key components that are involved with systolic failure. Systolic force generation starts at the level of the actin-myosin cross-bridge, which in turn is coupled via structural proteins to the surface membrane to transduce deformation to net chamber contraction. The contractile proteins themselves can play a central role in systolic depression both because of genetic mutations that depress the function of the molecular motors,<sup>9-11</sup> and by posttranslational changes particularly of regulatory thin filament proteins that modify contraction.<sup>12,13</sup> Mouse models recapitulating myosin mutations associated with dilated cardiomyopathy have shown weakened power generation and general loss of function in the actin-myosin cross-bridge.<sup>14</sup> Mutations in myosin-binding protein C (MyBP-C) are the most common cause of hypertrophic cardiomyopathy, though

**FIGURE 13-1** Contributors to systolic dysfunction include a wide range of abnormalities and are not solely reflective of myocyte contractile protein and calcium handling changes. Other major factors include a substantial array of altered molecular signaling influencing myocyte mechanics and EC coupling, electro-physiological changes that alter conduction and regional contraction, cell survival signaling, extracellular matrix and vascular abnormalities, mitochondrial function, and bioenergetics. Importantly, these are increasingly being targeted as therapeutic options with the goal not only to suppress maladaptive heart failure remodeling, but to improve systolic performance in a way that is beneficial in the long term.

loss of function of this protein results in a dilated myopathy associated with a reduced capacity of the muscle to sustain systolic contraction.<sup>15,16</sup> Equally important are changes in regulatory proteins that can involve phosphorylation, redox modulation, or enzymatic cleavage (see Chapter 3). Growing evidence supports changes in troponin I and troponin T phosphorylation in mediating systolic dysfunction in the failing heart because of a loss of normal muscle response to calcium. TnI can also undergo proteolytic truncation associated with the protease calpain. This was first reported in post-ischemic stunned myocardium, and by itself induces a heart with depressed systolic function and chamber dilation.<sup>17</sup> The MyBP-C phosphorylation state also impacts systolic function, and reduction in this phosphorylation in animal models and human heart failure may also contribute to depressed sarcomere function.<sup>16,18</sup> Indeed, while long ignored, the role of the sarcomere as a signal-transduction target of various kinases and phosphatases, and for other posttranslational changes because of oxidation, nitration, nitrosylation, and glycosylation, is a rapidly evolving area of research.

Critical changes also occur in proteins linking the myofibrils to the cell membrane to transduce shortening. Abnormalities in muscle limb protein (MLP), sarcoglycan, desmin, dystrophin, vinculin, metavinculin, laminin, and lamin have been coupled to a dilated depressed ventricle in humans.<sup>19-24</sup> Murine models involving these proteins have been associated with morphogenic abnormalities, congenital defects, and dilated cardiomyopathy.

Systolic dysfunction is also critically dependent upon abnormalities of calcium homeostasis (see Chapter 3).<sup>25-27</sup> Changes have been described from the level of the voltage-gated calcium channels and sodium-calcium exchanger to altered expression and function of major sarcoplasmic reticular proteins involved with calcium cycling, such as phospholamban and the SR calcium ATPase. Changes in these and related proteins are presently being explored as potential new therapeutic avenues. A related signaling pathway is the phosphatase inhibitor I-1, which inactivates PP1.<sup>28</sup> I-1 levels decline in heart failure, enhancing PP1 dephosphorylation of phospholamban, contributing to systolic depression. Protein kinase A activates I-1, and downregulation of this pathway in

the failing heart may contribute further to this change. Opposite effects occur from protein kinase Ca (e.g., inhibition of I-1, leading to greater dephosphorylation (inactivation) of phospholamban), and upregulation of PKGα in heart failure is another proposed mechanism of systolic dysfunction.<sup>29</sup> Changes in calcium release from the SR have been associated with sustained upregulation of calcium-calmodulin-dependent kinase IIδ and PKA-dependent phosphorylation of the ryanodine receptor to enhance SR calcium leak.<sup>30-32</sup> While prior focus was on the expression levels of key calcium handling proteins, more and more evidence also supports key changes at the posttranslational level involving more than just phosphorylation.<sup>33-35</sup> This has tightly linked excitation-contraction coupling with signal transduction mediated by stress response kinases, phosphatases, and transcription factors. These and other changes in calcium handling are reviewed more extensively elsewhere in this volume.

The molecular signaling changes observed in the failing heart are vast, and as more and more are manipulated by selective genetic gain- and loss-of-function studies, their role in contractile failure is being revealed. As a result, new approaches to treat depressed pump function are now focusing beneath the cell surface to more directly target enzyme and/or gene transcription programs. This work has been recently reviewed elsewhere and will not be further discussed in this chapter.<sup>1,2,36</sup> Two other major contributors to systolic dysfunction that are gaining more and more attention are energetics and metabolism. Abnormalities in mitochondrial function and ATP generation and changes in glucose and fatty acid metabolism in the failing heart have been mechanistically linked to chamber dilation and dysfunction.<sup>37</sup> A prime example is the impact of reduced levels of the transcription factor PGC1α, which serves as a master energy regulator.<sup>38,39</sup>

Systolic dysfunction also evolves from changes outside the myocyte, in particular from coupling of the cell to the extracellular matrix and to the vascular supply that surrounds each muscle cell. Signaling via proteins such as p53<sup>4</sup> and various growth factor signaling cascades<sup>5</sup> are thought to be important in maintaining adequate vasculogenesis to match the increased work and hypertrophy demands in the failing heart, and inadequacy of this matching results in depressed performance.

Recent studies have found changes in heart function can occur by gene-targeted manipulation of fibroblasts and vice versa—indicating strong signaling communication between systems.<sup>40</sup> Chamber dilation accompanying the activation of metalloproteinases (see Chapter 5), with its consequent remodeling of the extracellular matrix, is a highly active process and potentially contributes to systolic dysfunction.<sup>41–43</sup> Myocyte geometry is also altered (longer-thinner) and likely plays a role as well.<sup>44</sup> Reversal of chronic dilation and myocyte geometric remodeling with a variety of therapies is often coupled with improved systolic function, though precise cause and effect cannot be determined from these studies.<sup>45–47</sup>

## MEASURING SYSTOLIC FUNCTION BY PRESSURE-VOLUME RELATIONS

There are many ways that systolic dysfunction can be assessed, the most common being declines in fractional shortening or ejection fraction. Other parameters include the ability of the heart to generate maximal power (pressure  $\times$  flow), the peak rate of rise of pressure, the capacity of the heart to generate external work for a given end-diastolic volume, etc.<sup>7</sup> Development of such analytic measures was a major focus of physiology in the late 1970s and early 1980s, and the tools that ultimately evolved have largely remained the same since. Among the more powerful tools was the depiction of cardiac contractility by means of simultaneous pressure-volume loops and relations.<sup>48</sup> This framework is now widely used in genetically engineered mouse studies<sup>49</sup> and other experimental models, and has been used to define the pathophysiology of human heart failure and therapy advances for several decades.<sup>50,51</sup>

A central concept that initially drove the analysis of cardiac systolic function by pressure-volume relations was the notion that cardiac systolic muscle activation involved a change in its material properties that are reflected by its stiffness. As the contractile proteins interact, the muscle changes from a relaxed state in diastole to one that is quite stiff due to development of actively bound cross-bridges and compression of the intrasarcomeric molecular spring titin. If one fixed cardiac trabecula is at a constant length, this stiffening was directly proportional to changes in force during contraction. Stiffness can also be measured in an intact heart, but now the property was reflected in chamber elastance (inverse of compliance). This concept and its measurement are shown in Figure 13-2, A. Cardiac contraction is depicted by simultaneous plots of left ventricular chamber volume (x-axis) and pressure (y-axis), with each cycle generating a pressure-volume loop (loops advance counterclockwise with contraction). The set of lines fanning from the origin reflect isochrones (i.e., connecting points on each of the loops at the same instantaneous time in contraction). The slope of each line defines the elastance (stiffness) of the chamber at that time, and this gradually rises from diastole to peak systole.

The time course of stiffening or time-varying elastance from human subjects with normal and diseased hearts is shown in Figure 13-2, B. Data are shown normalized to the maximal stiffness generated and time to achieve this (adjusting for differences in underlying contractility and heart rate). The curves define the activation and deactivation process in the heart, and the striking similarity among disease conditions suggests this is a fundamental property of the ventricle.<sup>52</sup> Stiffening occurs rapidly at the start of systole during the period of isovolumetric contraction. When the aortic valve opens, the rate of ongoing stiffening during ejection declines but remains largely at a constant rate until the peak is achieved. As a result, about 60% of net cardiac muscle stiffening develops during the process of blood ejection. This time course is remarkably similar between species as

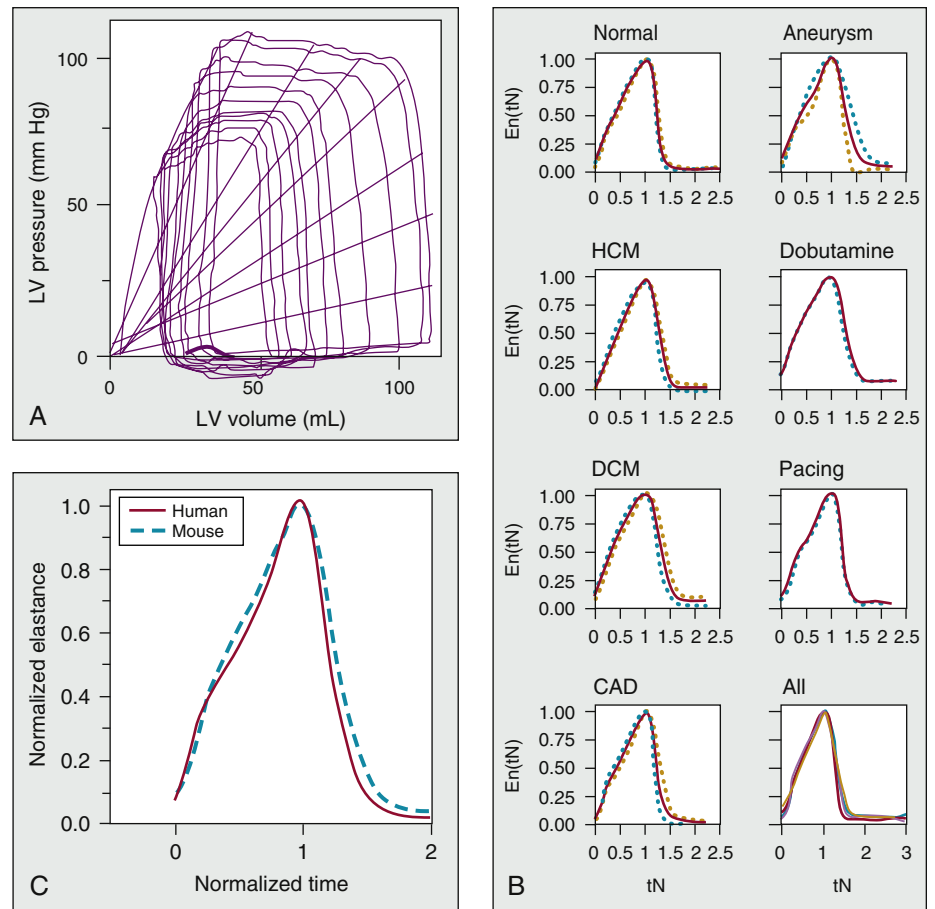

well—as shown in Figure 13-2, C, with a comparison between human and the mouse data.<sup>53</sup> The data were again normalized to peak magnitude and time scale adjusting for the tenfold difference in heart rate and greater than a 4000-fold difference in heart weight between species. This time course appears to depend in part on the function of MyBP-C, a protein linking myosin to actin and titin, and thought to control rates of cross-bridge attachment/detachment. Genetic MyBP-C deletion models are accompanied by an abbreviation of this time course during ejection, so that most all of stiffening occurs during the isovolumic period.<sup>16,54</sup>

Pressure-volume analysis began being applied to human studies of heart disease in the mid-1980s, and has more recently become widely used for assessing cardiac systolic function in basic science investigations conducted in genetically engineered mice.<sup>49,55,56</sup> By this approach, one can derive more accurate and specific quantitations of heart performance than are possible from standard clinical data. Figure 13-3, A, displays human left ventricular (LV) pressure-volume data obtained at rest and during transient reduction of preload volume. The bold loop represents the resting condition, and the labeling depicts end-diastole (point A), isovolumic contraction (point A-B), opening of the aortic valve (point B), ejection (point B-C), isovolumic relaxation (point C-D), opening of the mitral valve and initiation of diastolic filling (point D), and diastolic filling (point D-A). The loop width is stroke volume, the ratio of width to end-diastolic volume is EF, the loop area is external (or stroke) work. When ventricular preload is acutely reduced in the heart, there is a decline in stroke volume and peak pressures per beat (Frank-Starling dependence). Indeed, this set of data could be easily used to generate Frank-Starling curves plotting end-diastolic pressure versus stroke volume or cardiac output. However, one can also determine the ventricular end-systolic elastance by determining the slope of the upper left boundary defined by these loops. This occurs near end-ejection, and the locus of points comprises the end-systolic PV relation (ESPVR). The position and slope of this relation are used to define systolic function. An important feature of the ESPVR was its relative insensitivity to changes in cardiac vascular loading—either preload (sarcomere length or chamber volume) or afterload (force applied to the muscle or cell, or arterial impedance load). In work first conducted in the 1970s and 1980s, isolated and intact hearts demonstrated the utility of the ESPVR for this purpose.<sup>48,57</sup>

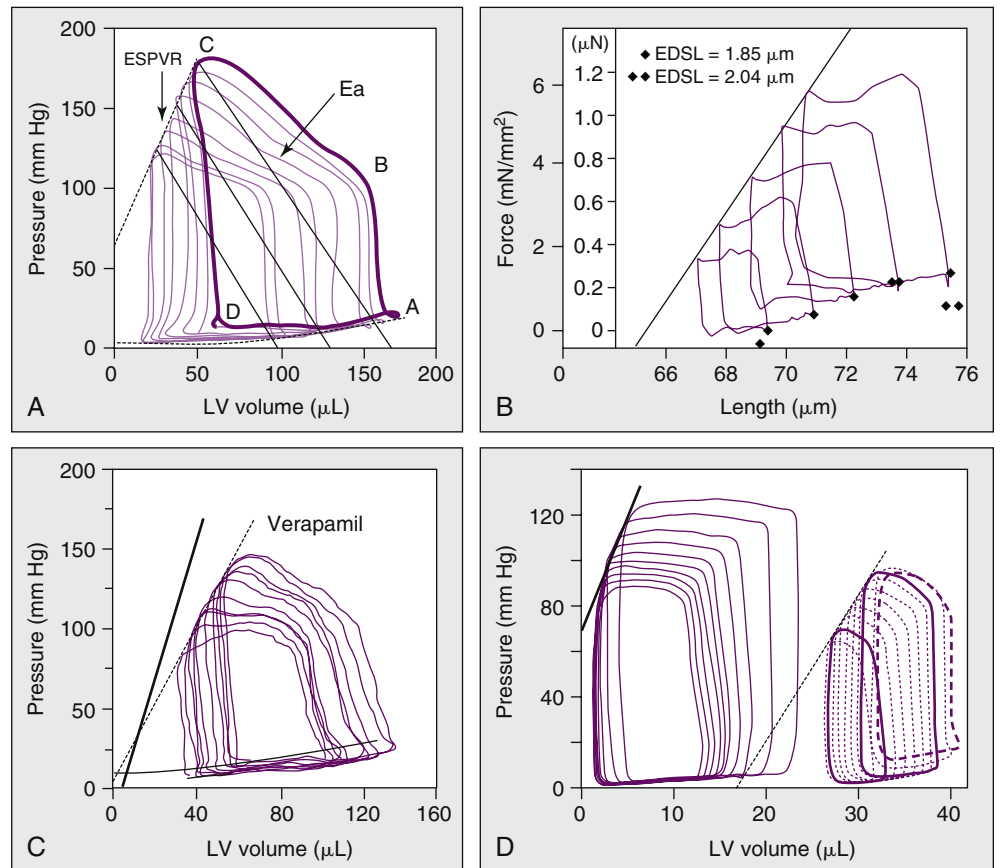

Figure 13-3, A, also shows another line—slanted upward from right to left as a diagonal across each pressure-volume loop. This depicts what is termed the “effective arterial elastance (Ea)”.<sup>58–60</sup> Ea is a lumped parameter that indicates the net arterial load on the ventricle. Ea equals the ratio of end-systolic pressure/stroke volume. It is not synonymous with vascular stiffness; indeed its numeric value is mostly influenced by mean arterial resistance ( $Ea = ESP/SV \times R \times HR$ ). However, it serves as a useful metric of net ventricular loading—both mean and pulsatile—and importantly, unlike arterial pressure, the fact that these diagonal lines shown in Figure 13-3, A, are all parallel indicates that the value of this ratio is not varying despite the change in cardiac preload. Studies have used this parameter in conjunction with PV relations and Ees to determine mechanisms of drug effects (e.g., inodilator drugs such as OPC-18790,<sup>61</sup> population studies of heart disease and aging.<sup>62,63</sup>

Recent studies have demonstrated very similar behavior in intact single myocytes, in which individual cell sarcomere length and force are measured and controlled to generate pseudo force-length loops.<sup>64</sup> As shown in Figure 13-3, B, a picture very similar to that first generated in intact canine and human hearts is revealed, again with a linear peak elastance defined by the upper left corners of these data. As shown in this study, myocyte end-systolic stiffening is also rather

**FIGURE 13-2** Time-varying elastance in the human heart. **A**, Generation of time-varying elastance from multiple cardiac cycles. Linear spokes represent isochrones (connecting points on each loop at the same time), and their slope reflects the instantaneous chamber stiffness or elastance achieved at that point in the cycle (Elastance = Pressure/(Volume- $V_0$ )). The time-varying elastance is the change in this slope throughout the heartbeat (E(t)). **B**, E(t) curves shown normalized to both peak amplitude and time to peak amplitude from human subjects with varying cardiac diseases or with normal hearts. There is remarkable consistency in their shape as shown by the superimposed data (lower right). **C**, The E(t) waveform is also similar across mammalian species. Shown here is superimposed mean data for normal human and mouse hearts. (B, From Senzaki H, Chen CH, Kass DA. Single beat estimation of end-systolic pressure-volume relation in humans: a new method with the potential for non-invasive application. *Circulation* 1996;94:2497-2506.)<sup>52</sup>

**FIGURE 13-3** Pressure-volume (PV) analysis of cardiac function. **A**, Resting (dark solid loop) PV loop and multiple cycles derived by varying preload in human subjects. Cycle loop moves counterclockwise; (a) end diastole, (b) ejection onset, (c) end systole, (d) onset of diastolic filling. The upper left corners of the set of loops define the end-systolic PV relation, a valuable measure of chamber systolic function. The group of diagonal lines drawn within several of the beats denotes the arterial load, indexed by  $E_a$  = end-systolic pressure/stroke volume. This is similar to the decline in preload (arterial impedance is not significantly preload dependent), and thus useful as a measure of ventricular afterload. **B**, Similar types of data but obtained from a single cardiac myocyte, with force and sarcomere length measured and controlled to generate “loops.” As in the intact heart, there is a time-varying stiffening of the myocyte, and a linear end-systolic force-length dependence. Thus this behavior is intrinsic to the cardiac myocyte. **C**, Prototypical response of ESPVR to a change in contractile state. Data shown are due to acute IV verapamil injection in human subjects.<sup>65</sup> **D**, Example of ventricular remodeling and cardiac systolic depression with sustained cardiac failure. Data are generated using a mouse model of disease (MKK3 overexpression, activating p38 MAP kinase). (B, With permission from Iribe G, Helmes M, Kohl P. Force-length relations in isolated intact cardiomyocytes subjected to dynamic changes in mechanical load. *Am J Physiol Heart Circ Physiol* 2007;292:H1487-H1497.)<sup>64</sup>

insensitive to the load applied before or during the contraction—so this is not simply a chamber-level phenomenon. This figure also shows a sort of Ea index (end-systolic force/end-diastolic sarcomere length), which as in the human example, reflects the effective load imposed by the servo system, and is also independent of preload (i.e., lines are parallel).

Changes in contractility are easily assessed by PV relations. This is shown by the prototype example in Figure 13-3, C, in a patient exposed to the calcium channel blocker verapamil. Indeed, the study from which this figure was taken was among the first to show the impact of this calcium channel blocker on human heart contractility, and the decline in maximal elastance (ESPVR slope shifts downward) was clear.<sup>65</sup> In this acute setting, the rise in end-systolic volume is not accompanied by a change in cardiac geometry. However, changes in systolic function typical of chronic heart failure involve both. An example of this behavior is shown from a study in mice,<sup>66</sup> with the control data shown in solid and heart failure data with dotted lines Figure 13-3, D. The latter display both a depression of the maximal stiffening generated by the heart, but also a marked rightward shift of the entire set of data that indicates structural remodeling/dilation. Patients with diffuse dilated cardiomyopathy typically display both components. In contrast, patients with infarctions that may result in chamber remodeling and a decline in ejection fraction but have otherwise relatively normal function of the residual wall will often display similar peak elastance but only the rightward shift of the relationship. Geometric formulas can be used to convert pressure-volume into myofibrillar stress and strain<sup>67</sup> to provide a less geometry-dependent parameter (i.e., assess muscle rather than chamber stiffness).

It is important to note that while acute changes in end-systolic elastance can reflect changes in contractile function, this property is not entirely load independent and may not itself be the primary reflector of systolic change. The entire relation linking end-systolic pressure-volume points (ESPVR) is rarely linear in the intact heart, but more often concave downward to the volume axis, giving rise to the frequently observed negative volume-axis intercept of the ESPVR.<sup>68</sup> This means higher slopes (end-systolic elastance, Ees) at reduced pressure loads, but lower ones at higher loads. Inotropic stimulation often enhances pressures and lowers systolic volumes, and this can result in apparent minimal change in Ees despite considerable leftward shifting of the relation itself. Secondly, systolic stiffening does not solely reflect contractile properties of the ventricle, but is also influenced by structural (matrix, fibroblasts, etc.) and vascular components in the myocardial wall. Chronic elevation of Ees does not automatically reflect enhanced contractile function of myocytes, but can be due to stiffening from other components of the heart. One likely example of such changes is the elevation of Ees that is observed with normal aging.<sup>63,69</sup> In this instance, other parameters of systolic function display negligible change, and the age-dependent Ees increase correlates with that in diastolic passive stiffness. Cardiac remodeling associated with chamber hypertrophy is also coupled with a rise in ventricular end-systolic elastance.<sup>70</sup> Whether this reflects intrinsic myocyte properties as opposed to more integrated myocardial/chamber properties remains unclear.

## BEAT-TO-BEAT REGULATION OF SYSTOLIC FUNCTION

Three mechanisms are thought to regulate beat-to-beat systolic performance of cardiac muscle. These can be defined by the dependencies of systolic force on sarcomere length, beat frequency, and tension during systole. In the intact heart, these translate to chamber end-diastolic volume, afterload impedance or wall stress, and heart rate. All impact integrated systolic function.

The dependence of force generation upon muscle length is thought to be principally related to changes in myofilament calcium sensitivity as a function of sarcomere length.<sup>71,72</sup> While thick-thin filament overlap differences may contribute in skeletal muscle, this model is not easily reconciled with the operational sarcomere lengths (1.8 to 2.2  $\mu\text{m}$ ) of the cardiomyocyte. Despite nearly 30 years of investigations, a precise mechanism to explain length-dependent changes in calcium sensitivity remains elusive. Studies have hypothesized that greater length resulted in a reciprocal reduction of lattice spacing between the thick and thin filaments, which would be coupled to a greater probability of forming a tightly bound cross-bridge to increase force.<sup>73-75</sup> However, studies employing x-ray diffraction analysis of lattice spacing and models with mutations of thin-filament regulation have not supported this hypothesis.<sup>76</sup> Other studies have coupled length-dependent force generation to muscle LIM protein located in the z-disk<sup>77</sup> and to the molecular spring titin,<sup>78</sup> though precise mechanisms remain unknown. This further impacts our understanding of how and/or whether this fundamental mechanism is altered in heart failure.

Another rapid modulator of muscle function that impacts myofilament cycling rates and the cooperative generation of cross-bridges is shortening velocity. Maximal unloaded shortening velocity ( $V_{\text{max}}$ ) depends on internal cellular viscous loading likely related to macromolecules such as titin<sup>53</sup> and microfilaments. Cooper et al reported that myocyte microtubular content profoundly alters unloaded cell shortening (the typical measure of systolic function in the cell, and myocyte correlate of  $V_{\text{max}}$ ), which may contribute to diminished shortening in hypertrophied failing myocytes.<sup>79-81</sup> Cell shape may impact on cytoskeletal linkage proteins<sup>82</sup> (e.g., as  $\alpha$ -actinin) to alter cross-bridge behavior as a function of shortening velocity. Another controller of actin-myosin interaction rate is MyBP-C, and in particular the phosphorylation state of this protein. In its nonphosphorylated state, early rates of cardiac contraction are slowed (revealed by lower early rates of pressure rise,  $dP/dt_{\text{max}}$ ), whereas increasing phosphorylation of the protein appears to be a major factor in why  $dP/dt_{\text{max}}$  is augmented by sympathetic stimulation.

The relation between force and velocity can be transformed at the whole chamber into velocity of fiber shortening ( $V_{\text{cf}}$ )—wall stress relations.<sup>83,84</sup> This is analogous to the midportion of a muscle force-velocity curve and has been employed to assess cardiac contractile performance in many studies. The relation is preload and heart rate dependent<sup>85</sup> (systolic stress is preload dependent in the intact heart). The integral under a force-velocity relation is power (force  $\times$  velocity), and for the intact chamber, power is the product of pressure and flow. While preload dependent, maximal power can be adjusted to take this into account, and the resulting index provides a useful and fairly specific measure of systolic function.<sup>86,87</sup>

In isolated muscle, sudden perturbations of systolic load during a twitch also influence the subsequently developed tension and rate of relaxation.<sup>88,89</sup> Load reduction and ensuing more rapid myofiber shortening leads to cross-bridge detachment and magnifies internal viscous effects to lower force.<sup>90-92</sup> In the intact ventricle, such load changes often occur in late systole because of enhanced systolic wave reflections. Wave reflections result from a rapid return of the pulse to the central vasculature due to artery stiffening,<sup>93</sup> and this can be particularly important in the elderly and in failing hearts.<sup>94-96</sup> Sudden changes in systolic load are also observed regionally in hearts rendered discoordinate because of ischemia/infarction or abnormal electrical conduction. This mechanical stretch applied in midsystole can negatively impact myocyte systolic performance.

Lastly, systolic function of cardiac muscle is very sensitive to acute changes in beat frequency. This results from enhanced  $\text{Ca}^{2+}$  entry into the myocyte and enhanced uptake into the sarcoplasmic reticulum, which becomes available

**FIGURE 13-4** Force-frequency dependence in intact heart from conscious dog with and without cardiac failure (DCM). The relation is depressed in cardiac failure. Furthermore, there is an augmentation in the dependence with  $\beta$ -adrenergic stimulation provided by dobutamine in normal hearts, consistent with an interaction between enhanced calcium cycling dependent on PKA signaling, and because of the beat frequency. This too is blunted by cardiac failure. Data are the percent increase relative to the resting heart rate. (From Senzaki H, Isoda T, Paolucci N, et al. Improved mechanoenergetics and cardiac rest and reserve function of in vivo failing heart by calcium sensitizer EMD-57033. *Circulation* 2000;101:1040-1048.)<sup>102</sup>

for release to increase contraction strength.<sup>97</sup> There is a large body of evidence supporting an important role of this mechanism in regulating systolic function in intact mammals and man.<sup>51,98,99</sup> Demonstration of the effect in in vivo hearts requires an analysis of systolic function that is itself insensitive to the loading changes occurring with altered heart rate. Using end-systolic elastance or other load-insensitive parameters, intact canine, human, and murine hearts have been shown to display a force-frequency dependence. In humans, contractile function rises nearly twofold for a heart rate increase from 70 to 150  $\text{min}^{-1}$ .<sup>51</sup> This is markedly blunted in cardiac failure, a primary manifestation of abnormal SR calcium handling (see Chapter 3).<sup>27,100,101</sup> Figure 13-4 shows this phenomenon in an intact canine model of dilated heart failure.<sup>102</sup> Two sets of relations are depicted: at rest and after stimulation with the  $\beta$ -adrenergic agonist dobutamine. Contractility was indexed by end-systolic elastance based on pressure-volume analysis. The normal positive dependence of contractility on beat frequency and its marked depression in heart failure are shown by the solid circles and triangles, respectively. When stimulated by dobutamine, the contractility-frequency dependence is further augmented in the normal hearts, but very little altered in the failing ones. In controls, the enhanced phosphorylation of the L-type  $\text{Ca}^{2+}$  channel and phospholamban (among other proteins) results in greater calcium loading, and this in turn is further augmented by frequency to provide even more trigger  $\text{Ca}^{2+}$  to the myofilaments.<sup>103</sup> However, in failing hearts, there is downregulation of the  $\beta$ -adrenergic pathway and SR function, so the augmentation is minimal.<sup>22,80,104</sup> During exercise, both stimulation pathways are relevant, and these data highlight the impact of their loss on contractile reserve in the failing heart.

## INTEGRATIVE MEASURES OF SYSTOLIC FUNCTION

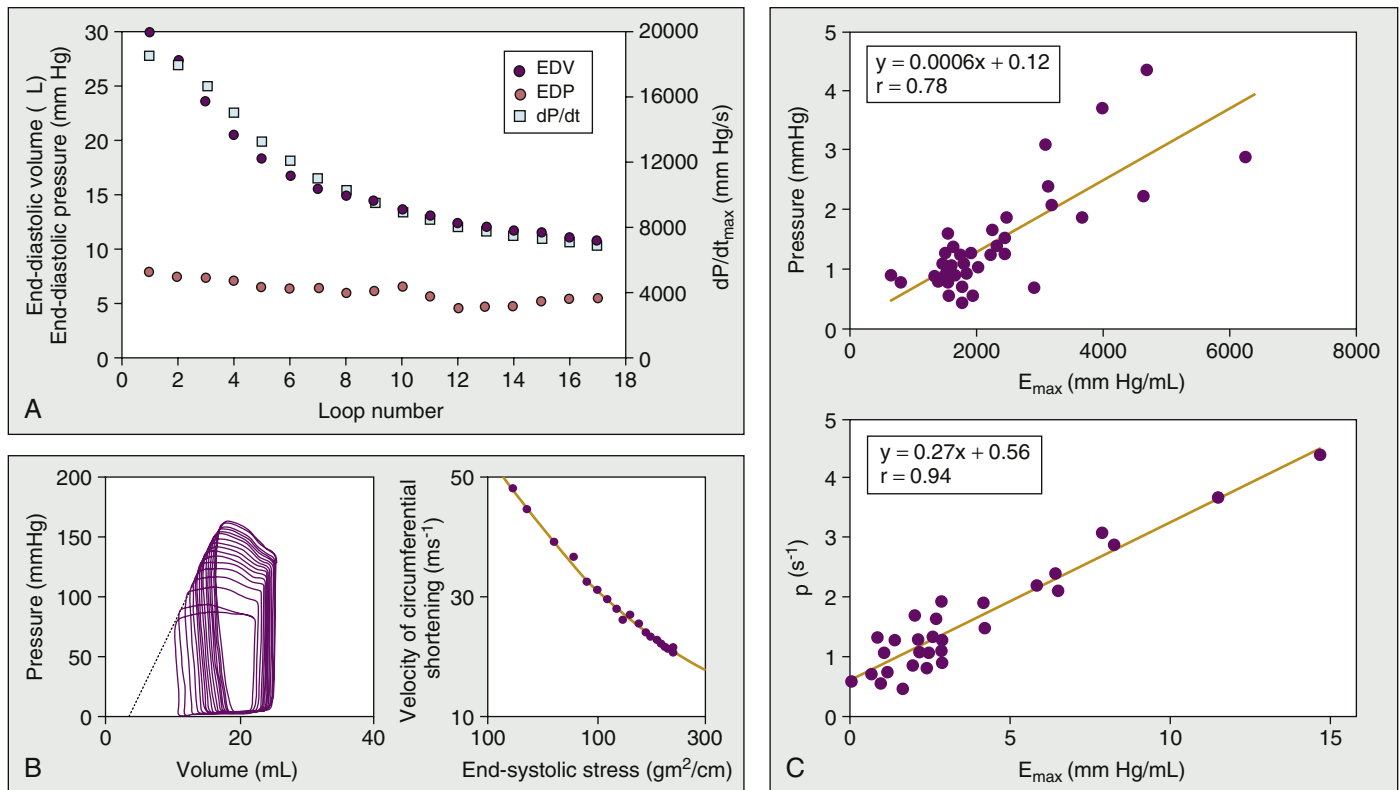

At the chamber level, analysis of systolic function generally relies on indirect measures of performance. As already noted, the ability to stiffen assessed by end-systolic elastance is very useful but not commonly employed. Many other parameters

have been developed and these can be conveniently divided into early isovolumic phase parameters (e.g.,  $dP/dt_{\text{max}}$ , isovolumic contraction time); early midsystolic-ejection phase parameters (e.g., maximal ventricular power, acceleration, velocity of shortening-stress relations); late systolic parameters (e.g., stroke work indexes, end-systolic elastance). To some extent, all are influenced by both intrinsic systolic properties of the sarcomere, by organization of the sarcomere, and muscle fiber into the chamber, and by the loading system to which they are coupled. In this regard, there is no direct measure of contractility—a term which itself remains conceptual rather than physical. Furthermore, not all measures of chamber function index the identical behavior, and there can be striking discrepancies among the measurements. This is less true of human myopathy, but it has been observed in various mouse models with gene targeting.

Chamber systole begins with isovolumetric contraction, and the earliest behavior that can be quantified is the rate of pressure (or force) development by the heart. The maximal rate ( $dP/dt_{\text{max}}$ ) is among the most common and historically used measures of chamber systolic function. Ironically, it is also among the least directly related to physiologically relevant function—i.e., amount of net ejection or work provided during ejection.  $dP/dt_{\text{max}}$  is depressed in cardiomyopathy, and the absolute level observed in human heart failure is remarkably consistent, being near 1000 mm Hg/sec (normal being near 1600 to 1800 mm Hg/sec). As an index, it has witnessed a remarkable renaissance with the dominance of genetically engineered murine models for studying cardiovascular pathophysiology.

$dP/dt_{\text{max}}$  is preload dependent in humans and other mammals. This is particularly so in the mouse where changes of even 2 to 3 microliters of end-diastolic volume (10% decline) often result in marked reductions in  $dP/dt_{\text{max}}$ .<sup>105,106</sup> (Figure 13-5, A). This preload dependence can be minimized by regression of multiple values of  $dP/dt_{\text{max}}$  versus end-diastolic volume from variably loaded cardiac cycles.<sup>107</sup> While the latter is rarely clinically used because of its complexity, it remains a valuable method to minimize load sensitivity of  $dP/dt_{\text{max}}$ .  $dP/dt_{\text{max}}$  is also influenced by internal loading (such as reflected by microfilaments, perhaps titin), extracellular matrix loading (i.e., edema, inflammation, collagen dysregulation), phosphorylation state of MyBP-C, myocyte contractile depression, and the coordination of the chamber walls. Discordinate contraction associated with bundle branch block depresses  $dP/dt_{\text{max}}$  acutely even without any primary change in contractile function of the myocytes. This is due to the effect of having part of the wall contract early against a still relaxed portion of the chamber. Pressure rises more slowly as force from one side is dissipated into stretch of the other. Acute increases in  $dP/dt_{\text{max}}$  associated with biventricular stimulation of a dyssynchronous failing heart occur within a single beat, and similarly do not indicate a change in underlying contractile function, but rather chamber-level consequences of improved coordination of wall contraction.<sup>108,109</sup>

Early midsystolic-ejection parameters are widely used to assess systolic function of the intact chamber. These have been briefly mentioned in the previous section with respect to their derivation from force-velocity behavior. The two most common approaches are preload-adjusted maximal power and stress/rate adjusted circumferential shortening velocity. Maximal power can be assessed from noninvasive-derived aortic flow and arterial pressure data.<sup>110</sup> The latter is measured by tonometer or other methods for noninvasive waveform reconstruction.<sup>111</sup> Once obtained, maximal power is normalized to chamber end-diastolic volume (or EDV<sup>2</sup> in dilated failing hearts) to obtain a parameter with relatively little preload and afterload dependence.<sup>86,87</sup> Importantly, its reliability depends upon a relatively high (i.e., arterial level) of afterload and the lack of notable changes in afterload. This limitation can preclude use in the right heart, for example.<sup>112</sup>

**FIGURE 13-5** Indices of contractility. **A**, Preload dependence of  $dP/dt_{max}$  in mouse. Data are from a series of cycles at varying preload; beat 0 is at high preload, beat 17 at low preload. While there is negligible change in end-diastolic pressure for these cycles, preload volume (EDV) declines in direct correlation with  $dP/dt_{max}$ . **B**, Generation of velocity of shortening-stress relations from pressure-volume data at varying afterloads. **C**, Correlation of myocardial strain rate ( $\epsilon \dot{p}$ ; y-axis) to chamber  $dP/dt_{max}$  and maximal systolic elastance ( $E_{max}$ ). (With permission from Greenberg NL, Firstenberg MS, Castro PL, et al. Doppler-derived myocardial systolic strain rate is a strong index of left ventricular contractility. *Circulation* 2002;105:99-105.)<sup>114</sup>

This index has been applied in a number of clinical studies, including during exercise testing where it displays far more marked sensitivity to contractile function than does the EF.<sup>89</sup> Its advantage in this regard is its simplicity and capacity to be recorded during stress procedures such as exercise. Low levels of reserve power have been shown to predict adverse outcome (need for urgent transplantation or death) in heart failure patients.<sup>113</sup>

The rate-adjusted Vcf-stress relation has also been widely used to index systolic function in animal and human studies. An example of this relation derived from a sequence of variably afterloaded contractions is shown in Figure 13-5, B. Vcf is obtained derived from 2-D midchamber level, short axis echocardiographic data, while stress is estimated based on cuff (or invasively measured pressures) and chamber long and short axis dimensions and thickness. While many studies have reported individual patient data as a single point—with stress plot on the x-axis, and Vcf on the y-axis, the actual dependence of each variable on the other depends on chamber preload as well. Furthermore, the stress estimates generally assume homogeneous material wall properties, and may not discriminate between myocyte and extracellular matrix-dependent geometric changes. Still, among parameters, this is relatively unique in attempting to incorporate chamber geometry and derive myocardial properties from chamber-level data.

More recent developments in tissue Doppler imaging have given rise to strain and strain-rate analysis.<sup>114-117</sup> These approaches essentially quantify myocardial wall motion—much as might be derived from MRI-based tissue tagging methods.<sup>118</sup> Actual regional stresses remain unknown, and can influence measured strains and strain rates. Nonetheless, strain rate has been found to correlate with  $dP/dt_{max}$  and indices derived from end-systolic pressure-volume relations

(Figure 13-5, C),<sup>114</sup> and clearly is prominently influenced by chamber systolic function. In genetic models of hypertrophic cardiomyopathy, tissue Doppler has been used to define early abnormalities of chamber function that precede the evolution of cardiac hypertrophy.<sup>119</sup> Tissue Doppler has been widely employed to index contractile discoordination in patients with cardiac failure and conduction delay.<sup>120,121</sup>

The most commonly used late-systolic parameter is ejection fraction—the chamber translation of fractional shortening. EF is easy to measure, its value is independent of calibration errors of absolute volume assessment (i.e., it is dimensionless), it is moderately sensitive to inotropic changes, and it is rather insensitive to pure alterations in cardiac filling volume (preload). However, EF is highly dependent on arterial impedance load, and so declines can easily reflect both a decrement in underlying myocyte function and reduced shortening because of higher load. This is particularly important in failing hearts where the depressed heart is coupled to high arterial impedance. EF is also heart rate dependent, declining at faster rates. This effect is likely important to the enhancement of EF with chronic  $\beta$ -blockade therapy—in addition to any primary augmentation of underlying systolic function because of the treatment. EF also reflects chamber dilation/remodeling since the denominator (EDV) is increased in such ventricles while the numerator is often near normal range short of severe cardiodepression or restrictive filling. In this sense, the pathophysiological implication of an acutely reduced EF, which is a strong correlate of other parameters—such as end-systolic elastance or even  $dP/dt_{max}$ —may not be present if the mechanism involves chronic chamber remodeling and myocyte depression. Lastly, EF is not the most sensitive parameter to contractile change.<sup>7</sup>

The Frank-Starling curve remains an important element of systolic analysis, but it is limited because of strong afterload

and heart rate dependencies, and ambiguities associated with the use of end-diastolic filling pressure to index preload. The latter is discussed in more detail in a subsequent section. An alternative approach has been to assess relations between cardiac stroke work and preload (preload-recruitable stroke work)—the latter indexed by end-diastolic volume rather than pressure.<sup>122</sup> Stroke work is less afterload dependent than stroke volume, as it incorporates pressure as well, and the SW-EDV relation is both linear and minimally influenced by chamber load, while still reflecting systolic function. A further advantage is that it has units of force, and is therefore chamber-size independent. Values for the slope of this relation are typically between 75 and 90 mm Hg and are very similar between rat, mouse, canine, porcine, and human, and other mammalian ventricles. As with Ees, methods to assess PRSW from single-beat data and noninvasive analysis have been reported.<sup>123</sup>

## IMPACT OF PERICARDIAL LOADING ON SYSTOLIC FUNCTION

The intact chamber not only imposes complex filling and ejection loads on the heart during systole to modify its function, but also contains the chambers by a pericardial membrane that couples filling pressures from one chamber to another. While the influence of the pericardium on cardiac diastolic function is long well recognized, its impact on systolic function relations such as the Frank-Starling relation, has remained underappreciated.<sup>124</sup> However, studies have shown the importance of this interaction for generating the apparent descending limb of the Frank-Starling relation. While increased length and thus sarcomere stretch over  $2.4 \mu$  has been suggested to explain a decline in force generated by skeletal muscle because of reduced myofilament overlap, cardiac tissue cannot be stretched to this extent because of the extracellular matrix and cytoskeletal membrane proteins within the myocyte. Yet, cardiac output is often observed to decline with high preloads or conversely increase with preload reduction—leading to the presumption of operation along a descending limb in the failure state. The more likely explanation has been demonstrated by Tyberg et al, and relates to the importance of transmural pressure (not absolute chamber pressure) for determining the net stretch on the heart.<sup>125,126</sup> In patients with DCM, increased end-diastolic pressures may not be associated with elevated transmural pressure because of concomitantly higher extrinsic (pericardial) pressures. With a reduction in preload volume, actual transmural distending pressures have been shown to rise, so that real myocyte stretch is actually increasing rather than declining with the fall in EDP. Plots of CO versus EDP can appear biphasic, whereas those between CO and EDV are linear. This affects any relationship in which filling pressure is used to index the level of chamber preload.

## VENTRICULAR-ARTERIAL INTERACTION

An important feature of systolic cardiac function is its dependence on the arterial loading system into which the heart must eject. The interaction of both components ultimately determines systemic variables such as cardiac output, ejection fraction, external work, mechanical efficiency, systolic pressure, and so forth. Depending upon the matching of cardiac and vascular properties, these variables can be optimized or compromised. Furthermore, the interaction of properties of the systolic ventricle and vascular system play a critical role in determining the cardiac output and blood pressure response of the heart failure patient to commonly used therapeutic interventions, such as vasodilators, diuretics, and

inotropes. This interaction is also important for understanding the syndrome of cardiac failure with preserved EF. Thus it is useful to both understand how coupling can be studied and the implications for ventricular-arterial interaction in cardiac failure.

Among the more successful methods used to assess ventricular-vascular coupling is the pressure-volume framework, employing the ESPVR and a parameter used to index arterial properties, termed the “effective arterial elastance” ( $E_a$ ).<sup>59,60,127</sup> As already noted in Figure 13-2,  $E_a$  is the ratio of end-systolic pressure to stroke volume and its value is dominated by mean arterial resistance and heart rate. It is also influenced by reactive loading properties of the arterial system—i.e., characteristic impedance and arterial compliance. In this description, coupling is generally expressed by a ratio of  $E_a$  to the ESPVR slope (i.e.,  $E_a/E_{es}$ ) (Figure 13-6, A).

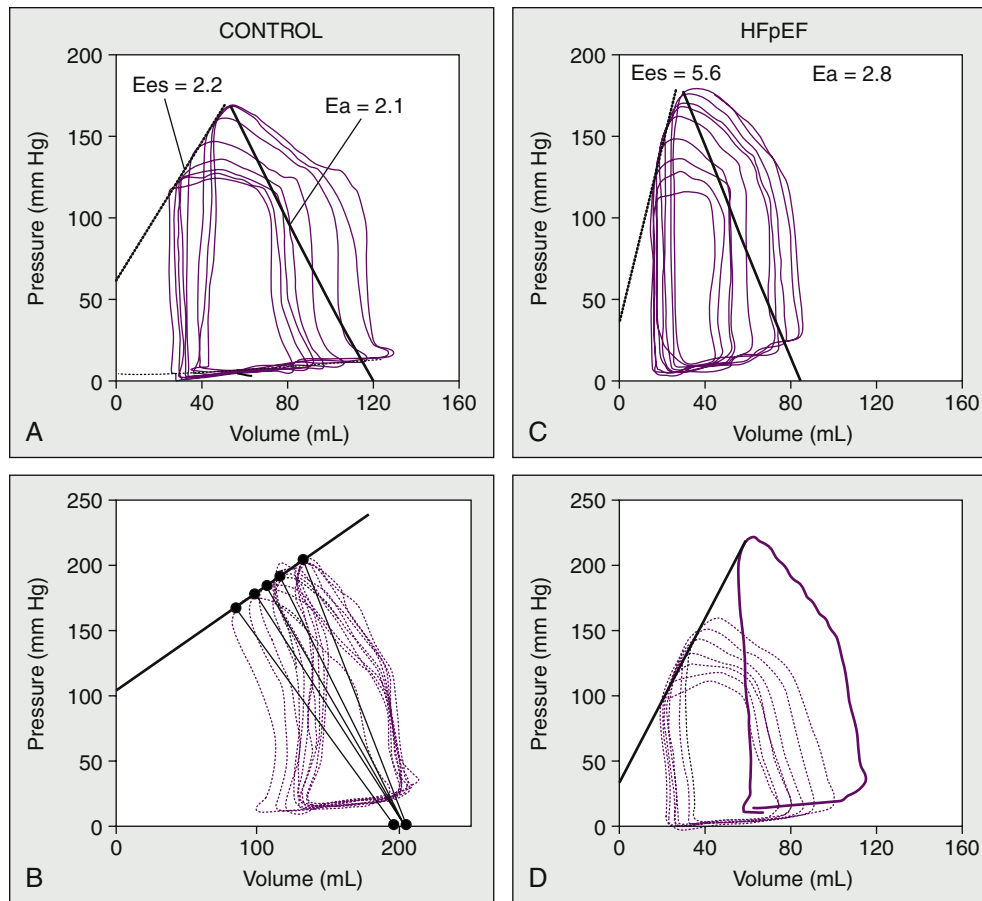

Prior studies have shown that when the  $E_a/E_{es}$  ratio is near 1.0, there is optimal transfer of energy or work (power or SW) from the heart to arterial system.<sup>128-130</sup> Data obtained in isolated canine hearts first displayed this dependence for both work and cardiac efficiency, and subsequent studies have confirmed similar relations in intact hearts.<sup>131</sup> In normal individuals, the coupling ratio is near 0.8, matching ventricular and arterial properties to yield maximal power, efficiency, and external work. Importantly, this optimally matched condition is maintained during exercise,<sup>129</sup> and may relate to an evolutionary process designed to maintain a minimum relative cardiac/body size ratio.<sup>132</sup>

Work or power output is far from optimal, however, in hearts with depressed contractility and increased vascular loading, typical of the failing dilated heart. Asanoi et al<sup>133</sup> first reported coupling ratios in patients with normal, moderate, and severely depressed LV function. In the patients with reduced EF, ratios rise greater than 3 (Figure 13-6, B), consistent with a decline in cardiac efficiency and effective external work. This relation between heart and artery can play a major role in determining whether a given pharmaceutical intervention will improve chamber function or diminish it. In this example, the DCM patient with high systemic resistance was administered a bolus of intravenous nitroglycerin. The resulting beat-to-beat decline in arterial resistance led to an increase in the width of the pressure-volume loop—increasing stroke volume (and thus cardiac output) by nearly 50% and improving power output. The same intervention in a normal subject would largely reduce work or power output if basal coupling were already near optimal.

Coupling between heart and arterial effective elastance is also central to understanding whether a given intervention is more likely to enhance cardiac output or alternatively influence blood pressures. Dilated cardiomyopathy is typically associated with a depressed maximal chamber elastance (reduced  $E_{es}$ ), and this predicts that for any decline in arterial afterload, the heart will behave principally as a pressure source, providing similar levels of systemic pressure by varying markedly the ejected volume. In contrast, hearts with increased systolic elastance—often observed in hypertrophied syndromes—behave as flow sources, providing similar levels of cardiac output despite changes in afterload (or preload), but inducing marked changes in systemic pressures. The latter behavior may play an important role in the syndrome of cardiac failure with preserved EF, often referred to as “diastolic heart failure.”

Nearly half of patients over age 65 who present with symptoms of cardiac failure have apparent preservation of ejection fraction (HFpEF). While this is generally taken to mean that systolic function is itself normal, that is not necessarily the case. Differences in wall geometry, such as smaller cavities with ventricular hypertrophy, might otherwise lead to elevated EFs so that an EF of 50% is not in fact normal. Another feature of these individuals is that they can develop

**FIGURE 13-6** Ventricular-arterial coupling. **A**, Resting human PV relations showing normal matching between end-systolic elastance (Ees) and arterial elastance (Ea). This matching results in optimized cardiac function and efficiency. **B**, In contrast, the failing heart displays a reduced Ees (depressed systolic function) and elevated Ea (higher afterload) yielding a decline in chamber power output and metabolic efficiency. **C**, Subject with CHF and preserved ejection fraction. In such patients, Ees appears elevated over age/pressure-matched controls, and is accompanied by a further rise in arterial elastance because of reduced vascular distensibility. **D**, This pathophysiology can explain marked increases in blood pressure and cardiac workload with exertion. Shown here is an example subject during isometric hand exercise, with the resting PV loops (dotted lines) and stress-response loop as solid. (From Kawaguchi M, Hay I, Fetis B, et al. Combined ventricular systolic and arterial stiffening in patients with heart failure and preserved ejection fraction: implications for systolic and diastolic reserve limitations. *Circulation* 2003;107:714-720.)<sup>134</sup>

exacerbated ventricular end-systolic stiffening—beyond that observed with aging and/or hypertension. Studies in asymptomatic patients of varying ages have revealed that Ees (chamber systolic stiffening) increases in tandem with age-related arterial stiffening.<sup>69</sup> This was recently demonstrated in a large population study, and intriguingly women developed greater age-dependent increases in both Ees and Ea than men.<sup>63</sup> This may play a contributing role to the higher prevalence of HFpEF in elderly women. Combined increases in Ees and Ea can potentially influence the pressures developed by the heart in response to changes in chamber filling and arterial load. Increased ventricular systolic stiffening means that even small increases or decreases in preload will amplify into marked changes in systolic pressure. This may contribute to the increased diuretic and orthostatic sensitivity in the elderly. In patients with cardiac failure symptoms yet EF greater than 50%, such stiffening is increased further<sup>134</sup>—though studies have shown this is likely related to the presence of systolic hypertension and ventricular hypertrophy, both common features of HFpEF patients.<sup>62,135</sup> The hemodynamic consequence is greater sensitivity of the heart to altered loading, exacerbated blood pressure lability, and potentially increased energetic demand to deliver reserve cardiac output.<sup>134</sup>

Figure 13-6, C, shows an example of a patient with heart failure and preserved EF, demonstrating the greatly increased stiffening of the ventricle during systole, and increased vascular stiffening. EF may appear normal in such individuals, but this does not necessarily mean that systolic function is normal and the problem resides solely with diastolic abnormalities. Increased chamber systolic stiffening and its impact on ventricular-arterial interaction may play an important pathophysiological role in symptom lability and hypertension and dysfunction during stress (Figure 13-6, D). Such abnormalities are consistent with the paroxysmal nature of

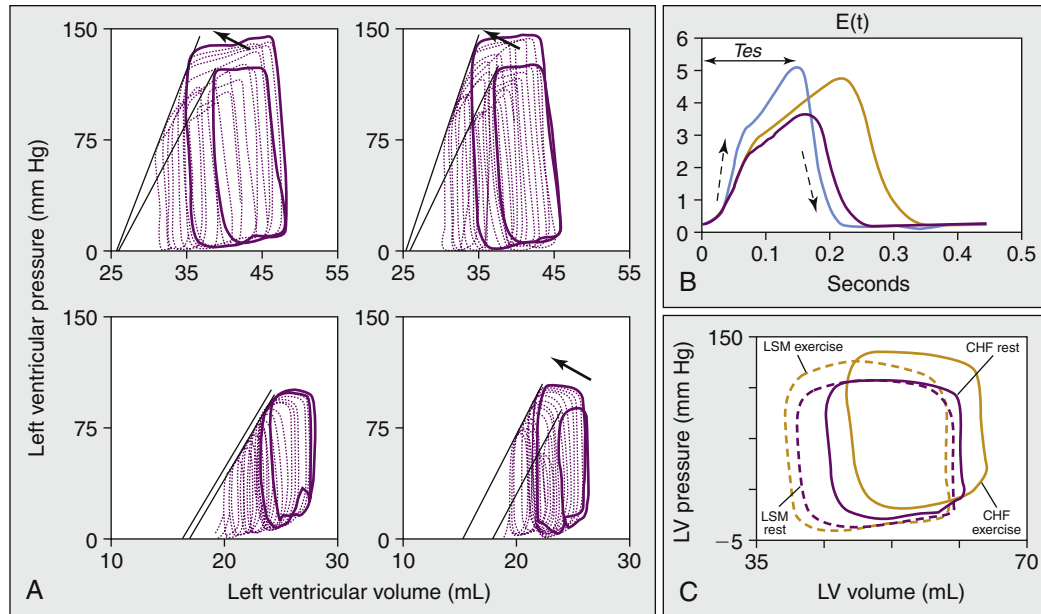

this disorder, frequent flash pulmonary edema associated with hypertension, and sensitivity to preload reduction (diuretics). In this respect, enhanced (as with the more traditional diminished) systolic elastance may be similarly a valuable target for therapeutic intervention.

## TREATING SYSTOLIC DYSFUNCTION

Despite a defining role in heart failure for many patients, the amelioration of systolic dysfunction by pharmacotherapy has generally not been a successful therapeutic approach to date (see Chapter 43). The oldest known treatment is digitalis, though the magnitude of contractile stimulation achieved by this agent in human heart failure remains essentially unknown, and it is not potent in experimental models. Acute human treatment has relied on cAMP generation either by stimulation of the  $\beta$ -adrenergic pathway (e.g., dobutamine) or by inhibition of a primary cAMP-targeted phosphodiesterase type 3 (e.g., milrinone). Both ultimately stimulate contraction by cAMP-dependent activation of protein kinase A, targeting calcium handling, and myofilament proteins among other key pathways involved with contractile force generation. Central to this effect is the rise in intracellular calcium involved with contraction. While useful for acute modulation, chronic effects are detrimental,<sup>136</sup> and this has stymied efforts in developing approaches targeting this signaling.<sup>137</sup>

The generation of genetically engineered mice revealed that stimulation of components of this signaling pathway can yield beneficial rather than worsening heart failure outcome. Many of these are now targets for early clinical trials using small molecules and/or gene transfer approaches. One prime example is inhibition of the  $\beta$ -receptor kinase GRK-2, which phosphorylates the  $\beta$ -receptor to suppress signaling and

**FIGURE 13-7** **A**, Influence of dobutamine versus a calcium sensitizer (EMD-57033) on contractile reserve in normal versus failing hearts. In the control hearts, both drugs stimulate contractility almost identically, reflected by the leftward shift and slope increase in the end-systolic PV relation. However, in failing hearts, the response to dobutamine is markedly depressed, whereas the contractile response to the sensitizer is maintained, consistent with its more distal site of action, directly on the myofilaments. **B**, Comparison of the time course of ventricular stiffening (Elastance,  $E(t)$ ) as modified by a prototypical  $\beta$ -adrenergic stimulation mechanism coupled with PKA phosphorylation, versus a direct calcium sensitizer. The adrenergic agonist stimulates the kinetics of contraction both early and late in systole, abbreviating the time to peak elastance. In contrast, the sensitizer prolongs systole (greater sensitivity to trigger calcium), leaving the kinetics of early contraction and often relaxation little altered.  $dp/dt_{max}$  is not a useful index of changes with such drugs. **C**, Enhanced effectiveness from a calcium sensitizer on systolic function during exercise in a canine model of heart failure. The improvement in function reflected by the left shift of the PV loop and increase in its width (stroke volume) is modest in the heart when at rest, but potentiated during exercise. (A, From Senzaki H, Isoda T, Paolucci N, et al. Improved mechanoenergetics and cardiac reserve function of in vivo failing heart by calcium sensitizer EMD-57033. *Circulation* 2000;101:1040–1048.)<sup>102</sup> C, With permission from Tachibana H, Cheng HJ, Ukai T, et al. Levosimendan improves LV systolic and diastolic performance at rest and during exercise after heart failure. *Am J Physiol Heart Circ Physiol* 2005;288:H914–H922.)<sup>146</sup>

stimulate receptor internalization and desensitization (see Chapter 10). Mutant versions of GRK-2 that lack this kinase activity have been successful in ameliorating various models of heart failure and myocardial infarction in rodents and large mammals.<sup>138–140</sup> Another approach is to target adenylate cyclase. Blockade of AC type 5 is associated with reduced heart failure<sup>141</sup> and improved longevity,<sup>142</sup> though upregulation of the other major isoform, AC-6, has been suggested to ameliorate heart failure.<sup>143</sup> This suggests where and how cAMP is generated is critical and compartmentation of this signaling central to the nature of long-term effects. Many have focused on deficiencies of the SR proteins such as phospholamban, SERCA2a, and I-1. Gene and/or small molecule clinical studies are under development to test whether upregulation of SERCA2a, for example, can ameliorate systolic dysfunction as it has clearly done in many different experimental animal models.<sup>144,145</sup>

Another major area of investigation is in agents that more directly influence the myofilaments to augment their response to a given level of trigger calcium. Referred to as a group as calcium sensitizers, this class can have many different targeting mechanisms such as modifying calcium–troponin C interactions or enhancing the myofibrillar ATPase. The theoretical advantages of such agents are several. First, by bypassing the adrenergic system and directly targeting the myofilaments, these drugs should work similarly well in failing as in normal hearts. An example of this behavior is shown in Figure 13-7, A. In this canine model of heart failure,<sup>102</sup> the dobutamine-stimulated contraction is markedly depressed compared with the normal control response, whereas the response to the sensitizer, EMD-57033, which is thought to target the myosin head to enhance actin attachment, is similar in both conditions. Another feature of these agents is that they can enhance contraction without requiring the level of energy use needed when this occurs via a cAMP-dependent pathway. In

this sense, pure sensitizers should improve cardiac efficiency. Third, their effects on the kinetics of contraction differ from traditional cAMP/PKA-dependent inotropes, in that they have little impact on early rates of contraction (i.e.,  $dp/dt_{max}$ ), but more impact on later phases of systolic function such as net work, end-systolic elastance, and the duration of systole. This is demonstrated in Figure 13-7, B, where three time-varying elastance curves are depicted. Dobutamine results in a more rapid contraction, earlier peaking systolic stiffness, and faster relaxation. In contrast, the  $Ca^{2+}$ -sensitizer results in little change in the early phase of contraction, and a similar overall rate of stiffening that occurs for a longer period so net ejection is also enhanced. Relaxation rates can be similar or even improved based on the ability of the heart to eject to smaller end-systolic volumes. Lastly, increasing calcium sensitivity means that the impact on systolic function will itself vary with the stimulation of calcium by other means. At rest, calcium activation is reduced, so the impact on rest contractility of the sensitizer is commensurately less. However, with exercise, there are the catecholamine- and heart rate-triggered changes that, even while depressed, can still enhance the calcium trigger and thus increase the inotropic effect from the sensitizer. This was nicely demonstrated in an animal study of levosimendan<sup>146</sup> (Figure 13-7, C). Improved systolic function assessed by pressure-volume relations was modest at rest, but much more marked in animals doing treadmill exercise.

The most widely studied example of a sensitizer is levosimendan, which was originally identified by its interaction with TnC and capacity to enhance myofilament force generation. However, the drug was also shown active in inhibiting phosphodiesterase type 3, which explained some calcium dependence to its effects, and ATP-sensitive potassium channels that likely contributed to systemic vasodilation.<sup>147</sup> While early trials were promising, larger controlled studies were ultimately disappointing.<sup>148</sup> Still, this was not a real test of

a pure sensitizer given the complex pharmacology involved. However, several other agents are currently being tested, including a small molecule identified to specifically enhance myofibrillar ATPase activity. This drug, CK-1827452, prolongs the systolic period due to its increasing the probability that a cross-bridge will be in the active force generating state. It does not appear to have any effects on cAMP signaling, and in this sense is one of the purer “calcium-sensitizing” types of agents yet tested. Clinical trials are ongoing.

Another novel approach to increasing contractility is the use of nitroxyl, or HNO. This is the reduced form of nitric oxide coupled with hydrogen; the molecule does not dissociate but attaches to thiolates (negatively charged cysteine residues) on selective proteins to modify function.<sup>149</sup> The reaction is reversibly controlled by redox state, in that enhancing reducing conditions can block it. HNO was first reported to enhance systolic function in the intact canine heart model of HF,<sup>150</sup> and later cellular mechanisms for this effect have been revealed.<sup>151</sup> These include demonstration of direct enhancement of SR calcium uptake and release, the former related to HNO targeting of C674 in SERCA2a,<sup>152</sup> and at one or more of the three cysteines in phospholamban.<sup>153</sup> Targeting of the ryanodine receptor is likely, though sites have yet to be identified, and there is also a calcium-sensitizing effect that may be linked to HNO modification of regulatory thin filament proteins. A clinical HNO donor has been developed and trials were initiated in class II HF patients in the spring of 2009.

## SYSTOLIC EFFECTS OF DYSSYNCHRONY AND RESYNCHRONIZATION (see Chapter 47)

It has long been recognized that discoordinate cardiac contraction itself reduces the systolic performance of the chamber, and recent developments in therapies to resynchronize contraction have shown this to be a valuable target for heart failure treatment. Conduction disease at or above the AV node affects chronotropic competence and effective preload (and left atrial pressure). Both short and excessively long AV delays reduce net LV filling.<sup>154,155</sup> Infranodal conduction delay—commonly left-bundle-branch block pattern—induces discoordinate contraction.<sup>156–159</sup> DCM hearts with an LBBB display early activation of the septal wall with lateral prestretch, followed by markedly delayed lateral contraction with late systolic septal stretch towards the RV. Cardiac discoordination induced by LBBB or RV-ventricular pacing depresses systolic function, increasing the end-systolic volumes at a given pressure (rightward shift of the ESPVR), prolongs isovolumic relaxation,<sup>160–162</sup> and has been coupled to widening of the QRS complex.<sup>160</sup> The energetic cost of contraction can increase relative to effective ejection, since the early activated myocardium largely serves to increase preload on the lateral freewall, leaving the late activated wall to contract at higher stress while wasting work by stretching the more pliable early activated territory.<sup>163–165</sup>

These mechanical effects of discoordinate contraction were the impetus for studies performed over a decade ago in which right ventricular preexcitation was used to treat patients with hypertrophic cardiomyopathy.<sup>166,167</sup> In such patients, the institution of RV-apex pacing increased end-systolic volumes, reduced  $dp/dt_{max}$  and other parameters of systolic function, and importantly in this instance, resulted in a decline in hyperdynamic ejection and thus cavity obliteration. Importantly, this effect did not depend upon the presence of asymmetric hypertrophy—but was equally if not more effective in individuals with concentric LVH associated with symptoms of cardiac failure.<sup>168</sup> Figure 13-8, A, shows time tracings of apical segmental volume in a patient with hypertrophic cardiomyopathy subjected to acute RV apical pacing. While the original data shows normal timing of systolic

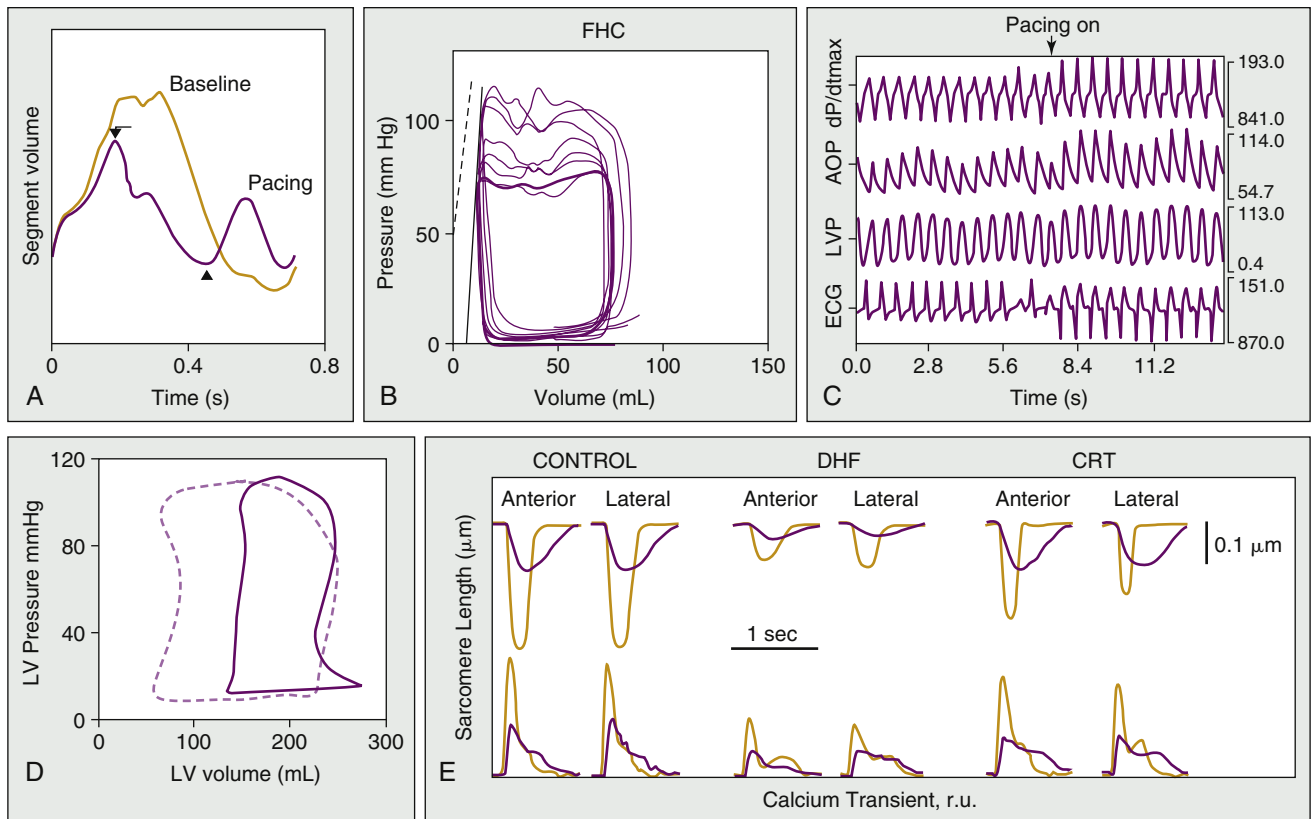

ejection and filling, pacing results in premature contraction of the region, and later restretch (volume increase) during what is still systole. This results in residual systolic volume that is not ejected, so the end-systolic pressure-volume relation shifts rightward (Figure 13-8, B).<sup>70</sup> Though therapeutic generation of ventricular dyssynchrony in patients with septal hypertrophy proved less effective,<sup>169,170</sup> a small single center trial in patients with concentric LVH and cavity obliteration found benefits from reducing systolic contraction in these patients. Larger controlled trials remain to be done.

The opposite approach—resynchronizing the left ventricle in individuals with dilated cardiomyopathy and underlying basal discoordination because of LBBB—has been far more successful (see Chapter 47). Biventricular pacing or univentricular pacing of the LV lateral free wall can re-coordinate contraction and is associated with systolic improvement.<sup>108,171–174</sup> Cardiac resynchronization effects manifest abruptly (i.e., rise in  $dp/dt_{max}$ , arterial pressures, Figure 13-8, C) occurring within one beat, and reflects increased systolic flow. Chronic noninvasive studies have reported sustained responses of similar magnitude.<sup>121</sup> When displayed as ventricular pressure-volume loops, the resynchronization effect can be observed as a widening of the loop (enhanced stroke volume), decline in end-systolic wall stress (left shift of end-systolic pressure-volume point), and increased cardiac work (Figure 13-8, D). Importantly, the latter is not accompanied by increases in energy consumption, but to the contrary, has been shown to be coupled with a decline in energy consumption.<sup>175</sup> Studies have not demonstrated major effects on diastolic function to date, although there is evidence of reverse cardiac remodeling associated with this therapy.

These initial studies established improvement in systolic function at the chamber level—though as with acute dyssynchrony, this was likely because of the coordination of contraction and not a primary improvement in myocardial contractility. However, chronic cardiac resynchronization therapy (CRT) treatment enhances rest and systolic reserve function, demonstrated by exercise capacity and the response to heart rate increases. This has been coupled to upregulation in myocardial gene expression of  $\beta_1$ -receptors, phospholamban, and SERCA2a, among other genes.<sup>176–178</sup> Importantly, new data from animal models of dyssynchronous heart failure and CRT have revealed improvement in resting myocyte function and adrenergic reserve. Myocyte results from canine hearts subjected to either 6 weeks of rapid atrial pacing in the presence of an LBBB (dyssynchronous failure, DHF) or 3 weeks of this mode followed by 3 weeks of rapid biventricular pacing (CRT) are displayed in Figure 13-8, E.<sup>179</sup> Both models involve 6 weeks of tachypacing, a method to induce dilated failure in the mammalian heart. While some global improvement with CRT was observed, overall both groups displayed features of dilated HF. Yet, while rest and isoproterenol stimulated sarcomere shortening and calcium transient responses in DHF myocytes were markedly depressed compared with normal controls, myocytes from CRT hearts displayed improvement in both variables under both conditions. The mechanisms include reversal of several abnormalities of cycling regulation, and improved adrenergic signaling cascades including enhanced suppression of inhibitory G protein and upregulation of both  $\beta_1$ -receptor-coupled signaling and adenylate cyclase activation.<sup>179</sup> Thus chronic CRT does enhance systolic function by means of direct myocyte benefits.

## SUMMARY

Advances in noninvasive techniques and availability of new systems to directly assess cardiac systolic function have advanced our understanding of its presence and modification by therapies in advanced heart failure. While central to much

**FIGURE 13-8** Impact of ventricular discoordination and resynchronization on chamber systolic function. **A**, Dyssynchrony generated by RV apex pacing in the human ventricle. The resting condition (baseline) shows normal timing of systolic ejection. With pacing, the region shortens early, and then is stretched late in what would be late systole for the rest of the heart. **B**, Global PV relations during RV apex pacing are compared with sinus controls (dashed ESPVRs). Dyssynchrony results in an increase in end-systolic volume and decline in effective systolic function. **C**, Resynchronization in human DCM patient with LBBB. Acute LV or biventricular stimulation enhances  $dP/dt_{\text{max}}$ , aortic pulse pressure, and peak LV pressure as shown after the arrow. This effect is very rapid. **D**, Example of pressure-volume loops with resynchronization (dashed line) showing enhanced function, increased loop width, and left shift of end-systolic point. This is the opposite to the effect observed in panel B with dyssynchrony induced by RV-apex pacing. **E**, Myocyte contraction and calcium transients from hearts with normal function, dyssynchronous heart failure (DHF), or resynchronized heart failure (CRT). DHF cells display markedly depressed function and transients with and without isoproterenol (ISO) stimulation, whereas CRT cells display improvements in both responses. These changes were demonstrated from cells obtained from both the early- and late-activated region. (B, From Pak PH, Maughan WL, Baughman KL, et al. Mechanism of acute mechanical benefit from VDD pacing in hypertrophied heart: similarity of responses in hypertrophic cardiomyopathy and hypertensive heart disease. *Circulation* 1998;98:242–248.)<sup>70</sup>

heart failure, systolic dysfunction has been difficult to therapeutically target thus far. However, the recent data on cardiac resynchronization showing chronic benefits on function, symptoms, and mortality for a therapy that improves systolic function, suggests optimism is warranted. Understanding how CRT functions at the molecular level may indeed provide insights into heart failure in general. Similar optimism stems from recent successes in animal models where systolic function is enhanced by gene manipulation of signaling and/or calcium handling distal to the adrenergic receptor. After nearly 15 years of relative inactivity on the inotropy front, new trials now under way may change the way we view improving systole for the failing heart. As these approaches are developed, the assessment of systolic function and its response to therapy should again become an important focus for heart failure researchers and practitioners.

both SHF and DHF are extremely high; in patients with DHF rehospitalization rate for heart failure is 50% in 6 months, and annual mortality rate is 10% to 15%/year. (Detailed discussion of epidemiology of DHF can be found in Chapter 48).

Over the past 30 years, a multitude of randomized clinical trials (RCTs) in patients with SHF have demonstrated that a variety of pharmaceutical and device treatments have successfully lowered both morbidity and mortality in these patients. Unfortunately, the five RCTs that have examined a significant number of patients with DHF have failed to demonstrate efficacy of any management strategy.<sup>8-12</sup> (Detailed discussion of treatment of DHF can be found in Chapter 48).

The neutral results of the RCTs in DHF have left an enormous unmet need in at least half of all patients with chronic heart failure. Why have these RCTs failed to provide effective therapy? One possible reason may be that the mechanisms targeted by the therapies were not appropriate. If the underlying mechanisms causing the development of DHF differ from those that cause SHF, then it is likely that new management strategies must be developed that target mechanisms specific to patients with DHF. The purpose of this chapter is to describe the alterations in left ventricular and myocardial structure and function that occur in patients with DHF, define the mechanisms that underlie these functional abnormalities, and suggest how knowledge of these mechanisms can lead to the development of novel and effective treatments to correct diastolic dysfunction and decrease morbidity and mortality in patients with DHF.

Approximately half of all patients with chronic heart failure have a normal or near-normal (i.e., “preserved”) left ventricular ejection fraction (HFPEF).<sup>1-7</sup> Because the dominant abnormality present in patients with HFPEF is abnormal diastolic function, this clinical syndrome is called “diastolic heart failure” (DHF). By contrast, the dominant abnormality present in patients with heart failure and a reduced ejection fraction (HFREF) is abnormal systolic function. This clinical syndrome is called “systolic heart failure” (SHF). In the context of this chapter, we will use the terms SHF and DHF unless otherwise specified.

The demographic characteristics present in patients with DHF differ significantly from those with SHF. Patients with DHF are older, are more often female, more often have hypertensive heart disease, and less often have ischemic heart disease than patients with SHF.<sup>1-7</sup> Morbidity and mortality rates in

of which came from the Framingham Study<sup>13</sup> (Table 14-1). Defining the mechanisms that cause this clinical syndrome requires measurement of both systolic and diastolic function. When heart failure is accompanied by a dominant abnormality in diastolic function, this clinical syndrome is called DHF (or HFPEF). From a conceptual perspective, diastolic heart failure occurs when the ventricular chamber is unable to accept an adequate volume of blood during diastole, do this at normal diastolic pressures, and at volumes sufficient to maintain an appropriate stroke volume and do this both at rest and during exercise. The functional abnormalities that result in DHF include abnormal ventricular relaxation and filling, decreased left ventricular (LV) suction, and/or an increase in ventricular stiffness. Diastolic heart failure can produce symptoms that occur at rest (NYHA Class IV), symptoms that occur with less than ordinary physical activity (NYHA Class III), or symptoms that occur with ordinary physical activity (NYHA Class II).

*Diastolic dysfunction* refers to a condition in which abnormalities in mechanical function are present during diastole. Abnormalities in diastolic function can occur in the presence or absence of a clinical syndrome of heart failure and with normal or abnormal systolic function. Therefore, whereas diastolic dysfunction describes an abnormal mechanical property, diastolic heart failure describes a clinical syndrome. Conceptually, diastole encompasses the time period during which the myocardium loses its ability to generate force and shorten, and returns to an unstressed length and force. By extension, diastolic dysfunction occurs when these processes are prolonged, slowed, or incomplete. Whether this time period is defined using the classical concepts of Wiggers or the constructs of Brutsaert, the measurements that reflect changes in this normal function generally depend on the onset, rate, and extent of left ventricular pressure decline and filling, and the relationship between pressure and volume or stress and strain during the period of diastole.<sup>14</sup> Moreover, if diastolic function is truly normal, these measurements must remain normal both at rest and during the stress of a variable heart rate, stroke volume, end-diastolic volume, and blood pressure.

## DEFINITIONS

### Differentiating Diastolic Dysfunction from Diastolic Heart Failure

*Diastolic heart failure* is a clinical syndrome characterized by symptoms and signs of increased tissue/organ water, and decreased tissue/organ perfusion. Standardized criteria to diagnose heart failure have been developed, perhaps the best validated

TABLE 14–1 Diagnostic Criteria for Diastolic Congestive Heart Failure

Required Criteria

- 1. Clinical evidence of left heart failure  
Framingham\* or Boston criteria  
Plasma BNP and/or chest x-ray  
Cardiopulmonary exercise testing
- 2. Normal EF ( $\geq 50\%$ )
- 3. Exclude nonmyocardial disease

Confirmatory Evidence

- 1. LVH or concentric remodeling
- 2. Left atrial enlargement (in absence of AF)
- 3. Doppler or catheterization evidence of LV diastolic dysfunction

Major	Minor
PND or orthopnea	Ankle edema
JVD or venous pressure >16 mm Hg	Nocturnal cough
Rales or acute pulmonary edema	Exertional dyspnea
Cardiomegaly	Pleural effusion
Hepatojugular reflex	Vital capacity <2/3 normal
Circulation time >25 sec	Hepatomegaly
Response to treatment (weight loss >4.5 kg/5 days) bpm	Tachycardia >120 bpm

\*Framingham criteria: Two major or one major and two minor criteria must be present.

Heart Failure with a Preserved Ejection Fraction Versus Diastolic Heart Failure

HFPEF is a clinical syndrome characterized by symptoms and signs of heart failure, a preserved ejection fraction, and abnormal diastolic function. The term “preserved” EF refers to EFs that are normal or very near normal. “Normal” EF is a somewhat controversial notion. The average EF for a standard adult population is 60% to 65% with a lower boundary (2 standard deviations less than the mean) that approaches 50% to 55%. While some authors believe that 50% may be abnormal, an EF between 35% and 50% is clearly abnormal. EFs greater than 35% are often referred to as “preserved” in relation to EFs less than 35%. Most authors reserve the term “diastolic heart failure” for patients with an EF of 50% and clear evidence of diastolic dysfunction.

The use of the term HFPEF became necessary to describe heart failure populations studied in recent RCTs in which various lower limit boundaries for EF were allowed (between 35% and 50%)<sup>8-12</sup> (Figure 14-1). The focus of these studies was heart failure patients with an unmet need (i.e., those with no evidenced-based treatment to lower morbidity and mortality. These studies therefore broadened inclusion criteria to include patients with heart failure and an EF greater than 35% or greater than 40% or greater than 45%, all of which have now been grouped in HFPEF. These populations should be thought of as different from patients with heart failure and an EF of 50% (i.e., patients with DHF). Data from recent studies suggest that the epidemiology, natural history, and response to treatment in patients with heart failure and an EF between 35% and 50% are different from patients with heart failure and an EF of 50%.<sup>8-12</sup> In fact, it is becoming clearer that patients with heart failure and an EF between 35% and 50% share many or most characteristics with patients with heart failure and an EF less than 35%. Therefore, it may be more reasonable to group patients with EFs 35% to 50% into the HFREF group and conceptualize patients with CHF into two groups: SHF defined as heart

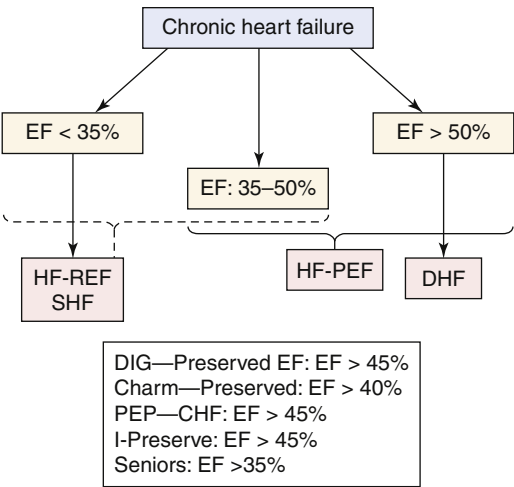

FIGURE 14–1 Ejection fraction (EF) determinants of heart failure categorizations. HFPEF, heart failure with preserved EF; HFREF, heart failure with reduced EF; SHF, systolic heart failure; DHF, diastolic heart failure. Dig—Preserved,<sup>9</sup> Charm—Preserved,<sup>8</sup> PEP—CHF,<sup>10, 11</sup> seniors.<sup>12</sup>

failure with EF less than 50% and DHF defined as heart failure with EF of 50%.

DIAGNOSIS

European Society of Cardiology Diagnostic Criteria

The European Society of Cardiology recently published the following recommendations for DHF diagnostic criteria. The diagnosis of DHF requires the following conditions to be satisfied: (1) signs and symptoms of heart failure; (2) normal or mildly abnormal LV ejection fraction; (3) normal LV volume; and (4) evidence of diastolic LV dysfunction. Normal or mildly abnormal EF is an EF greater than 50% and a normal LV end-diastolic volume index (LVEDVI) is an LVEDVI less than 97 mL/m<sup>2</sup>. Diagnostic evidence of diastolic LV dysfunction can be obtained invasively (LV end-diastolic pressure >16 mm Hg or mean pulmonary capillary wedge pressure >12 mm Hg) or noninvasively by Doppler (propagation velocity, transmitral flow velocity, pulmonary vein flow velocity) and tissue Doppler (mitral annular velocity, myocardial strain, or strain rate). Among the most common and well-validated indices of abnormal diastolic function is the ratio of early diastolic transmitral flow velocity (E) to early diastolic myocardial tissue Doppler velocity (E'). The E/E' ratio serves as a good index of pulmonary capillary wedge pressure (PCWPP) with an E/E' greater than 15 indicating a PCWP greater than 20 mm Hg (see also Chapter 36). If the E/E' ratio is suggestive of diastolic LV dysfunction (E/E' 8-15), additional noninvasive investigations are recommended for diagnostic evidence of diastolic LV dysfunction. These can consist of other Doppler measures of diastolic function, echo measures of LV mass index or left atrial volume index, electrocardiographic evidence of atrial fibrillation, or plasma levels of natriuretic peptides (BNP or NT-proBNP). If plasma levels of natriuretic peptides are elevated, additional confirmatory diagnostic evidence of diastolic LV dysfunction is recommended.

Lahey Clinic Criteria

Table 14-1 presents a pragmatic set of diagnostic criteria representing a synthesis of all existing guidelines.<sup>16</sup> To make the diagnosis of DHF, clear clinical evidence of heart failure must

be present. This includes both signs and symptoms of heart failure (e.g., the Framingham or Boston criteria). The presence of clinical heart failure can be supported by elevated levels of plasma brain natriuretic peptide or specific abnormalities on the chest x-ray. Exercise limitation can be quantified by performing cardiopulmonary exercise testing. In addition to definite clinical evidence of heart failure, a normal ejection fraction is required. An EF lower limit cutoff value of greater than 50% is recommended. Evidence that confirms the diagnosis includes structural changes such as left ventricular hypertrophy or concentric remodeling. In addition, left atrial enlargement in the absence of atrial fibrillation or mitral valve disease is suggestive of increased LV diastolic pressures. Finally, echo Doppler or catheterization evidence of diastolic dysfunction can be used. Any one of these three confirms the diagnosis. Nonmyocardial diseases such as chronic obstructive lung disease must be excluded.

### Natriuretic Peptides (see also Chapter 37)

A number of studies have suggested that brain natriuretic peptide (BNP or NT-ProBNP) could be used as a serum marker of increased diastolic pressures, abnormal diastolic function as evidenced by an abnormal echo-Doppler filling pattern, and the presence of diastolic heart failure.<sup>17-22</sup> To date, the evidence suggests that there is a good correlation between left ventricular diastolic, left atrial diastolic, and pulmonary venous pressures and the level of BNP in patients with diastolic heart failure. However, the time course of change in BNP is not definitively known from the incident diastolic heart failure episode to a compensated convalescent condition. In addition, a clear discriminatory cutoff value with acceptable sensitivity, specificity, and predictive accuracy has not been firmly established. Nonetheless, BNP may prove to be useful as a serum marker indicating the presence of diastolic dysfunction, diastolic heart failure, or both. However, brain natriuretic peptide must be interpreted in the contexts that cause false-positive and false-negative. DHF may be absent in patients with an increased brain natriuretic peptide under the following circumstances: advanced age, renal insufficiency, atrial fibrillation, chronic lung disease, pulmonary embolism, and LVH. BNP levels are often higher in women than men. DHF may be present in patients with a normal brain natriuretic peptide under the following circumstances: obesity, after adequate treatment of DHF sufficient to normalize diastolic filling pressures. Future studies will examine the diagnostic potential of other plasma proteins, peptides, and microRNA.

### MEASUREMENT OF DIASTOLIC FUNCTION IN PATIENTS WITH DHF

The dominant functional abnormality in patients with DHF is abnormal diastolic function. These functional abnormalities are associated with and may be causally related to chamber, cellular, and extracellular structural remodeling. In fact, differences in structural and functional remodeling have been used to characterize patients with DHF versus those with SHF (Table 14-2). Each of these differences is highlighted in this chapter.

Measurements of diastolic function can be divided into those that reflect the process of active relaxation and those that reflect passive stiffness. This division is in some ways arbitrary because structures and processes that alter relaxation and recoil can also result in measurable abnormalities in stiffness. However, this division is pragmatic and provides a necessary scaffold on which to develop methods of measurement. Measurements that reflect active relaxation and passive stiffness can be made both in vivo, using clinically

**TABLE 14-2** LV Structure and Function in Chronic Heart Failure

	Systolic Failure	Diastolic Failure
<b>Remodeling</b>

applicable methods to examine the intact left ventricle, or in vitro, using experimental methods to examine isolated cardiomyocytes and isolated cardiac muscles. These in vitro measurements are important because they provide the methods by which the underlying basic mechanisms responsible for altering diastolic function can be defined. In this chapter, both in vivo and in vitro methods will be discussed.

### In Vivo Quantitation of Left Ventricle Chamber Diastolic Function

#### Relaxation

Diastole encompasses the time period during which the myocardium loses its ability to generate force and shorten and then returns to resting force and length. Relaxation occurs in a series of energy-consuming steps beginning with the release of calcium from troponin C, detachment of the actin-myosin cross-bridge, phosphorylation of phospholamban, sarcoplasmic reticulum calcium ATPase-induced calcium sequestration into the sarcoplasmic reticulum, sodium/calcium exchanger-induced extrusion of calcium from the cytoplasm, slowing of cross-bridge cycling rate, and extension of the sarcomere to rest length.<sup>23-27</sup> Adequate energy supplies and the mechanisms to regenerate them must be present for this process to occur at a sufficient rate and extent.<sup>24-27</sup> The rate and extent to which these cellular processes occur determine the

**FIGURE 14-2** Schematic drawing of LV pressure and LV  $dP/dt$  showing methods used to quantitate isovolumic relaxation rate. The time constant of isovolumic pressure decline, tau ( $\tau$ ), is the inverse slope of the natural log of the pressure versus time relationship and can be calculated using the equation shown. Peak  $(-dP/dt)$  is the maximum rate of LV pressure decline. MVO, mitral valve opening. An example of a patient with normal relaxation is shown as solid lines; a patient with impaired and slowed relaxation is shown as dashed lines. Abnormal relaxation results in a decreased  $(-dP/dt)$  and an increased  $\tau$ .

rate and extent of active ventricular relaxation. At the chamber level, this process results in LV pressure decline at a constant volume (isovolumic relaxation), then LV chamber filling that occurs with variable LV pressures (auxotonic relaxation). Measurements made during auxotonic relaxation are affected both by active relaxation and passive stiffness.

#### Isovolumic Relaxation

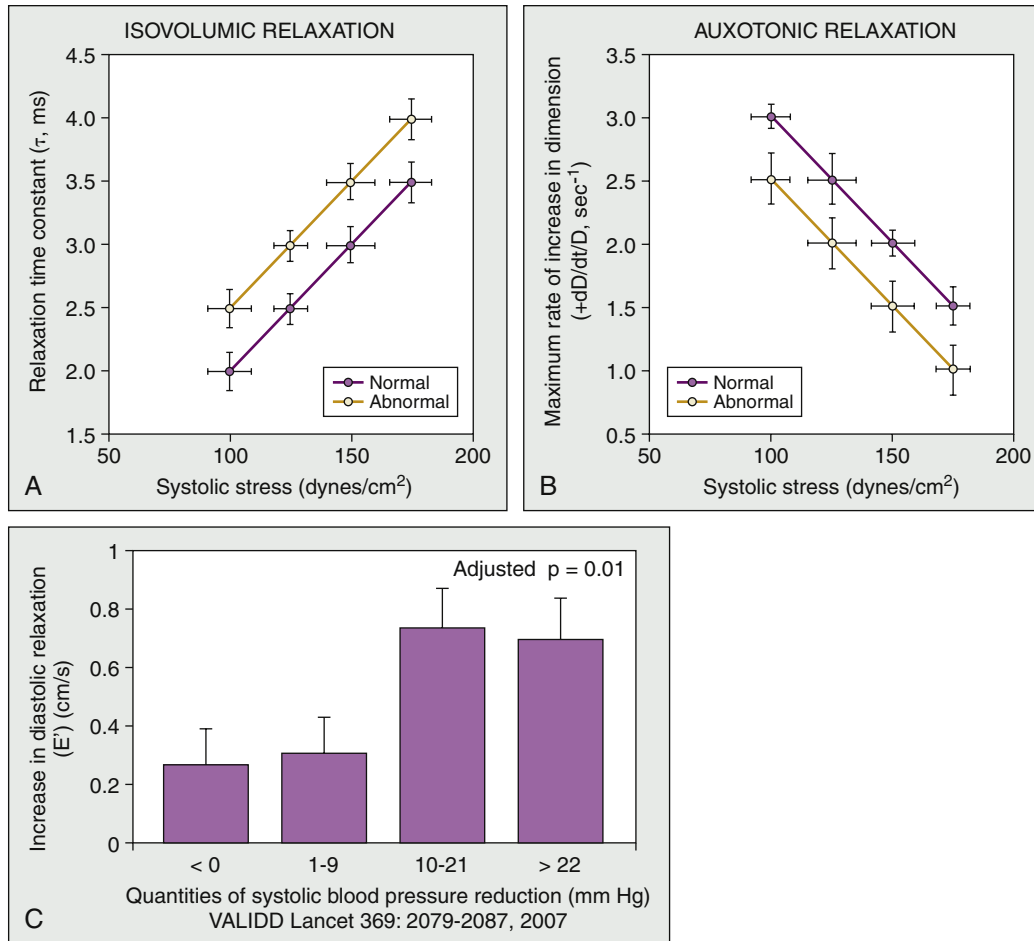

Isovolumic relaxation can be quantitated by measuring LV pressure using a high-fidelity micromanometer catheter and calculating the peak instantaneous rate of LV pressure decline, peak  $(-dP/dt)$ , and the time constant of isovolumic LV pressure decline,  $\tau$ .<sup>28-30</sup> Peak  $(-dP/dt)$  is calculated as the first derivative of LV pressure with respect to time. It reflects a single instantaneous event that occurs very early during LV pressure decline. This value not only reflects changes in the isovolumic relaxation rate but also is affected by changes in mechanical factors such as preload, afterload, and heart rate. The relaxation time constant,  $\tau$ , reflects the time course of LV pressure decline from peak  $(-dP/dt)$  to MVO. Tau is generally quantitated using a method which assumes that pressure declines in a monoexponential fashion. Because LV pressure is fit to monoexponential decay, the plot of the natural log of LV pressure versus time over this period forms a linear relation (Figure 14-2).  $\tau$  is equal to the inverse slope of this linear relation. This relation can be expressed mathematically as  $P = P_0 e^{-t/\tau}$ , where  $P$  is LV pressure,  $e$  is the base of the natural logarithm,  $t$  is the time in milliseconds after peak  $(-dP/dt)$ , and  $P_0$  is the pressure at the time of peak  $(-dP/dt)$ .<sup>28</sup> Stated in more conceptual terms,  $\tau$  is the time that it takes for LV pressure to fall by  $1/e$  from its initial pressure (i.e., to fall by approximately two thirds of its initial value). When isovolumic pressure decline is slowed,  $\tau$  is prolonged and the numeric value of  $\tau$  increases. This method of calculating  $\tau$  makes three assumptions: LV pressure decline is monoexponential, LV cavity pressure is equal to transmural pressure, and LV pressure will fall asymptotically to zero.<sup>29</sup> Alternative methods of calculating  $\tau$  in which the zero pressure asymptote is not assumed to be zero include the derivative method and the use of a three-constant nonlinear regression analysis.<sup>30</sup> Comparison of these three methods has not demonstrated significant differences in interpretation of the effects of a pathological state on measurements of active relaxation.<sup>30</sup>  $\tau$ , like peak  $(-dP/dt)$  is influenced by changes in loading conditions.<sup>31</sup> Therefore, no index of relaxation (isovolumic or auxotonic) including  $\tau$ , can be considered an index of “intrinsic” relaxation rate unless loading conditions (and other modulators) are held constant or at least specified. One practical way to overcome this limitation is to examine indices of relaxation over a range

of loads (Figure 14-3). Afterload can be altered acutely using mechanical or pharmacological methods. Abnormal relaxation is indicated by the shift in the position of the relaxation rate versus the afterload relationship where  $\tau$  is prolonged at any equivalent systolic stress.<sup>31</sup> Therefore, indices of active relaxation must be measured at equivalent loading conditions or at least interpreted in light of differing loading conditions. A practical clinical application of this concept was proven in a recent clinical study in which a pharmacologically induced decrease in blood pressure resulted in an improvement in the relaxation rate.<sup>32</sup>

While active relaxation may, in the strictest sense, be regarded as an early “diastolic” event, the time of onset of this process depends, at least in part, upon “systolic” events such as the duration of contraction.<sup>14</sup> Conversely, the time of onset of relaxation can modify systolic events. Therefore the rate and extent of relaxation, in addition to being dependent on ventricular load, is also dependent on the duration of systole, the time of onset of relaxation, and the time during systole in which load is altered.<sup>14,31,33</sup> If the onset of relaxation is delayed, for example, by an increase in load early in systole, this may prolong the duration of systole, increase cardiac work during systole, and may prolong relaxation. Conversely, if the onset of relaxation occurs earlier, for example, because of an increase in load late in systole, this may shorten the duration of systole and may abbreviate relaxation. Thus a complex interaction between events traditionally considered to occur during “systole” can affect the measurement and interpretation of active relaxation.

#### Recoil/Suction

Normal LV relaxation is rapid and causes early LV diastolic pressures to fall toward and often reach zero. The resultant early transmitral pressure gradient plus the release of the potential energy created by systolic contraction create suction, or recoil that pulls blood from the left atrium toward the apex of the left ventricle. This normal recoil force can be quantitated from color m-mode echocardiography as the velocity of flow propagation ( $V_p$ ). In patients with DHF, recoil is decreased because the release of the stored potential energy is apposed by the increased viscoelastic passive properties of the heart in DHF. As a consequence  $V_p$  declines, left atrial pressures rise, and blood is pushed rather than pulled into the left ventricle. While  $V_p$  is also reduced in patients with SHF, the mechanisms that underlie this abnormality are quite different. In SHF, contraction is notably reduced and therefore there are marked decreases in stored potential energy during systole and a resultant decrease in the recoil force available during diastole.

**FIGURE 14-3** Examples of the relationship between indices of relaxation rate and afterload. The isovolumic time constant,  $\tau$  (an index of isovolumic relaxation rate) versus LV systolic stress (an index of afterload) is plotted in (A), maximum rate of increase in LV dimension,  $(+dD/dt/D)$  (an index of auxotonic diastolic filling rate) versus LV systolic stress is plotted in (B). When relaxation is abnormal and slowed, both  $\tau$  and  $(+dD/dt/D)$  are decreased at any equivalent systolic stress. The downward shift in these relationships indicate that relaxation is impaired. The results of the clinical study VALIDD (C)<sup>32</sup> showed that a decrease in blood pressure resulted in an increase in relaxation velocity.

### Auxotonic Relaxation

The auxotonic LV filling phases of diastole can be characterized using Doppler-echocardiography, radionuclide, conductance, or MRI techniques. While each technique has advantages and disadvantages, all assess diastolic function by measuring indices of volume transients during ventricular filling. M-mode echocardiograms can be digitized to provide LV dimension versus time ( $dD/dt$ ) or LV wall thickness versus time ( $dH/dt$ ) data. Peak  $(+dD/dt)$  (dimension increasing) and peak  $(-dH/dt)$  (wall thinning) can be used as indices of an early auxotonic relaxation rate. In addition, LV cavity area from 2-D images can be digitized on a frame-by-frame basis with sufficient sampling frequency to examine cavity area versus time ( $dA/dt$ ). If carried throughout diastolic filling, both early and late filling rates can be quantified. Transmitral LV inflow velocity during diastole can be assessed using Doppler echocardiography. This technique provides the means to assess temporal distribution of LV filling, provides indices of auxotonic filling rates, and provides indirect indices of LV chamber compliance. Early diastolic filling velocity (E wave), late diastolic filling velocity consequent to atrial contraction (A wave), the E/A ratio, E wave deceleration time, and A wave duration can be used to assess auxotonic relaxation. Radionuclide ventriculography can be used to derive time versus activity and/or time versus volume relationships from which indices of diastolic filling rate can be derived. Magnetic resonance imaging (MRI) can be used to measure

transmitral flow velocities from which indices of diastolic filling rate can be derived. In addition MRI tagging can provide measurements of myocardial strain and strain rate, and twist and untwist rates. Likewise recent advances in tissue Doppler methods and strain rate imaging have provided new tools for assessment of diastolic filling and diastolic filling pressure assessment. Tissue Doppler imaging (TDI) is based on measurements of regional length and velocity, which, when normalized to initial length, can be used to derive strain and strain rate.

However, like all relaxation indices, all auxotonic indices must be interpreted in light of simultaneous changes in load, both afterload and filling load (load present during filling).<sup>14,35,36</sup> For example, the precise pattern of early and late diastolic transmitral flow velocities will depend on factors governing instantaneous atrial and LV pressures before and after mitral valve opening and the resultant atrial-ventricular pressure gradient (filling load). It is thus not surprising that interventions or pathological conditions that increase left atrial pressure increase early transmitral flow velocities, while interventions that reduce left atrial pressure also reduce early filling velocities. To correctly interpret changes in transmitral flow velocities, concomitant changes in filling load must be considered. These considerations can now be provided by tissue Doppler and pulmonary venous Doppler and color m-mode velocities using the scheme shown in Figure 14-6.<sup>37</sup>

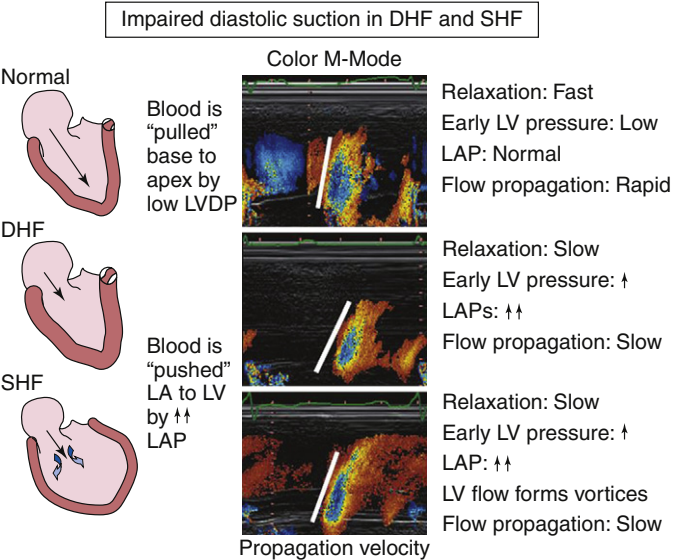

CH14

In addition to active relaxation, passive viscoelastic properties contribute to the process that returns the myocardium to its resting force and length. These passive viscoelastic properties are dependent both on intracellular and extracellular structures (see “Mechanisms” section). Changes in the stiffness of the ventricular chamber can be assessed by examining

the pressure and volume relationship during diastole. Chamber stiffness is determined both by the stiffness of the constituent myocardium and LV mass and the LV mass/volume ratio. Changes in myocardial stiffness can be assessed by examining the myocardial stress, strain, and strain rate relationships during diastole.

**Chamber Stiffness**

Chamber stiffness can be quantified by examining the relationship between diastolic LV pressure and volume. LV diastolic pressure can be changed either by a volume-dependent change in instantaneous operating stiffness or by a volume-independent change in the overall chamber stiffness (Figure 14-7). The instantaneous operating stiffness at any point along a given pressure-volume curve is equal to the slope of a tangent drawn to the curve at that point ( $dP/dV$ ) (see Figure 14-7). Operating stiffness changes throughout filling, and stiffness is lower at smaller volumes and higher at larger volumes (see Figure 14-7 point a to point b, volume-dependent change in diastolic pressure and stiffness). Obtaining sufficient data to characterize the entire LV diastolic pressure versus volume curve may be difficult using currently available methods. At a minimum, an index of end-diastolic operating stiffness may be determined by examining the ratio of end-diastolic pressure (EDP) versus end-diastolic volume (EDV). Under some circumstances, end-diastolic operating stiffness may reflect overall chamber stiffness. For example, if EDP is increased with a normal EDV, end-diastolic operating stiffness (and likely overall chamber stiffness) is increased (Figures 14-7 and 14-8, as seen in DHF). If EDP is normal and EDV is increased, end-diastolic operating stiffness (and likely overall chamber stiffness) is decreased (see Figures 14-7 and 14-8, as seen in SHF). If EDP is increased and EDV is also increased, stiffness may be normal, increased, or decreased. In this later

**FIGURE 14-4** Schematic and examples of color M-mode propagation velocity demonstrating changes in diastolic suction in patients with systolic heart failure (SHF) versus diastolic heart failure (DHF). LV, left ventricular; DP, diastolic pressure; LAP, left atrial pressure.

**FIGURE 14-5** Examples of the changes in tissue Doppler myocardial velocity, strain, and strain rate in a normal subject and a patient with diastolic heart failure.

condition, measuring the entire pressure-volume relationship becomes essential in determining overall chamber stiffness. The shape and position of the entire pressure-volume relationship can be used to calculate an overall chamber stiffness constant (see Figure 14-7). Because the diastolic pressure-volume relationship is curvilinear and generally exponential, the relationship between  $dP/dV$  and pressure is linear, the slope ( $K_c$ ) is called the “modulus of chamber stiffness” (or “chamber stiffness constant”) and can be used as a single numeric value to quantitate overall chamber stiffness.  $K_c$  can be represented mathematically using a monoexponential equation:  $P = P_0 e^{K_c V}$ , where  $P$  is LV pressure,  $V$  is LV volume,  $P_0$  is LV pressure at equilibrium volume, and  $K_c$  is the chamber stiffness constant. When overall chamber stiffness is increased, the pressure-volume curve shifts to the left, the slope of the  $dP/dV$  versus pressure relationship becomes steeper, and  $K_c$  is increased (volume-independent change in diastolic pressure and stiffness).<sup>30,31</sup> Thus diastolic pressure can be changed either by a volume-dependent change in instantaneous operating stiffness or by a volume-independent change in the overall chamber stiffness. In patients with DHF, a number of recent studies have shown that both the overall diastolic chamber stiffness and end-diastolic operative stiffness are significantly increased compared with normal control subjects.

Diastolic pressure versus volume (and stress vs. strain, described later) relationships can be derived from a single cardiac cycle or from multiple cardiac cycles. Using a single cardiac cycle, pressure versus volume coordinates during a single diastole—from mitral valve opening to mitral valve closure—must be obtained. Using multiple cardiac cycles, end-diastolic values are obtained from cardiac cycles in which

end-diastolic volume or pressure are altered using pharmacological or mechanical means. To accurately compare indices of chamber stiffness between pathological states, these indices must be derived from data that share common ranges of pressure. Specifically, the range of pressure over which stiffness is calculated must be similar in each left ventricle.

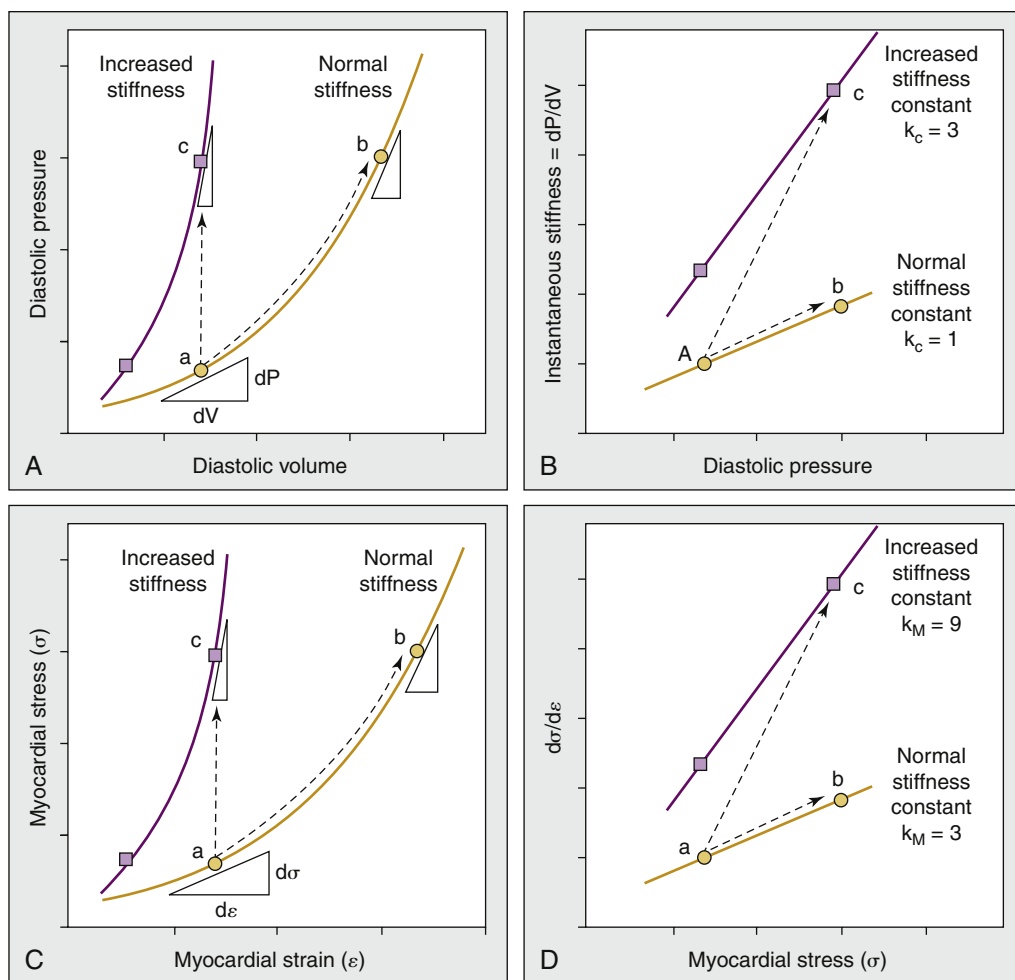

A multitude of recent studies has shown definitively that LV chamber stiffness is increased in patients with DHF.<sup>38-43</sup> In patients with DHF, LV diastolic pressures are increased at normal LV diastolic volumes, the diastolic pressure-volume curves are shifted up and to the left, and the chamber stiffness constants are increased (Figure 14-9). By comparison, patients with SHF have been shown to have LV diastolic pressure volume curves that are shifted down and to the right with decreased chamber stiffness constants.

### Myocardial Stiffness

Cardiac muscle behaves as a viscoelastic material, developing a resisting force (stress,  $\epsilon$ ) as myocardial length is increased (strain,  $\epsilon$ ) by ventricular filling. Strain is the deformation (increased length) of the muscle produced by the application of a force (increased stress). Strain ( $\epsilon$ ) is generally expressed as the percent change in length ( $L$ ) from the unstressed length. Using Lagrangian strain, the unstressed length ( $L_0$ ) is equal to the equilibrium length (i.e., the length of the muscle when subjected to no external forces). Myocardial stiffness can be quantitated by examining the relationship between myocardial stress and strain during diastole (see Figure 14-7). At any given strain, myocardial stiffness is equal to the slope ( $d\sigma/d\epsilon$ ) of a tangent drawn to the stress-strain relationship at that strain. Because the stress-strain relationship is curvilinear and exponential, the relationship between  $d\sigma/d\epsilon$  and stress

Schematic drawing of the myocardial diastolic stress versus strain relationship showing methods used to quantitate myocardial stiffness;  $K_m$  is the myocardial stiffness constant (C and D).

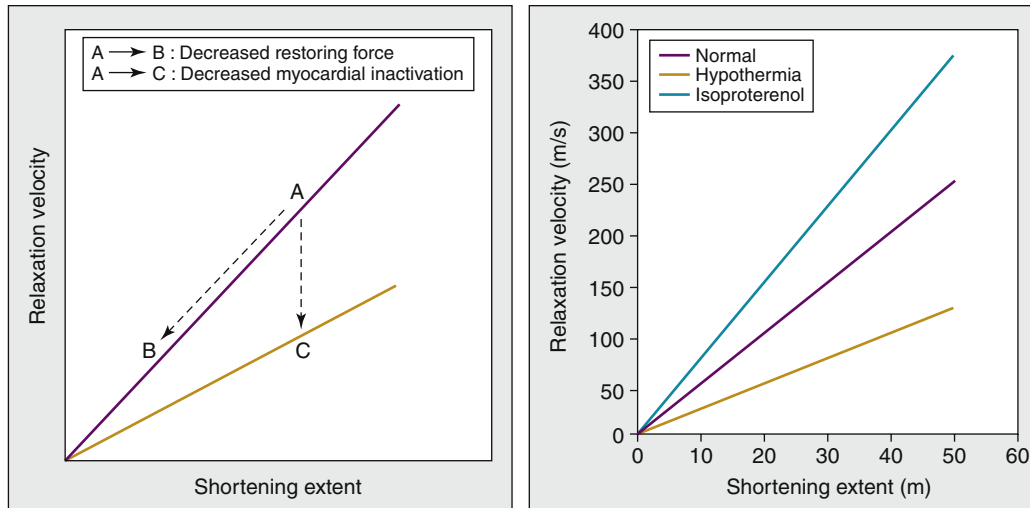

**FIGURE 14-8** Schematic pressure-volume loops contrasting diastolic heart failure (C) with systolic heart failure (A) and normal (B). The dashed lines represent end-systolic elastance. The dotted lines represent diastolic stiffness (or distensibility).

**FIGURE 14-9** Diastolic pressure versus volume data from normal control subjects, patients with systolic heart failure (SHF), and diastolic heart failure (DHF). LV chamber stiffness was increased in DHF and decreased in SHF patients.

is linear and the slope of this relation,  $K_m$ , is the modulus of myocardial stiffness (or myocardial stiffness constant). When myocardial stiffness is increased, the stress-strain relationship shifts to the left, so that for any given change in myocardial length (strain), there is a greater increase in force (wall stress) that develops to resist this deformation.

In addition, the slope of the  $d\sigma/d\epsilon$  versus stress relationship becomes steeper and  $K_m$  increases when myocardial stiffness is increased.  $K_m$  can be represented mathematically using a monoexponential equation:  $\sigma = \sigma_0 (e^{K_m \epsilon})$ ,  $\sigma$  = LV wall stress,  $\epsilon$  = strain,  $\sigma_0$  is stress at zero strain and  $K_m$  is the elastic stiffness constant.<sup>30,31</sup> Comparison of myocardial stiffness using

**FIGURE 14-10** Example of the direct linear relationship between cardiomyocyte relaxation velocity and systolic shortening extent (similar techniques can be applied to isolated cardiac muscles). In a normal cardiomyocyte (solid line) relaxation, velocity decreases when shortening extent is decreased because there is a decrease in restoring force. In an abnormal cardiomyocyte (dashed lines), relaxation velocity is decreased to a value less than normal at any equal shortening extent because of a decrease in myocardial inactivation. Hypothermia caused a decrease in myocardial inactivation and decreased the slope of the relaxation velocity versus shortening extent relationship. Isoproterenol caused an increase in myocardial inactivation and increased the slope of the relaxation velocity versus shortening extent relationship.

these methods is only appropriate when the calculations are made over common ranges of LV wall stress.

## In Vitro Quantitation of Diastolic Function

### Relaxation

The process of relaxation can be measured in vitro in isolated muscle tissue or isolated cardiomyocytes. Isometric force decline and isotonic lengthening rates can be measured in an isolated muscle. In contrast, only the isotonic lengthening rate can be assessed in an isolated cardiomyocyte.<sup>52-56</sup> However, it should be noted that these in vitro indices of active relaxation, like the in vivo indices, must be interpreted in light of simultaneous changes in load. For example, the cardiomyocyte isotonic lengthening rate may be decreased by two possible mechanisms: (1) a decrease in restoring force or (2) abnormal myocardial inactivation (Figure 14-10). Restoring forces are created during contraction when potential energy is stored by deformation in cellular structures. This potential energy changes into kinetic energy during diastole and acts to restore the cardiomyocyte to rest or equilibrium length. Changes in myocardial inactivation alter lengthening rate independent of concomitant changes in restoring force. Studies have shown that examining the relaxation velocity versus shortening extent relationship (see Figure 14-10) provides an analytic method to distinguish between these two factors.<sup>54-56</sup>

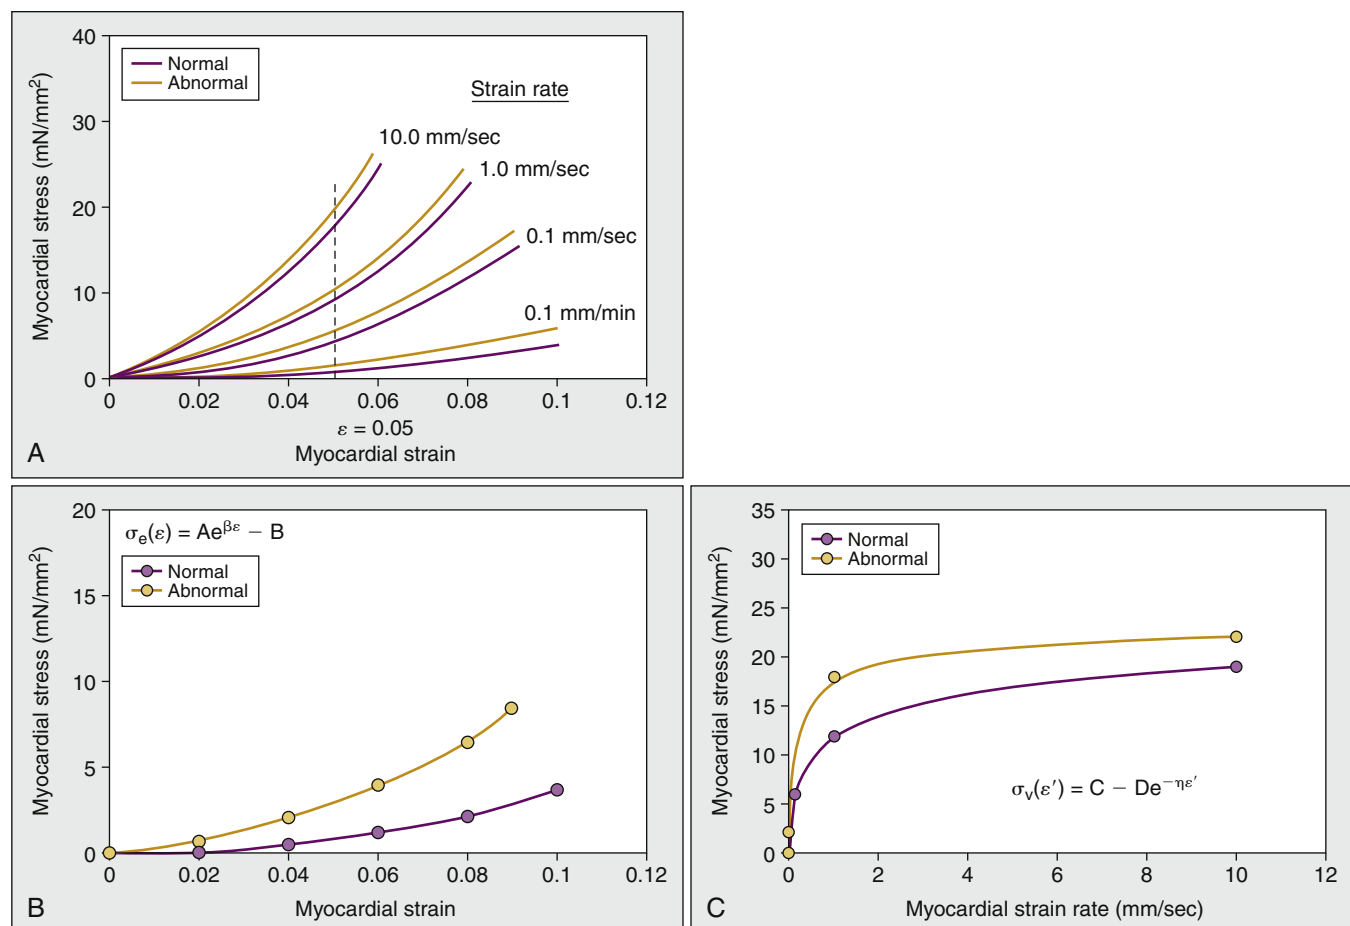

If a given pathological process causes the relaxation velocity to change along a common relationship between relaxation velocity and shortening extent (see panel A, Figure 14-10, from point A to point B), this indicates that these changes were caused by alterations in restoring forces that occurred concomitantly with alterations in systolic function. In contrast, if a pathological process causes the relaxation velocity to change along a distinctly different relationship (see panel A, Figure 14-8, from point A to point C), this would indicate that there had been changes in the rate of myocardial inactivation. Two interventions (hypothermia and isoproterenol) known to produce primary alterations in myocardial inactivation were examined in normal cardiomyocytes<sup>54-56</sup> (see Figure 14-8, panel B). During hypothermia, the slope of the relaxation velocity versus shortening extent relationship decreased such that for any given shortening extent, relaxation velocity was

less at 30° C than at 37° C.<sup>54-56</sup> During isoproterenol infusion, the slope of the relaxation velocity versus the shortening extent relationship increased significantly.<sup>54-56</sup> Thus the slope of the relaxation velocity versus the shortening extent relationship is sensitive to and dependent on changes in the rate of myocardial inactivation. This analytical method can be applied to isolated cardiomyocyte and muscle preparations.

### Viscoelastic Stiffness

A number of mechanical and bioengineering models and experimental designs have been used to describe the constitutive material viscoelastic properties of myocardial tissue and cardiomyocytes.<sup>57-59</sup> One such method, applicable to both isolated cardiac muscle and cardiomyocyte consists of a two-element model composed of a nonlinear spring in parallel with a nonlinear viscous damper. Conceptually, the passive elastic spring consists of structures or processes that resist deformation in a time-independent manner (i.e., it resists deformation to the same extent irrespective of the rate of deformation). The viscous damper consists of structures or processes that resist stretch in a time-dependent manner (i.e., it resists deformation to a greater extent when the rate of deformation is increased). While this kind of analysis is difficult to perform in vivo, it can be done in vitro. There are a number of important reasons to examine elastic stiffness and viscous damping, separately and independently. This kind of analysis may provide clues to which specific cellular or extracellular mechanism is altered by a particular pathological state and which specific mechanism leads to changes in diastolic function.

To calculate elastic stiffness ( $\beta$ ) and viscous damping ( $\eta$ ) constants, measurements of muscle or cardiomyocyte stress, strain, and strain rate are obtained using uniaxial variable rate stretches (Figure 14-11). These data can be fit by a constitutive equation for a nonlinear viscoelastic composite biomaterial where  $\sigma(\epsilon, \dot{\epsilon}) = (Ae^{\beta\epsilon} + B) + (C - D\epsilon^{\eta})$ , and A, B, C, and D are curve fitting constants. The elastic stiffness constant is assessed using the slowest uniaxial stretch. Under these conditions, strain rate approximates zero, the second portion of the equation equation  $(C - D\epsilon^{\eta})$  becomes constant, stress becomes a function of strain alone, and  $\beta$  can be determined. When elastic stiffness is increased, the  $\sigma$  versus  $\epsilon$  relationship shifts up and left and  $\beta$  increases (see Figure 14-11). The

**FIGURE 14-11** Schematic showing the results of uniaxial variable rate stretches performed in isolated cardiac muscles (similar techniques can be applied to isolated cardiomyocytes) **(A)**. Stress, strain, and strain rate data obtained from these methods can be used to calculate elastic stiffness and viscous damping constants. Stress versus strain data at the lowest strain rate **(B)** were fit to the equation shown to calculate the elastic stiffness constant. Stress versus strain rate data at constant strain **(C)** were fit to the equation shown to calculate the viscosity constant.

viscous damping constant is assessed using all four uniaxial variable rate stretches. From these stretches, the relationship between stress and strain rate is defined at constant strain. At any selected constant strain, the relationship between stress and strain rate is curvilinear. Under these experimental conditions, strain is constant, the first portion of the equation ( $Ae^{B\epsilon} + B$ ) becomes constant, and stress becomes a function of strain rate alone. Therefore, the stress versus strain rate data can be fit to the equation, and  $\eta$  determined. When viscous damping is increased, the  $\sigma$  versus  $\epsilon'$  relationship shifts up and  $\eta$  increases (see Figure 14-9).

Recent studies were performed in patients with DHF in which cardiomyocytes were isolated from myocardial biopsies and the cardiomyocyte stiffness properties measured. These studies showed that myocardial stiffness and cardiomyocytes are increased in patients with DHF.<sup>47-51</sup>

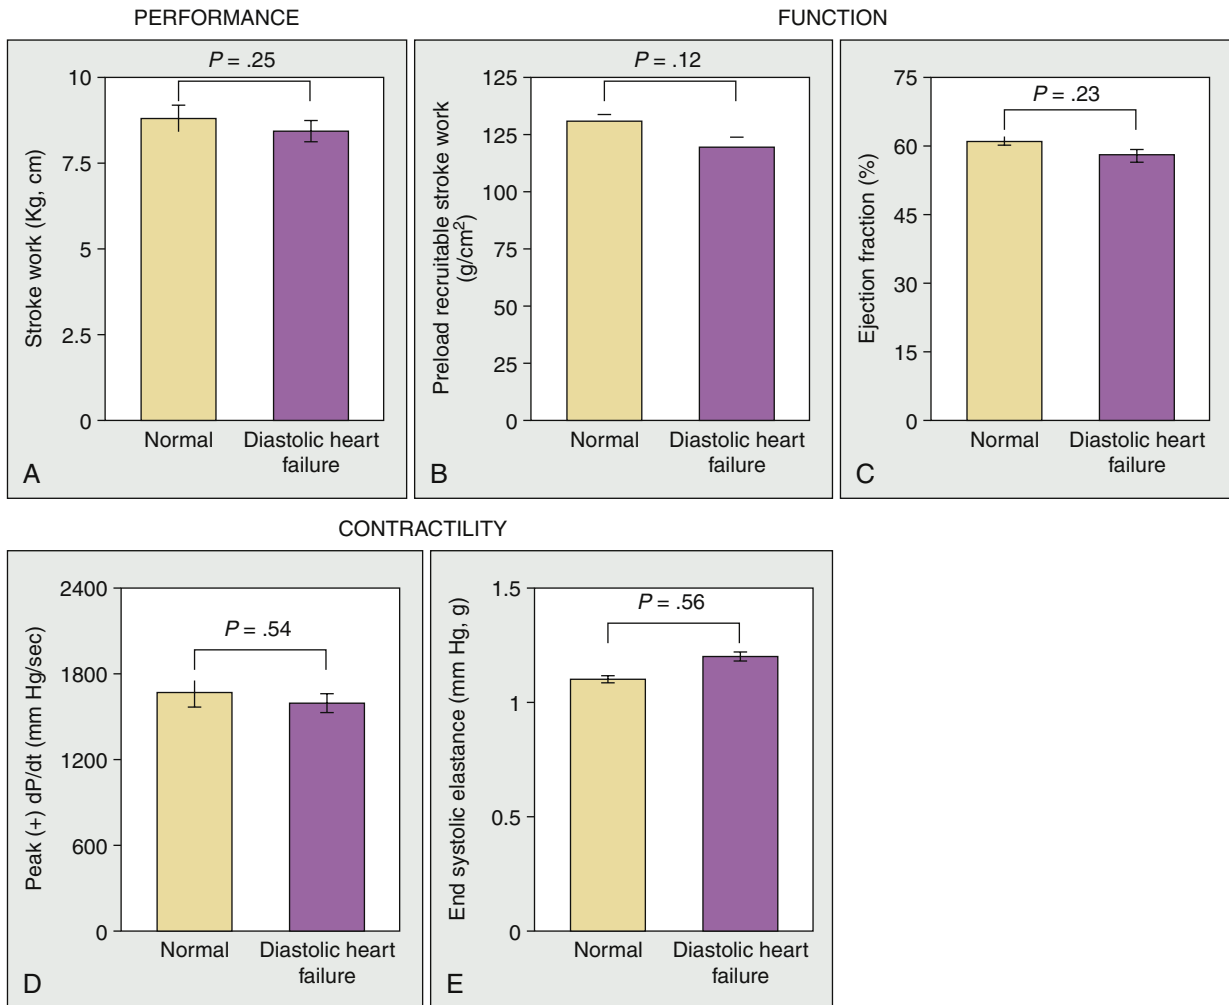

## MEASUREMENT OF SYSTOLIC PROPERTIES IN PATIENTS WITH DHF

There is an emerging consensus that the most important functional abnormalities in patients with DHF are the dominant abnormalities in diastolic function. However, questions have been raised about concomitant abnormalities in systolic function and arterial stiffness. To determine whether and to what extent patients with DHF have abnormalities in the systolic properties of the left ventricle, load and remodeling independent indices were examined in a study by Baicu et al. Many

such indices have been proposed, but there is no single, universally applicable index of systolic properties that is independent of load and remodeling (see also Chapter 13).<sup>60,61</sup> It was hypothesized that if multiple indices are measured and if the results are in general agreement and viewed in aggregate, it should be possible to determine whether patients with DHF have significant abnormalities in the systolic properties of the left ventricle. Accordingly, a full assessment of the contractile behavior of the ventricle required measuring the combined indices that reflect LV systolic performance, function, and contractility, and global and regional function were examined in a group of patients with DHF.<sup>60</sup>

*Ventricular performance* is a term that is used to describe the pumping ability of the left ventricle. The performance of the ventricle as a pump may be assessed by measuring the pressure developed by the ventricle, the stroke volume ejected by the ventricle, or preferably the stroke work generated by the ventricle. Stroke work can be determined invasively in the catheterization laboratory or estimated non-invasively with the use of echocardiographically measured stroke volume multiplied by the mean arterial pressure. A limitation of the noninvasive method is that total pressure (i.e., peak systolic pressure) rather than developed pressure (i.e., LV systolic pressure minus end-diastolic pressure) is often used; this results in an overestimation of the work performed by the ventricle. Thus stroke work calculated as the product of developed pressure and stroke volume credits the ventricle for pressure and shortening work in a single integrated index. To date, studies have shown that patients with

**FIGURE 14-12** Systolic properties in normal control subjects and patients with diastolic heart failure (DHF). Each measurement of LV systolic chamber performance, function, and contractility was normal in the DHF patients.

DHF have normal stroke work compared with normal control subjects (Figure 14-12).<sup>60</sup>

A classic *ventricular function* curve can be constructed by plotting coordinates of performance (e.g., stroke work) against an index of preload (e.g., end-diastolic pressure or volume). When contractility is increased, the stroke work versus preload relationship is shifted upward, and when contractility is decreased, the relationship is shifted downward. A family of such ventricular function curves credits the ventricle for pressure development and ejection, and, importantly, it incorporates load and contractility. Thus plots of stroke work against preload allow construction of a Frank-Starling ventricular function curve or a preload recruitable stroke work relationship.<sup>60</sup> To date, studies have shown that patients with DHF have normal stroke work versus preload and normal preload recruitable stroke work compared with normal control subjects (see Figure 14-12).<sup>60</sup>

The term *ventricular contractility* refers to the contractile or inotropic state of the whole ventricle. Indices of ventricular contractility have conventionally been divided into isovolumic phase indices (e.g., peak positive dP/dt), ejection phase indices (e.g., systolic wall stress versus endocardial shortening), and indices determined at the end of ejection (e.g., end-systolic elastance). The concept of ventricular contractility is similar to that of myocardial contractility, but all indices of ventricular contractility are inextricably linked to and influenced by loading conditions and ventricular remodeling. Only if loading conditions and ventricular remodeling are

considered or incorporated in the analysis can these parameters of “function” reflect changes in ventricular “contractility.” For example, peak positive dP/dt can be altered by an acute change in preload, but the influence of chronic geometric changes and remodeling on dP/dt is not well defined. By contrast, systolic elastance is not affected by acute changes in preload (it is determined by altering load); however, systolic elastance is affected by chronic changes in LV volume and mass. It is for this reason that indices of end-systolic elastance should be normalized for the LV mass/volume ratio. To date, studies have shown that patients with DHF have normal dP/dt, endocardial fractional shortening versus mean systolic stress relationship, and normal mass/volume corrected end-systolic elastance compared with normal control subjects (see Figure 14-12).<sup>60</sup>

In summary, every index of LV systolic performance, function, and contractility examined to date was normal in DHF patients compared with normal controls.

Some studies have shown that arterial stiffness estimated as Ea is increased in DHF patients compared with controls; however, the arterial-ventricular coupling index, Ea/Ees ratio, was not different in DHF patients than in controls. In addition, when patients with hypertension-induced LVH but no DHF were compared with patients with hypertensive LVH and DHF, there were no differences in arterial stiffness.<sup>60,42</sup>

Patients with DHF may have some detectable abnormalities in LV systolic properties despite the presence of a normal ejection fraction.<sup>62-68</sup> It has been suggested that these

abnormalities of LV systolic properties constitute an important pathophysiological mechanism for the occurrence of heart failure in these patients. This notion is based on studies that examined the extent and velocity of LV long-axis shortening, mitral annular systolic velocity, myocardial strain, and strain rate. However, it is likely that these measurements, like all indices of LV systolic function, are affected by alterations in LV loading conditions and geometry, and changes in contractility. In addition, it is possible, if not likely, that some of these indices of LV systolic function reflect changes in ventricular remodeling independent of changes in contractility.<sup>69-71</sup>

Therefore, we conclude that the dominant functional abnormality in patients with DHF is abnormal diastolic function. These changes in diastolic function along with the concomitant changes in left ventricle, cardiomyocyte, and extracellular matrix structure (see later discussion) form the substrate from which patients develop DHF.

## STRUCTURAL CHANGES IN PATIENTS WITH DHF

The hearts of patients with systolic heart failure differ dramatically from those of patients with diastolic heart failure in regard to both gross and microscopical anatomical features (Figures 14-13 and 14-14). These anatomical differences tend to parallel physiological and functional differences in systolic and diastolic heart failure<sup>72-78</sup> (see Table 14-2). Patients with diastolic heart failure generally exhibit a concentric pattern of LV remodeling and hypertrophic process that is characterized by a normal or near-normal end-diastolic volume, increased wall thickness, and high ratio of mass to volume with a high ratio of wall thickness to chamber radius. By contrast, patients with systolic heart failure exhibit a pattern of eccentric remodeling with an increase in end-diastolic volume, little increase in wall thickness, and substantial decrease in the ratio of mass to volume and thickness to radius. The aforementioned dramatic differences in organ morphology and geometry are paralleled by anatomical differences at the microscopic level. As shown in Figure 14-14, in diastolic heart failure the cardiomyocyte exhibits an increased diameter, and there is an increase in the amount of collagen with a corresponding increment in the width and continuity of the fibrillar components of the extracellular matrix.<sup>72-78</sup> By contrast, in systolic heart failure, the cardiomyocytes are elongated, and there are degradation and disruption of the fibrillar collagen.<sup>72-78</sup>

## MECHANISMS CAUSING DIASTOLIC DYSFUNCTION

Conceptually the mechanisms causing abnormalities in diastolic function that lead to the development of diastolic heart failure can be divided into factors intrinsic to the myocardium itself (myocardial) and factors that are extrinsic to the myocardium (extramyocardial) (Box 14-1). Myocardial factors can be divided into structures and processes within the cardiac muscle cell (cardiomyocyte), within the extracellular matrix (ECM) that surrounds the cardiac muscle cell, and those that activate the autocrine or paracrine production of neurohormones.

Abnormalities in diastolic function can be caused by changes in extramyocardial mechanisms such as acute changes in (1) hemodynamic loading conditions including an increase in afterload caused by hypertension and (2) heterogeneity, either asynchrony or asynergy, caused by coronary artery disease. In addition, chronic changes in these extramyocardial factors can result in changes in the myocardial factors discussed next.

## Cardiomyocyte

### Calcium Homeostasis (see also Chapter 3)

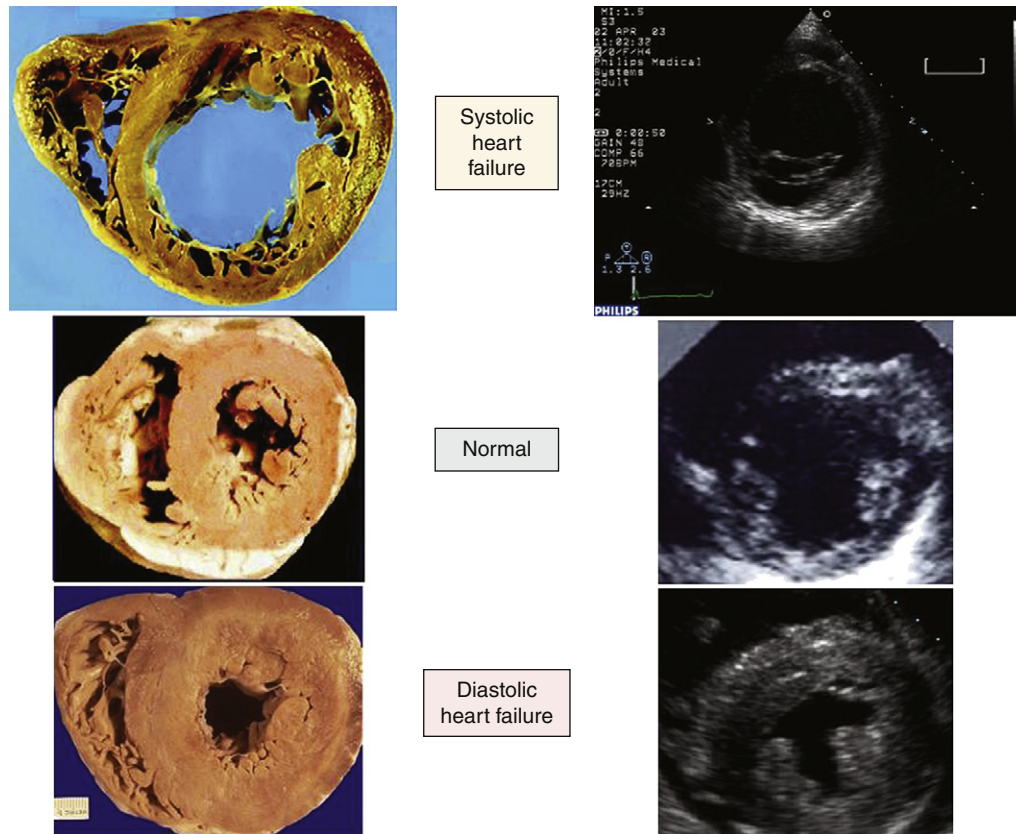

Diastolic dysfunction can be caused by mechanisms that are intrinsic to the cardiac muscle cells themselves. These include changes in calcium homeostasis caused by (1) abnormalities in the sarcolemmal channels responsible for short- and long-term extrusion of calcium from the cytosol such as the sodium calcium exchanger and the calcium pump; (2) abnormal sarcoplasmic reticulum calcium (SR  $\text{Ca}^{++}$ ) reuptake caused by a decrease in SR  $\text{Ca}^{++}$  ATPase; and (3) changes in the phosphorylation state of the proteins that modify SR  $\text{Ca}^{++}$  ATPase function such as phospholamban, calmodulin, and calsequestrin (Figure 14-15). Changes in any of these processes can result in increased cytosolic diastolic calcium concentration, prolongation in the calcium transient, and delayed and slowed diastolic decline in cytosolic calcium concentration (see Figure 14-15). These changes have been shown to occur in cardiac disease and cause abnormalities in both active relaxation and passive stiffness.<sup>23</sup> Studies in pathological myocardium such as pressure overload hypertrophy or dilated cardiomyopathy have shown that alterations in calcium homeostasis can slow the myocardial and cardiomyocyte relaxation rate and increase viscoelastic stiffness.<sup>57-59</sup> Abnormal calcium homeostasis can lead to an increase in the residual diastolic actin myosin cross-bridge cycling and persistent diastolic activation which can resist force decline and lengthening.

### Myofilaments (see also Chapter 3)

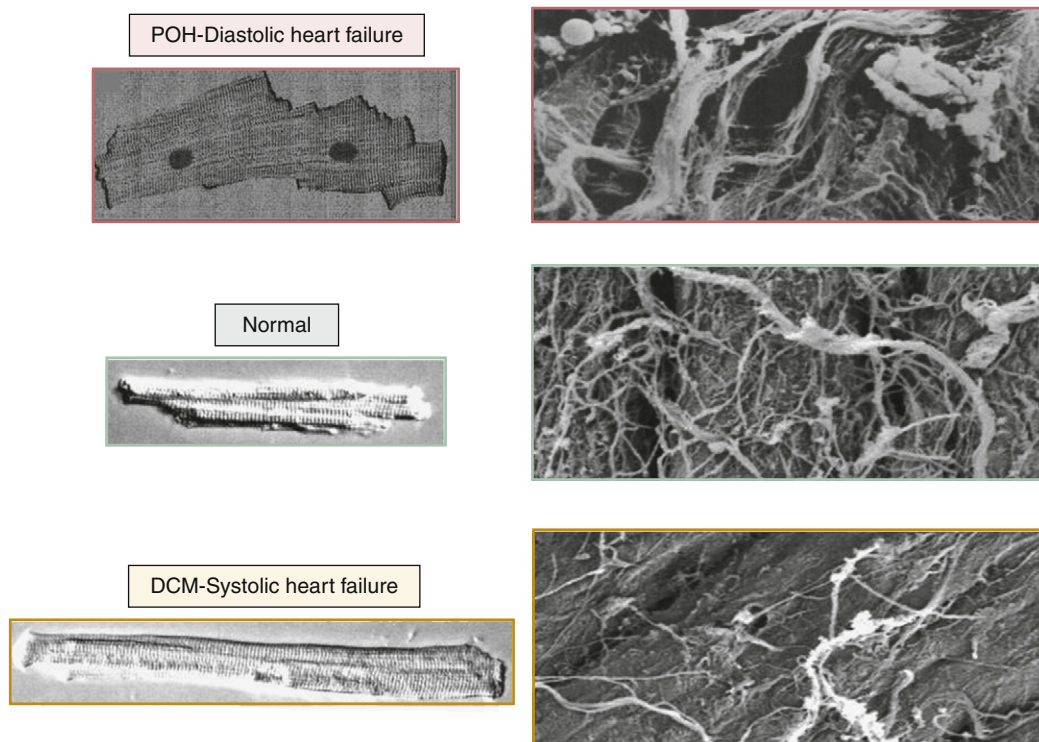

The myofilament contractile proteins consist of thick filament myosin and thin filament actin proteins. Bound to actin are a complex of regulatory proteins, which include tropomyosin and troponin-T, C, and I. During relaxation, ATP hydrolysis is required for myosin detachment from actin, calcium dissociation from Tn-C, and active sequestration of calcium by the sarcoplasmic reticulum (Figure 14-16). Modification of any of these steps, the myofilament proteins involved in these steps, or the ATPase that catalyzes them can alter diastolic function.<sup>23-27</sup> In the relaxed state, in the absence of calcium, myosin cannot bind to actin because the binding site is occupied by troponin-I. During contraction when calcium and ATP become available, calcium is bound to Tn-C, a conformational change in this protein complex occurs, Tn-I dissociates from actin, tropomyosin shifts toward the middle of the actin filament, and myosin can bind to actin. Myosin ATPase catalyzes ATP hydrolysis, causing a conformational change in the actin myosin cross-bridge and contraction. During relaxation, additional ATP hydrolysis is required for myosin detachment from actin, calcium dissociation from Tn-C, and active sequestration of calcium by the sarcoplasmic reticulum. Modification of any of these steps or the proteins involved can alter diastolic function.

### Energetics (see also Chapter 7)

Relaxation is an energy-consuming process. Energetic factors necessary to maintain normal diastolic function include the requirement that the concentration of the products of ATP hydrolysis (adenosine diphosphate, ADP and inorganic phosphate, Pi) must remain low and produce the appropriate relative ADP/ATP ratio.<sup>24-27</sup> Diastolic dysfunction will occur if the absolute concentration of ADP or Pi increases or if the relative ratio of ADP/ATP rises. Abnormalities in these energetics factors may be caused by a limited ability to recycle ADP to ATP because of a decrease in phosphocreatine (PCr). These kinds of abnormalities in energetics have been found in clinical pathological conditions of pressure overload and ischemia/reperfusion where diastolic function is clearly abnormal.<sup>24-27</sup>

**FIGURE 14-13** Examples of autopsy and echocardiographic LV short axis cross-sectional images in normal control subjects, patients with systolic heart failure (SHF), and diastolic heart failure (DHF). Patients with SHF are characterized by eccentric remodeling with increased LV volume, increased LV mass, and a decreased mass/volume ratio. Patients with DHF are characterized by concentric remodeling with increased LV mass, no change in LV volume, and an increased mass/volume ratio.

**FIGURE 14-14** Examples of cardiomyocyte and extracellular matrix (ECM) changes in systolic heart failure (SHF) and diastolic heart failure (DHF) compared with normal. DHF has an increased cardiomyocyte diameter, little or no change in length, and markedly increased ECM fibrillar collagen. SHF has an increased cardiomyocyte length, little or no change in diameter, and disrupted ECM fibrillar collagen.

## BOX 14–1 Diastolic Heart Failure: Mechanisms

- A. Extramyocardial
  1. Hemodynamic load: early diastolic load, afterload
  2. Heterogeneity
  3. Pericardium
- B. Myocardial
  1. Cardiomyocyte
    - a. Calcium homeostasis
      - 1) Calcium concentration
      - 2) Sarcolemmal and sarcoplasmic reticulum calcium transport function
      - 3) Modifying proteins (phospholamban, calmodulin, calsequestrin)
    - b. Myofilaments
      - 1) Troponin-C calcium binding
      - 2) Troponin-I phosphorylation
      - 3) Myofilament calcium sensitivity
      - 4)  $\alpha/\beta$ -myosin heavy chain ATPase ratio
    - c. Energetics
      - 1) ADP/ATP ratio
      - 2) ADP and Pi concentration
    - d. Cytoskeleton
      - 1) Microtubules
      - 2) Intermediate filaments (desmin)
      - 3) Microfilaments (actin)
      - 4) Endosarcomeric skeleton (titin, nebulin)
  2. Extracellular matrix
    - a. Fibrillar collagen homeostasis
    - b. Basement membrane proteins
    - c. Proteoglycans
    - d. MMP/TIMP
  3. Neurohormonal activation
    - a. Renin-angiotensin-aldosterone
    - b. Sympathetic nervous system
    - c. Endothelin
    - d. Nitric oxide
    - e. Natriuretic peptides

Abbreviations: *ATP*, adenosine triphosphate; *ADP*, adenosine diphosphate; *Pi*, inorganic phosphate; *MMP*, matrix metalloproteinase; *TIMP*, tissue inhibitor of matrix metalloproteinase.

### Cytoskeleton

The cardiomyocyte cytoskeleton is composed of microtubules, intermediate filaments (desmin), microfilaments (actin), and endosarcomeric proteins (titin, nebulin,  $\alpha$ -actinin, myomesin, M-protein).<sup>79</sup> Changes in some of these cytoskeletal proteins have been shown to alter diastolic function.<sup>57-59,79-83</sup> Changes in titin isoforms have been shown to alter relaxation and viscoelastic stiffness (Figure 14-17). During contraction, potential energy is gained when titin is compressed and during diastole, titin acts like viscoelastic springs, expends this stored potential energy, and provides a recoiling force to restore the myocardium to its resting length.<sup>81,82</sup> In addition, titin extension during diastole is limited and protects the myocardium from being stretched too far beyond resting length. In experimental end-stage dilated cardiomyopathy, titin isoforms and distribution have been shown to change in a manner that confers an increase in stiffness.<sup>82</sup> Likewise, an increase in microtubule density and distribution has been shown in some forms of pressure overload to act as a viscous load and increases myocardial and cardiomyocyte viscoelastic stiffness.<sup>57-59,80</sup> This change in diastolic function is reversible when microtubules are acutely depolymerized by chemical or physical agents.<sup>57-59,80</sup>

### Extracellular Matrix (see also Chapter 5)

Changes in the structures within the extracellular matrix (ECM) can also affect diastolic function. The myocardial ECM is composed of three important constituents: (1)

fibrillar protein such as collagen type I, collagen type III, and elastin; (2) proteoglycans; and (3) basement membrane proteins, such as collagen type IV, laminin, and fibronectin. It has been hypothesized that the most important component within the ECM contributing to the development of diastolic heart failure is fibrillar collagen.<sup>84-88</sup> Within the myocardial ECM, fibrillar collagen exists in a complex 3D, geometric distribution. This distribution is divided into three layers: (1) endomysial collagen, which surrounds and connects individual cardiomyocytes; (2) perimysial collagen, which surrounds and connects bundles of cardiomyocytes; and (3) epimysial collagen, which forms the outermost layer (Figure 14-18). Because these fibrillar proteins surround and envelope individual and groups of cardiomyocytes, it has been hypothesized that in normal myocardium they connect cardiomyocytes into fascicular structures, coordinate their mechanical activity, transmit and transduce mechanical and perhaps neurohumoral input, protect against and limit cardiomyocyte strain, and coordinate and recruit preload recruitable work. The evidence that suggests that changes in ECM fibrillar collagen play an important role in the development of diastolic dysfunction and diastolic heart failure follows three lines of evidence. First, disease processes that alter diastolic function also alter ECM fibrillar collagen particularly in terms of its amount, geometry, distribution, degree of cross-linking and ratio of collagen type I versus collagen type III. Second, treatment of these disease processes, which is successful in correcting diastolic function, is associated with normalization of fibrillar collagen. Finally, experiments in which a chronic alteration in collagen metabolism is performed results in an alteration of diastolic function.<sup>89-94</sup> The role played by other fibrillar proteins, the basement membrane proteins, and the proteoglycans remains largely unexplored.

The regulatory control of collagen homeostasis has a number of major determinants: transcriptional regulation of procollagen biosynthesis by physical, neurohormonal, and growth factors; postsynthetic procollagen processing influenced by matricellular and extracellular proteins and peptides; post-translational regulation including collagen cross-linking; and fibrillar collagen degradation influenced by matrix metalloproteinases (MMPs) and their endogenous tissue inhibitors (TIMPs) (Figure 14-19). Collagen synthesis is altered by load, including preload and afterload; neurohumoral activation, including the renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous system; and growth factors. Collagen degradation is under the control of proteolytic enzymes, including a family of zinc dependent enzymes—the matrix metalloproteinases (MMP).<sup>95-97</sup> The balance between synthesis, processing, posttranslational modification, and degradation results in the total fibrillar collagen content present in a given pathological state. Changes in each of these determinants and their regulatory processes have been shown to alter diastolic function and lead to the development of diastolic heart failure.

Fibrillar collagen biosynthesis begins within the fibroblast endoplasmic reticulum with the synthesis of procollagen  $\alpha$ -chain monomeric proteins.<sup>98,99</sup> These monomers undergo hydroxylation, glycosylation, and disulfide bond formation to form the triple helical structure of a procollagen molecule. After synthesis, a procollagen molecule is secreted into the extracellular space where it must undergo a series of very ordered time-sensitive and location-sensitive sequential post-synthetic processing steps in order to become a mature cross-linked insoluble structural collagen fibril.

Once secreted into the extracellular space, postsynthetic procollagen processing can have two major outcomes: (1) ordered procollagen processing within the extracellular space that favors formation of, or incorporation into, a mature cross-linked insoluble structural collagen fibril, or (2) procollagen association with cell surface receptors, which leads to

**FIGURE 14-15** Left panel—Examples of normal (solid line) and abnormal (dashed line) calcium transients (top) and cardiomyocyte contractions (bottom). Calcium transient is prolonged, calcium decay is slowed, cardiomyocyte lengthening rate is slowed in a cardiomyocyte with abnormalities in calcium homeostasis. Right panel—Schematic drawing showing steps involved in calcium homeostasis during diastole. Calcium is released from myofilaments (A), sequestered into the sarcoplasmic reticulum (B), and calcium is extruded into the extracellular space (C). Changes in any of these steps, or the proteins that cause them, can result in the abnormalities shown in the left panel and abnormalities in relaxation and stiffness.

### RELAXATION (DIASTOLE)

**FIGURE 14-16** Schematic of myofilament proteins during contraction and relaxation. Tn, troponin; ATP, adenosine triphosphate; ADP, adenosine diphosphate;  $Ca^{2+}$ , calcium. Changes in the structure or function of any of these myofilament proteins may result in abnormalities in relaxation and stiffness.

FIGURE 14-17 Schematic of titin molecule.

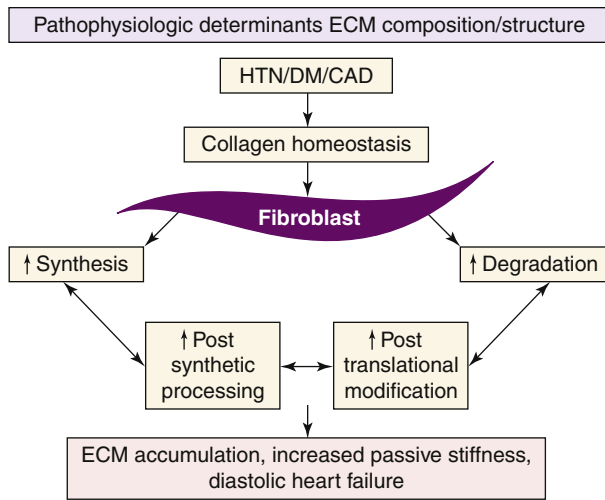

FIGURE 14-18 Schematic of fibrillar collagen distribution within the myocardial extracellular matrix.

**FIGURE 14-19** Schematic of the determinants of extracellular matrix (ECM) composition and structure. Pathological processes such as hypertension (HTN), diabetes (DM), and coronary artery disease (CAD) act on the myocardial fibroblast to change rates of synthesis, processing, posttranslational modification, and degradation.

degradation of procollagen before incorporation into a mature cross-linked insoluble structural collagen fibril, and/or premature disordered procollagen processing associated with the cell surface, which does not promote formation of, or incorporation into, a mature cross-linked insoluble structural collagen fibril. To form a mature collagen fibril, procollagen is processed by extracellular determinants. The C-terminal propeptide of procollagen must be cleaved by BMP-1 (bone morphogenetic protein or related tolloid receptors). The activity of BMP-1 is enhanced by PCPE-1 (procollagen C-proteinase enhancer 1) and 2. The N-terminal propeptide of procollagen is cleaved by ADAMTS-2 (a disintegrin-like and metalloproteinase domain with a thrombospondin-type motif). The resulting collagen molecules are then cross-linked into mature collagen fibrils. The covalent intermolecular cross-linkages are catalyzed by the enzymes lysyl oxidase and hydroxylysyl oxidase. This procollagen processing is highly ordered and appears to be most efficient in leading to formation of, or incorporation into, a mature cross-linked insoluble structural collagen fibril when it occurs in the extracellular space. Factors that decrease procollagen association with the cell surface increase collagen incorporation into mature collagen fibrils. The process of procollagen processing can be influenced by “matricellular” proteins; SPARC is one example.<sup>98,99</sup> SPARC is a procollagen-binding protein with counteradhesive activity, which is hypothesized to coordinate procollagen processing and facilitate collagen fibril assembly and formation. Studies by Bradshaw et al have shown that when SPARC binds to newly secreted procollagen in LV myocardial tissues and fibroblasts it chaperones the procollagen molecule through processing within the extracellular space and limits binding of procollagen to cell surface receptors such as transmembrane  $\alpha_1\beta_1$  integrin.<sup>98,99</sup> By diminishing procollagen engagement of cell surface receptors, SPARC facilitates the optimal sequence and timing of the processing steps and prevents procollagen from being prematurely degraded or improperly processed. Processing of procollagen to form a mature cross-linked insoluble structural collagen fibril does not absolutely require SPARC but SPARC enhances and facilitates this process. In studies of animal models of pressure overload, changes in matricellular and other extracellular proteins and peptides have been shown to be one mechanism that contributes to the development of diastolic dysfunction that underlies the clinical syndrome of DHF.

Myocardial collagen structure and composition can also be altered by changes in posttranslational modification (PTM).<sup>100-105</sup> Collagen can be cross-linked enzymatically by lysyl oxidase acting shortly after collagen fiber synthesis. In addition, and potentially more important to changes seen in DHF, collagen can also undergo nonenzymatic cross-linking that begins with formation of advanced glycation end products (AGEs). AGE-modified collagen forms nonenzymatic cross-links that change the physical properties of collagen, making collagen more resistant to degradation and increasing collagen content. Myocardial fibroblasts express cell surface receptors for AGE-modified proteins (such as RAGE, receptor for age-modified proteins). RAGE binds AGE-modified proteins and begins a signal transduction process that can result in an increase in bioactive proteins and peptides that can increase collagen synthesis, decrease degradation, and increase the number of RAGEs present.<sup>107-113</sup> Myocardial AGE/RAGE interaction may contribute to the development of diastolic dysfunction and DHF. Currently both clinical and animal experiments are being conducted that will test the hypothesis that in DHF there are an increased number of AGE-modified proteins and increased interaction with RAGE, which together play a causal role in the development of diastolic dysfunction and DHF.

Collagen degradation is influenced by the zinc-dependent interstitial proteases, MMPs. MMPs are generally grouped into classes according to their enzyme activity and the proteins and structures that they act upon. The activity of MMPs is regulated by TIMPs.<sup>106</sup> TIMPs bind to the activated MMP or proMMP in a 1:1 stoichiometric molar ratio and therefore form an important endogenous system for regulating MMP activity in vivo. Changes in MMP and TIMP levels can be measured in myocardial tissue and plasma samples. Both tissue and plasma techniques have been applied to animal models of POH and patients with clinical evidence of POH. Data suggest that changes in MMP/TIMP stoichiometry and expression play an important role in the structural and functional remodeling during the development of diastolic dysfunction and DHF. Ongoing studies are examining what ECM-regulatory mechanisms that control how MMP/TIMP dependent change LV/ECM structure/function or cause the development of diastolic dysfunction.

#### Neurohormonal

Both acutely and chronically, neurohumoral and cardiac endothelial activation and/or inhibition have been shown to alter diastolic function.<sup>114-118</sup> Chronic activation of the RAAS has been shown to increase ECM fibrillar collagen and can be associated with increased stiffness. Inhibition of RAAS prevents or reverses this increase in fibrillar collagen and generally but not consistently reduces myocardial stiffness. In addition, acute activation or inhibition of neurohumoral and cardiac endothelial systems have been shown to alter relaxation and stiffness. These acute pharmacological interventions act in a time frame too short to alter the ECM; therefore their effect on diastolic function must be caused by acting directly on the cardiomyocyte to alter one or more cellular determinants of diastolic function. For example, acutely treating patients with pressure overload with an angiotensin-converting enzyme (ACE) inhibitor, a direct NO donor, or an indirect endothelin dependent NO donor, caused LV pressure decline and LV filling to be more rapid and complete and caused the LV pressure versus volume relationship to shift to the right, decreasing stiffness. In addition, there is a cyclical release of NO in the heart, most noted subendocardially, which peaks at the time of relaxation and filling. These brief bursts of NO release provide a beat-to-beat modulation of relaxation and stiffness.<sup>119</sup>

It is now generally recognized that heart failure progresses through a process of structural remodeling (see Chapters 9 and 10) of the heart to which neurohormonal and cytokine activation make an important contribution (see Chapter 11). The term *ventricular remodeling* refers to deviation in ventricular architecture from normal, with changes in volume, wall thickness, and/or shape. The term has initially been applied to the pathological changes, related to myocardial hypertrophy and fibrosis with associated chamber dilation, that have been well described following a large myocardial infarction.<sup>1-3</sup> The term has also been applied to other conditions associated with ventricular dilation in a spherical configuration and eccentric myocardial hypertrophy, referred to as “dilated cardiomyopathy,” and to conditions associated with concentric left ventricular (LV) hypertrophy with a normal or reduced chamber volume, as is seen in hypertensive heart disease. There is now a large body of evidence indicating that these forms of pathological ventricular remodeling are independently associated with adverse clinical outcomes, and more importantly, that interventions that attenuate or reverse these changes are usually associated with improved clinical outcomes (see Chapter 8).<sup>4</sup>

## REMODELING CONCEPT OF HEART FAILURE

It is well known that the heart can enlarge or shrink in response to hemodynamic demands (Figure 15-1).<sup>5</sup> Critical to our understanding of heart failure are observations that heart failure is related to progres-

sive alterations in structure and function of the heart. The earliest reference to the role of cardiac structure in the development of heart failure dates back to the nineteenth century.<sup>6</sup> In *The Principles and Practice of Medicine*, William Osler pointed to hypertrophy as a step in the development of heart failure, since it is followed by a “period of broken compensation . . . that commonly takes place slowly and results from degeneration and weakening of the heart muscle.”<sup>7</sup> However, in the modern era, Linzbach has been credited for being the first to recognize that alterations in cardiac structure are the primary determinants of heart failure, and that LV weight of about 200 g was critical in the natural history of the disorder.<sup>8</sup>

hypertrophic growth of the heart was seen as “compensatory” and hence beneficial.<sup>9,10</sup> Animal models of pressure overload led Meerson to suggest that cardiac growth induced by biomechanical stress plays a protective role, at least in the short term.<sup>11</sup> Moreover, in the 1970s and 1980s, hemodynamic measurements in patients with valvular heart disease provided support for the concept of adaptive hypertrophic growth, which when “inadequate” could lead to systolic dysfunction.<sup>12-14</sup>

Recent clinical studies have called into question the idea that structural changes of the ventricle are adaptive and protective. Progressive LV hypertrophy, enlargement, and cavity distortion over time have consistently been shown to be directly related to deterioration of LV performance and an increase in mortality and morbidity<sup>15-19</sup> irrespective of the cause of heart failure.<sup>20</sup> Current concepts of ventricular remodeling have largely been derived from studies on patients and animal models of myocardial infarction.<sup>21-24</sup> However, the idea that changes in ventricular size and shape are a dynamic response to hemodynamic and metabolic needs imposed on the ventricle was firmly established in the early experimental work on hypertension. Studies by Chanutin and Barsdale<sup>25</sup> on an experimental model of arterial hypertension demonstrated that LV weight and myocyte fiber diameter increased in relation to the severity of hypertension. Later, Janice Pfeffer et al<sup>26,27</sup> studied the relationship between LV mass and function over time in the spontaneously hypertensive rat model. They demonstrated that despite continuous and marked LV wall thickening, the left ventricle eventually dilates and then fails. At this stage, the stimulus for LV hypertrophy is not only elevated arterial pressure, but also chamber dilation that further aggravates the hemodynamic load by increasing wall stress. This seminal finding laid the foundation for the concept that regardless of the initial insult, ventricular dilation may become a self-sustaining process of deterioration in LV structure and function. In effect, progressive chamber enlargement becomes a stimulus for further ventricular hypertrophy and dilation, without additional myocardial injury.

It is well known that the heart can enlarge or shrink in response to hemodynamic demands (Figure 15-1).<sup>5</sup> Critical to our understanding of heart failure are observations that heart failure is related to progres-

sive alterations in structure and function of the heart. The earliest reference to the role of cardiac structure in the development of heart failure dates back to the nineteenth century.<sup>6</sup> In *The Principles and Practice of Medicine*, William Osler pointed to hypertrophy as a step in the development of heart failure, since it is followed by a “period of broken compensation . . . that commonly takes place slowly and results from degeneration and weakening of the heart muscle.”<sup>7</sup> However, in the modern era, Linzbach has been credited for being the first to recognize that alterations in cardiac structure are the primary determinants of heart failure, and that LV weight of about 200 g was critical in the natural history of the disorder.<sup>8</sup>

In the 1960s, a different view of LV hypertrophy and enlargement began to emerge. In accordance with Laplace’s law, which dictates that afterload-induced increases in systolic wall stress are offset by increases in wall thickness,

**FIGURE 15-1** Conditions leading to remodeling of the heart and resulting in atrophy or hypertrophy. Depending on the circumstances, remodeling can be normal or pathological. Pathological remodeling is associated with a propensity toward decompensation, ventricular dilation, systolic dysfunction, and electrophysiological changes leading to malignant ventricular arrhythmia. (From Hill JA, Olson EN. Cardiac plasticity. *N Engl J Med* 2008;358:1370-1380.<sup>5</sup>)

A recent consensus statement helped define remodeling as the “genomic expression resulting in molecular, cellular and interstitial changes that are manifested clinically as changes in size, shape and function of the heart after cardiac injury.<sup>28</sup>” The remodeling process is regulated by mechanical, genetic, and neurohormonal factors.<sup>29</sup> The importance of ventricular remodeling has increased with the observation that agents such as inhibitors of the sympathetic and renin-angiotensin-aldosterone systems that have beneficial effects in heart failure also generally attenuate or reverse ventricular remodeling (see Chapters 8, 45, and 46),<sup>30-34</sup> whereas agents that fail to improve clinical outcomes either have no effect on remodeling or have been associated with adverse remodeling.<sup>4</sup> Ventricular remodeling has therefore emerged as a credible surrogate endpoint and an important therapeutic target in heart failure.<sup>35,36</sup>

## MECHANISMS OF LEFT VENTRICULAR REMODELING

Although ventricular remodeling may occur following any form of myocardial injury,<sup>20</sup> most of our knowledge has been acquired from the study of remodeling following myocardial infarction. Acute coronary occlusion in the clinical setting or in the experimental animal leads to loss of myocardial tissue, depression of myocardial function, and hypotension. This causes baroreceptor-mediated activation of a number of neurohormones that help stabilize the hemodynamics through an increase in heart rate, contractility, and fluid retention. However, continuous activation of these mechanisms, designed for short-term support of blood pressure,<sup>37</sup> may lead to progressive LV remodeling and dysfunction. Two distinct phases

have been identified following myocardial infarction: early infarct expansion and late progressive LV remodeling.

### Early Postinfarct Left Ventricular Remodeling

Loss of regional wall function after acute myocardial infarction results in an abrupt increase in loading conditions of the ventricle that brings on a unique pattern of remodeling involving the infarct area and border zone and the remote noninfarcted myocardium. Thinning and stretching of the acutely infarcted myocardium leads to infarct expansion, the first feature of LV remodeling.<sup>21,22</sup> Although later thinning of the LV wall also occurs in the noninfarcted myocardium, the cellular mechanisms are different in the two regions. In infarcted myocardium, as expected, wall thinning is pronounced and is a result of the loss of myocytes, collapse of the intercellular space, and stretching of surviving myocytes.<sup>21-23,38,39</sup> This may lead to bulging of the infarct zone that may result in ventricular rupture, aneurysm, mitral insufficiency, and ventricular tachyarrhythmias. In the noninfarcted regions, the myocardium thins because of a decrease in the number of myocytes across the wall.<sup>38,39</sup> Two mechanisms—myocyte slippage,<sup>38</sup> and myocyte loss from necrosis<sup>40-42</sup> and apoptosis<sup>41,43</sup>—have been proposed to explain this decrease.

It has been suggested that “myocyte slippage” plays a major role in progressive chamber dilation leading to failure,<sup>8,38,44</sup> though much of the literature mentioning this phenomenon is rather vague. This concept usually refers to slippage of myocytes past one another transversely or linear slippage of individual myofibrils within myocytes.<sup>44,45</sup> It would seem more likely that linear slippage of myocytes past one another could occur only at fascial planes because of the

234 complex interdigitating connections between myocytes and the presence of intermyocyte collagen struts.<sup>46</sup>

It is believed that increased myocardial collagenase activity (see later discussion) disrupts intermyocyte collagen struts, leading to side-to-side slippage of myocyte (see Chapter 5).<sup>47</sup> Such a process could reduce wall thickness and increase the volume of the ventricle. Linzbach<sup>44</sup> and others<sup>38</sup> have noted a reduction in the number of myocytes across the wall as evidence of myocyte slippage. However, this explanation may be too simplistic. For a meaningful discussion of the slippage concept, however, we need to take into account the three-dimensional nature of myocyte-to-myocyte interconnections. Each myocyte is connected to an average of 5 to 10 neighboring myocytes via end-to-end and side-to-side intercalated disks (Figure 15-2).<sup>48</sup> Slippage implies disruption of intercalated disks. Once the disks are disrupted, they may be unable to reconnect, resulting in poorly coordinated contractions. If, however, disks at the ends of the main body of the cell were to be disrupted, disks on smaller side-to-side branches may remain intact, and contractile coordination between cells may be impaired but not destroyed. Thus myocyte slippage could occur if there is disruption of intercalated disks and loss of intermyocyte collagen struts. However, such widespread disruption of the intercalated disks has not been demonstrated, and this attractive hypothesis remains controversial and unproven. This issue is complicated by likely sliding and rearrangement of myocyte bundles along fascial planes, especially during contraction.

#### Factors Affecting the Magnitude of Remodeling after Myocardial Infarction

The magnitude of infarct expansion and development of LV remodeling depend on a number of factors. The most important determinant is the extent of myocardial damage. In the rat model, the increase in LV diastolic volume has been related to the size of the infarct and correlated with the extent of impaired systolic performance.<sup>49,50</sup> A critical infarct size of 17% of LV myocardium was necessary for significant infarct expansion, and the degree of expansion correlated with infarct size occurring in 66% of transmural infarcts but in none of the nontransmural infarcts.<sup>22</sup> Preservation of a normal LV contour was observed in only 20% of the myocardial infarction in that series.<sup>22</sup> Likewise, infarct expansion is observed more frequently in patients with large anterior transmural infarction compared with other regions of the left ventricle.<sup>51-53</sup> Distortion of the ventricular contour leading to aneurysm formation is frequent in patients with infarct expansion and is associated with increased mortality and morbidity.<sup>1</sup> Patients developing an aneurysm early in the course of anterior infarction have a much higher 1-year mortality than patients with anterior infarction and comparably reduced ejection fraction but without aneurysm.<sup>54</sup>

The loading conditions of the ventricle are also of central importance in influencing ventricular remodeling and eventual outcome. In dogs, early transient increases in afterload after an acute myocardial infarction have been shown to increase infarct expansion and thinning, and slow infarct healing.<sup>55</sup> In the rat, sustained increase in afterload following aortic banding also increased infarct expansion independent of infarct size.<sup>56</sup> Patients with hypertension and LV hypertrophy have increased morbidity and mortality after myocardial infarction.<sup>57</sup> Thus careful afterload reduction early in the course of myocardial infarction may have important effects on LV remodeling by reducing infarct expansion and limiting infarct size.<sup>58</sup>

Patency of the infarct-related coronary artery may also confer a beneficial effect on ventricular remodeling and long-term survival. In patients with acute myocardial infarction, the prompt restoration of antegrade flow in the infarct-related coronary artery, whether accomplished pharmacologically<sup>59</sup> or mechanically,<sup>60</sup> improves LV systolic function and reduces

**FIGURE 15-2** Scanning electron micrograph (top) and a drawing (bottom) of the cardiac myocardial fibers. The cardiocyte Ci connects with five neighboring cardiomyocytes (A<sub>1</sub>, A<sub>2</sub>, C<sub>1</sub>, C<sub>2</sub>, and C<sub>3</sub>). (From Yamamoto S, et al. Generation of new intercellular junctions between cardiomyocytes. A possible mechanism compensating for mechanical overload in the hypertrophied human adult myocardium. *Circ Res* 1996;78:362-370.<sup>48</sup>)

mortality. Initially, these salutary effects of reperfusion therapy were thought to be tightly linked: successful reperfusion salvaged ischemic but still viable myocardium, which led to improved LV function and, in turn, improved survival. Conversely, reperfusion of the infarct-related artery more than 12 hours after the onset of infarction was thought not to achieve these beneficial results. However, several studies suggested that the effects of reperfusion on LV function and survival might, to some extent, be independent of one another. In the Western Washington trial,<sup>61</sup> fibrinolytic therapy (with streptokinase) improved survival without improving LV function. In the Second International Study of Infarct Survival,<sup>62</sup> streptokinase reduced mortality even when given 13 to 24 hours after the onset of chest pain, at a time when myocardial salvage was unlikely. These initial studies formed the basis for the so-called open-artery hypothesis: that the restoration of antegrade flow in the infarct-related artery days, weeks, or even several months after myocardial infarction would improve survival even though LV function did not improve. The Occluded Artery Trial was a large randomized, prospective study assessing the open-artery hypothesis.<sup>63</sup> The study unequivocally demonstrated that the late restoration of antegrade flow did not reduce the incidence of death, reinfarction, or heart failure. In the Total Occlusion Study of Canada (TOSCA)-2 Trial,<sup>64</sup> opening a persistently occluded infarct-related artery beyond the acute phase of myocardial

infarction effectively maintained long-term artery patency but had no effect on LV dimensions and ejection fraction.

## Late Progressive Postinfarct Left Ventricular Remodeling

Early infarct expansion after myocardial infarction may be followed by progressive ventricular dilation and dysfunction over subsequent months and years, involving predominantly the noninfarcted segments. The mechanisms responsible for this inexorable deterioration of LV structure and function are not entirely clear but are related to continued activation of neurohormones and cytokines such as norepinephrine, angiotensin II, aldosterone, endothelin, and tumor necrosis factor. These factors, in combination with increased wall stress and mechanical stretch of the myocytes, upregulate a large number of signaling pathways (see later discussion), leading to structural and functional changes in the myocyte and non-myocyte compartments that underlie a reduction in LV function and the progression of heart failure. In the discussion that follows, changes in these individual components will be described and their implications discussed.

## ALTERATIONS IN THE MYOCYTE COMPARTMENT

The remodeling process results in important changes in the cardiac myocytes. These include myocyte hypertrophy, myocyte loss by necrosis<sup>41,42,65</sup> and apoptosis,<sup>41,66-69</sup> and changes in the structural proteins with downregulation of contractile and sarcomeric skeleton proteins, and upregulation of cytoskeletal and membrane-associated proteins.<sup>70</sup> In addition, loss of myofilaments, nuclear enlargement, development of multiple small mitochondria, and a decrease in the T-tubular system and sarcoplasmic reticulum are common histological features of the failing myocardium.<sup>71</sup>

### Myocyte Hypertrophy

Individual cardiac myocytes are considered terminally differentiated cells that are unable to reenter the cell cycle, and, therefore, the postnatal growth of cardiac myocytes occurs through hypertrophy of existing cells.<sup>72-74</sup> In nonmyocyte cells, which include both fibroblasts and endothelial cells, growth is predominantly through a hyperplastic process.<sup>75</sup>

Grossman and coworkers proposed that alterations in myocyte shape and size determine the type of cardiac hypertrophy.<sup>76</sup> In conditions with pressure overload such as aortic stenosis or hypertension, parallel addition of sarcomeres causes an increase in myocyte cross-sectional area with no increase in myocyte length (Figure 15-3).<sup>77-79</sup> This leads to an increase in wall thickness and concentric LV hypertrophy (increase in ratio of wall thickness to chamber dimension).<sup>76,80</sup> In conditions with volume overload such as aortic and mitral regurgitation, ventricular volume and wall thickness increase proportionally, and this is associated with a corresponding proportional increase in both myocyte length and cross-sectional area (addition of sarcomeres both in parallel and series)<sup>81</sup> (see Figure 15-3). It appears that during the compensated stage of concentric LV hypertrophy, wall stress does not increase.

After a large myocardial infarction, progressive LV dilation is due to an increase in myocyte size, which occurs predominantly by laying of sarcomeres in a series, resulting in an increase in myocyte length, with only a mild increase in width and cross-sectional area<sup>82-85</sup> (Figure 15-4). This further increases cavity volume with no change or a decrease in wall thickness. Myocyte length is the major determinant of changes in LV size, and most of the increase in LV

**FIGURE 15-3** Schematic representation of myocyte change in left ventricular concentric and eccentric hypertension. In pressure overload hypertrophy, myocyte cross-sectional area increases and the ventricular wall becomes thicker during the compensatory phase. In volume overload hypertrophy, ventricular volume and wall thickness increase proportionally, and this is associated with a corresponding proportional increase in both myocyte length and cross-sectional area (CSA). CSA  $\propto$  L, cross-sectional area and length. (From Gerdes AM. The use of isolated myocytes to evaluate myocardial remodeling. *Trends Cardiovasc Med* 1992;2:152-155.<sup>79</sup>)

volume can be explained by an increase in myocyte length (Figure 15-5).<sup>82,84-86</sup> Although LV mass increases, the increase in LV volume is proportionately greater, so that mass-to-volume ratio, an important determinant of wall stress, is reduced. Development of myocardial hypertrophy after myocardial infarction, therefore, results in eccentric hypertrophy (cavity dilation with a decrease in wall thickness to chamber dimension ratio) that increases wall stress.

In volume overload conditions such as mitral and aortic regurgitation, ventricular hypertrophy remains appropriate and helps to maintain normal wall stress for variable periods of time (see Chapter 29). Transition from a compensated to a decompensated state is associated with a further increase in chamber volume but no increase in wall thickness. This results in a decrease in mass-to-volume ratio and an increase in wall stress. The cellular mechanisms responsible for this are not entirely clear, but they could be related to an arrest in the growth of the myocytes in the transverse diameter, resulting in myocyte lengthening without further change in myocyte cross-sectional area. Studies of mitral regurgitation in the dog, and in patients at the time of mitral valve surgery also show a decrease in myocardial myosin content, proportional to degree of LV dysfunction.<sup>81,87</sup> Thus reduced contractility in mitral regurgitation could, in part, be due to loss of contractile elements. Although aortic and mitral regurgitation are often considered together as volume overload conditions, the two have their specific pathophysiological features.

In aortic regurgitation, the sum of the regurgitant and forward stroke volume is ejected into the aorta in systole, resulting in a wide pulse pressure and systolic hypertension. Therefore, aortic regurgitation creates both volume and pressure overload on the left ventricle. Systolic wall stress is always higher in aortic regurgitation than in mitral regurgitation,<sup>88</sup> and is often as high as in aortic stenosis (the classic pressure overload condition).<sup>89</sup> These different loading conditions in mitral and aortic regurgitation create two different types of ventricular geometry. In mitral regurgitation, there is an enlarged thin-walled left ventricle in which the mass-to-volume ratio is less than 1.0.<sup>90</sup> In contrast, in aortic regurgitation, the mass-to-volume ratio is normal at 1.0.<sup>91</sup> Whether the cellular hypertrophy, at the onset of failure, is different in these two conditions remains to be determined.

**FIGURE 15-4** Cardiac myocyte remodeling in the rat infarct model. Myocyte length and width from rats 1, 2, 4, and 6 weeks after myocardial infarction are compared with those from a sham-operated animal. Note that myocyte hypertrophy after myocardial infarction is predominantly due to an increase in myocyte length. MI, Myocardial infarction. (From Anand IS, Liu D, Chugh SS, et al. Isolated myocyte contractile function is normal in postinfarct remodeled rat heart with systolic dysfunction. *Circulation* 1997;96(11):3974-3984.<sup>85</sup>)

**FIGURE 15-5** Scatterplot showing the relation between left ventricular volume and mean length of myocytes obtained from 1- to 6-week-old post-MI rat hearts ( $r = 0.79$ ). The relationship suggests that most of the increase in LV volume after MI could be explained by an increase in myocyte length. (From Anand IS, Liu D, Chugh SS, et al. Isolated myocyte contractile function is normal in postinfarct remodeled rat heart with systolic dysfunction. *Circulation* 1997;96(11):3974-3984.<sup>85</sup>)

In pressure-overload conditions, concentric ventricular hypertrophy (thick wall, normal chamber volume, and high mass-to-volume ratio) helps to keep wall stress normal despite high ventricular pressure. Because systolic stress (afterload) is a major determinant of ejection performance, normalization of systolic stress helps to maintain a normal stroke volume despite the need to generate high levels of systolic pressure.<sup>12</sup> Transition to failure is accompanied by progressive cavity enlargement and a decline in the mass-to-volume ratio, resulting in eccentric ventricular hypertrophy. In spontaneously hypertensive rats, transition to failure is preceded by myocyte lengthening without an increase in myocyte cross-sectional area.<sup>77,78</sup> Whether the same occurs in aortic stenosis is not known.

Data from many mammalian species suggest that the myocyte length-to-width ratio is normally regulated within a somewhat narrow range.<sup>92,93</sup> Although the length-to-width

ratio declines slightly in concentric hypertrophy, it remains normal in volume-overload conditions such as arteriovenous fistula, mitral regurgitation, and aortic insufficiency.<sup>81,94</sup> There is a dramatic increase in myocyte length-to-width ratio, however, in ischemic or dilated cardiomyopathy.<sup>84,95</sup> Thus it appears that the onset of myocyte lengthening without transverse growth may be the critical early cellular event elevating wall stress, leading to progressive LV dilation and deterioration of LV function. In postinfarct remodeling, this process may start from the very beginning. Data are not available to confirm whether arrest of myocyte transverse growth is also responsible for the deterioration of LV function in aortic and mitral regurgitation.

#### Mechanisms of Myocyte Hypertrophy and Signaling Pathways

The molecular mechanisms whereby cardiac myocytes regulate the addition of new sarcomeres, in series or parallel, in response to different hemodynamic load and lead to eccentric or concentric LV hypertrophy remain unknown. A clearer understanding of these mechanisms may help develop therapeutic strategies to arrest abnormal myocardial growth.

Myocyte hypertrophy is usually accompanied by complex changes in gene reprogramming (see Chapter 3).<sup>75</sup> These changes include the reexpression of immature fetal cardiac genes such as those for A- and B-type natriuretic peptides (ANP and BNP) and genes that modify motor unit composition and sarcomere deposition.<sup>96,97</sup> However, changes in gene and protein expression may not be identical in the two forms of hypertrophy. For example, the  $\alpha$ -adrenergic agonist phenylephrine, which acts through G protein-coupled receptors, induces a pressure-overloaded type of myocyte hypertrophy, whereas the cytokine-related agonist cardiotrophin-1 produces a volume-overloaded myocyte morphology.<sup>98</sup> The signaling pathways responsible for these differences are not clear.

Reversible protein phosphorylation and/or dephosphorylation play a central role in signal transduction in cardiomyocyte hypertrophy. Although multiple pathways probably mediate hypertrophy, two groups of regulatory proteins: the mitogen-activated protein kinases (MAPKs)<sup>99,100</sup> and  $\text{Ca}^{2+}$ /calmodulin-activated protein kinases/phosphatases<sup>101,102</sup> are considered to be important. The MAPK pathways consist of three major phosphorylation cascades: the extracellular

signal-regulated protein kinases 1 and 2, the c-Jun N-terminal kinases, and the p38 MAPKs.<sup>103-105</sup> When activated, the MAPKs translocate to the nucleus, where their primary targets, the transcription factors, are located.<sup>106</sup> These transcription factors regulate the induction of genes that determine the ultimate biological response of the cells, including cardiac hypertrophy. Recent data suggest that differential activation of MAPKs by systolic and diastolic load may underlie differences between pressure- and volume-overload hypertrophy.<sup>107</sup>

The  $\text{Ca}^{2+}$ /calmodulin-activated protein kinases/phosphatases include  $\text{Ca}^{2+}$ /calmodulin-activated protein kinases (CAM kinases) and calcineurin, a  $\text{Ca}^{2+}$ /calmodulin-dependent phosphatase. Transgenic mice that overexpress components of the calcineurin signaling pathway develop a hypertrophic phenotype that can be suppressed by pharmacological inhibitors of calcineurin.<sup>101</sup> However, calcineurin inhibitors fail to suppress experimental hypertrophy in several animal models<sup>108,109</sup> and in humans with hypertension after cardiac transplantation.<sup>110</sup> These observations suggest that redundant signaling pathways are likely to modulate load-induced hypertrophy, with the potential for recruitment of alternate signaling cascades when a single pathway is suppressed.<sup>111</sup>

How is an increase in myocardial mechanical load sensed and transduced into biochemical events that lead to the addition of sarcomeres in the myocyte? Although the sensor mechanisms are unclear, they are likely to be different for the two types of hypertrophy. The role of the cytoskeleton is probably pivotal in this regard as it is not only involved in cellular stability and integrity but it also plays a significant role in transmitting signals from the cellular membrane to the nucleus.<sup>112</sup> Changes in different loading conditions in the heart may be sensed by the extracellular matrix and transduced by the cytoskeletal proteins, leading to phosphorylation of proteins that then translocate to the nucleus as transcription factors.<sup>113</sup> Integrins can act as mechanoreceptors, and transfer of force from integrins to the cytoskeleton is thought to represent a proximal step in an intracellular mechanical signaling that leads to global cytoskeletal rearrangements.<sup>114</sup>

#### Myocyte Death (see also Chapter 6)

Cell death is an important determinant of progressive cardiac remodeling and LV wall thinning. A reduction of contractile material is a prominent feature in heart failure and myocyte loss may occur either by necrosis or apoptosis.<sup>41</sup>

**Myocyte necrosis:** Necrosis generally occurs in the setting of catastrophic events, such as myocardial infarction or inflammation, and is characterized by severe membrane alterations, release of cell breakdown products, and polymorphonuclear infiltration. However, slow myocyte loss by necrosis is also a common feature of chronic heart failure.<sup>40-42,115</sup> During the progression of heart failure, there is activation of several neurohormones including norepinephrine, angiotensin II, and endothelin. These neurohormones are directly toxic to the myocardium, and have been shown to cause myocyte necrosis in various animal models.<sup>116,117</sup> Moreover, in patients with severe heart failure, circulating levels of troponin are often increased, suggesting ongoing myocyte necrosis.<sup>118,119</sup> Myocyte loss through necrosis probably contributes to progressive LV dilation and wall thinning. Even very low plasma concentrations of troponin are predictive of adverse outcomes in patients with chronic heart failure.<sup>118</sup>

**Myocyte apoptosis:** Apoptosis, or programmed cell death, is an evolutionarily conserved process of cell death, wherein cells die without provoking significant inflammatory response. There is convincing evidence that apoptosis contributes to the progression of heart failure. Apoptosis occurs through a cascade of subcellular events including cytochrome *c* release into the cytoplasm and activation of proteolytic caspases.<sup>120</sup> Activated caspases lead to fragmentation of cytoplasmic proteins, including contractile apparatus.<sup>121</sup> Caspase

3 (the final executioner in the apoptotic cascade) overexpression or activation has been shown to directly reduce the contractile performance of the left ventricle.<sup>122</sup> The degree of myosin cleavage with caspases correlates with the contractile performance of the heart.<sup>123</sup> It has been proposed that the release of cytochrome *c* from mitochondria and contractile protein loss in living heart muscle cells contribute to systolic dysfunction.<sup>120</sup> Apoptosis is involved at multiple points in the natural history of heart failure. This includes initial events such as ischemia, infarction, inflammation, and those events occurring later in established LV dysfunction. Several of the factors implicated in the pathogenesis of heart failure such as myocardial stretch,<sup>124</sup> norepinephrine,<sup>125</sup> angiotensin II,<sup>126,127</sup> tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ), and oxidative stress<sup>128,129</sup> may provoke apoptosis.

While the presence of myocardial apoptosis has been confirmed in end-stage human heart failure<sup>68,69</sup> and in several animal models,<sup>41,43,66,67</sup> questions remain whether apoptosis is a cause or a consequence of heart failure. Myocyte apoptosis may be a factor in the transition from compensated to uncompensated heart failure.<sup>121</sup> This has been demonstrated in several animal models of experimentally induced LV hypertrophy and heart failure.<sup>130-132</sup> Several studies have demonstrated the presence of apoptosis late after myocardial infarction.<sup>133-135</sup> Consistent with the open artery hypothesis, patients with occluded infarct-related arteries tend to have more apoptosis as compared to the ones with patent infarct-related arteries. The presence of apoptosis, late after myocardial infarction, correlates with worsening heart failure, probably via the loss of functional myocardium and increased LV remodeling. In autopsy studies on patients dying 10 to 60 days after MI, myocyte apoptosis in the infarct zones and in areas remote from the infarct site have been found to be a major determinant of adverse LV remodeling.<sup>133,136</sup> This has in general translated into unfavorable hemodynamic performance and adverse clinical outcomes in heart failure.<sup>28</sup>

#### Myocyte Hyperplasia (see also Chapter 4)

Although cardiac myocytes are generally considered to be terminally differentiated cells, unable to regenerate, replicate, and replace damaged myocardium,<sup>73,74</sup> recent observations in human and animal models suggest that under conditions of intense and prolonged stress on the myocardium, myocytes can reenter the cell cycle and replicate.<sup>137,138</sup> The area of cardiac regeneration has gained considerable attention lately, especially with the finding that immature muscle cells and/or autologous stem cells can regenerate function in a previously injured heart.<sup>138-140</sup> Controversy exists concerning the potential for cardiovascular self-repair evidenced by chimerism in an allografted human heart. Several investigators have examined the explanted allografted female hearts transplanted into human male recipients for the presence of Y chromosome-positive cells either in the coronary vasculature or within cardiomyocytes.<sup>141-144</sup> Conflicting results have been obtained. Glaser et al<sup>141</sup> reported that regeneration is possible to a certain degree in the coronary vasculature but fails to occur within cardiomyocytes.<sup>141</sup> In contrast, Quaini et al<sup>144</sup> claimed not only that vascular regeneration occurs, but also that repair of up to 30% of the donor myocardium takes place within 1 month of transplantation. The paradigm shift, from the dogma of nonregenerating myocardium to that of a self-repairing heart, therefore requires proof and further reproduction of the data.<sup>145</sup>

#### Alterations in Myocyte Structural Proteins (see also Chapter 5)

The complexity of events involved in the pathogenesis of ventricular remodeling cannot be solely attributed to myocyte hypertrophy and cell loss. The hypertrophied myocytes in the remodeled failing heart also show alterations in most

238 of the structural proteins (Table 15-1).<sup>70</sup> A brief description of the structural proteins (Figure 15-6), alterations that occur in these proteins in heart failure, and their functional consequences follows.

Contractile Proteins

CH 15 The contractile apparatus includes thick filament myosin and thin filament complexes composed of  $\alpha$ -actin,  $\alpha$ -tropomyosin, and troponins C, I, and T. Ventricular remodeling involves transcriptional and translational downregulation of these proteins with resulting functional consequences.<sup>70</sup> One of the earliest changes is a decrease in  $\alpha$ -myosin heavy chain and an increase in  $\beta$ -myosin heavy chain.<sup>146</sup> Mechanoenergetic alterations commonly accompany remodeling of the contractile machinery. The attachment and detachment of the cross-bridge cycle requires cleavage of ATP. Depression of maximal  $\text{Ca}^{2+}$ -activated myofibrillar ATPase activity (by as much as 50%) was the first biochemical abnormality described in failing human myocardium<sup>147</sup> and reflects a slower rate of cross-bridge cycling in the failing state. An alteration of this magnitude is likely to be an important contributor to myocyte contractile dysfunction.

Sarcomeric Skeleton Proteins

The contractile apparatus is kept in register by different proteins localized in the Z-disk, M-band of the sarcomere, and the giant filament molecule titin, which spans the entire half-sarcomere from the Z-disk to the M-line. The Z-disk is a region of overlapping tails of actin microfilaments, cross-linked by  $\alpha$ -actinin. The M-line is the region where the myosin tails are linked and organized by the M-line proteins—myomesin, M-line protein, and myosin-binding protein C. Titin is anchored with its N-terminus at the Z-disk and reaches the M-line region with its C-terminal head portion where it

interacts with the M-line protein and myomesin.<sup>148</sup> It spans the Z-disk of the sarcomere<sup>149</sup> and overlaps in the M-line region of the sarcomere,<sup>150</sup> thus functioning as a molecular spring and a source of elastic properties of the cardiomyocyte (see Figure 15-6). The interplay between titin and actomyosin suggests a possible role for titin in the Frank-Starling mechanism of the heart.<sup>148</sup> Several studies have reported that the amount of titin is reduced in the myocardium of patients with dilated cardiomyopathy and that this could be responsible for the altered ventricular compliance in this condition.<sup>112,151</sup> Because titin is required for sarcomere formation, lack of titin may also contribute to contractile dysfunction of failing hearts.<sup>152</sup>

Cytoskeletal Proteins

The cytoskeleton is a complex network of microtubules (primarily tubulin), nonsarcomeric actin, and intermediate filaments (primarily desmin). Tubulin is the protein of microtubules, which are hollow tubes formed from  $\alpha$ - and  $\beta$ -tubulin, with a diameter of 25 nm surrounding the nucleus and spreading, mostly in the longitudinal direction, throughout the entire cell. Microtubules undergo continuous polymerization and depolymerization, which under normal conditions results in a stable relationship between free cytosolic tubulin and structure-related tubulin (i.e., the microtubules). This dynamic process can be enhanced or arrested by the application of agents such as taxol or colchicine, which respectively promotes or prevents polymerization from the tubulin pool. Under steady-state conditions, about 70% of the total tubulin in the cell is typically in the depolymerized form. The multifunctional roles of microtubules include mitosis, intracellular transport, organization of organelles, cell motility, determination of cell shape, receptor modulation, and signaling.<sup>153</sup>

Desmin belongs to the family of intermediate filaments with a diameter of 12 to 15 nm ranging between microtubules (25 nm) and actin filaments (8 to 10 nm). It surrounds the Z-disks and connects the sarcomeres so that these are kept in register during contraction. Desmin filaments also link myofibrils to one another, to the sarcolemma, and to the nuclear envelope.<sup>154</sup> The desmin network plays a role in the underlying structural integrity of the myocyte and participates in the signaling processes necessary for integration of cellular responses to external and internal stimuli.<sup>154</sup>

The cytoskeleton contributes substantially to cell stability by anchoring subcellular structures, such as mitochondria, Golgi apparatus, nuclei, and myofibrils. The cytoskeleton proteins also act as a stabilizing force and as mechanotransducers through their connection with membrane-associated proteins.<sup>155</sup> A close cytoskeleton-integrin linkage system also exists at the level of the sarcolemma, which allows cells to respond to physical and biochemical influences exerted by the

TABLE 15-1 Myocyte Protein Families	
Contractile proteins	Myosin, $\alpha$ -actin, $\alpha$ -tropomyosin, troponins C, I, and T
Sarcomeric skeleton	Titin, $\alpha$ -actinin, M-line proteins: M-protein, myosin-binding protein C
Cytoskeletal proteins	Tubulin, desmin, nonsarcomeric actin
Membrane-associated proteins	Vinculin, talin, dystrophin, spectrin, integrins
Proteins of the intercalated disk	Connexins, cadherins, catenins

From Kostin S, Heling A, Hein S, et al. The protein composition of the normal and diseased cardiac myocyte. *Heart Fail Rev* 1998;2:245-260.<sup>70</sup>

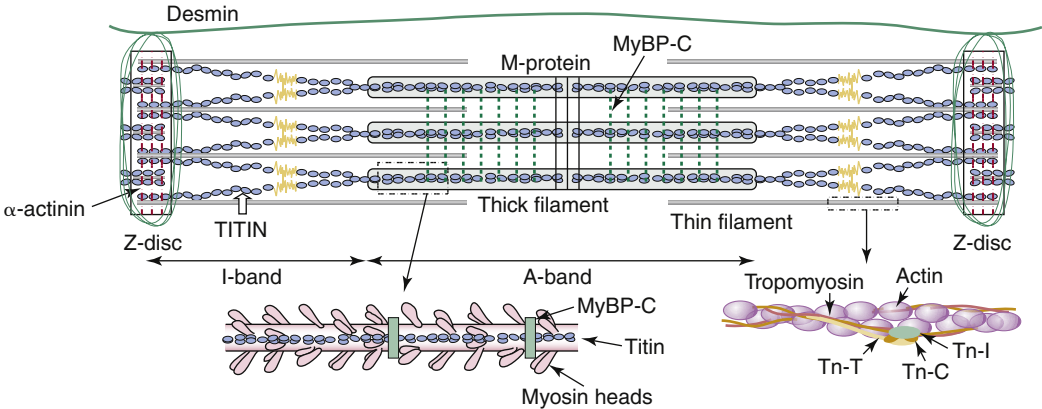

FIGURE 15-6 Diagram of the myocyte sarcomeric proteins. MyBP-C, myosin binding protein-C; Tn-C, troponin C; Tn-I, troponin I; Tn-T, troponin T. (Courtesy H. L. Granzier.)

extracellular matrix. When the matrix resists movement, the linkage to the cytoskeleton is strengthened via an increased number of integrins.<sup>156</sup> At the intercalated disk, the cytoskeleton is anchored to sites of cadherin-mediated adhesion between adjacent plasma membranes via catenins and desmoplakins.<sup>157</sup>

In failing human myocardium, both tubulin and desmin are increased.<sup>158</sup> The increase in these proteins mainly occurs in cells that lack myofilaments and could, therefore, help maintain cellular stability. Tubulin accumulation plays a role in certain models of pressure-overload hypertrophy.<sup>159</sup> In feline right ventricular hypertrophy, resulting from pulmonary artery banding, isolated myocytes show contractile dysfunction and loss of compliance.<sup>160-162</sup> These changes are accompanied by an increase in total and polymerized tubulin. Reduction of microtubule hyperpolymerization by colchicine treatment reverses myocyte stiffness and normalizes contractile dysfunction. Taxol treatment of normal myocytes hyperpolymerizes tubulin and produces functional disturbances similar to chronic pressure overload.<sup>160-162</sup> The results of these studies underscore the role of the cytoskeleton in myocyte contractile dysfunction in at least one model of heart failure. Whether this is a universal finding in heart failure is debatable.

There are increasing reports of desmin-related cardiomyopathies that have, as a hallmark, abnormal deposits of desmin aggregates. A progressive increase of desmin protein and filaments was shown to accompany the transition from hypertrophy to heart failure.<sup>163</sup> Overexpression and altered distribution of desmin were also observed in human hearts with end-stage congestive heart failure in dilated cardiomyopathy.<sup>158</sup> Absence of an intact desmin filament system may also be involved in cardiomyocyte hypertrophy and cardiac dilation with compromised systolic function.<sup>164</sup> Whether alteration in desmin quantity is a cause or a consequence of heart failure remains to be elucidated.

#### Membrane-associated and Intercalated Disk Proteins

Membrane-associated proteins include dystrophin, vinculin, talin, spectrin, and integrins, which are involved in fixation of sarcomeres to the lateral sarcolemma and stabilization of the T-tubular system.<sup>70,165,166</sup> It was recently shown that mutations of these proteins could cause dilated cardiomyopathy.<sup>167-169</sup> Dystrophin connects intracellular actin and extracellular laminin independent of integrin binding<sup>155</sup> and plays an important role in promoting the action of the cytoskeleton as a stabilizing force and as mechanotransductor.<sup>170</sup>

The intercalated disk consists of three different types of specialized membranes: fasciae adherens, desmosomes, and gap junctions.<sup>171</sup> Fasciae adherens establish the longitudinal connections with the contractile filaments. The desmosomes are connections with intracellular desmin via the desmoplakins, and the gap junction consists of the membrane-spanning connexins. Gap junctions are responsible for the orderly spread of electrical excitation from one myocyte to the next in the heart. Gap junction channel proteins are termed “connexins.” Different connexins exhibit different biophysical properties. Remodeling of gap junction and connexin expression is a conspicuous feature of human congestive heart failure and other cardiac conditions with a dysrhythmic tendency. Remodeling of gap junctions and reduced connexin<sup>43</sup> levels may contribute to slowing of conduction.<sup>172,173</sup> Evidence from studies in experimental animals strengthens the case that gap junction remodeling is a key determinant of arrhythmias in the diseased heart.<sup>174,175</sup>

## ALTERATIONS IN THE NONMYOCYTE COMPARTMENT

While historically considered a static structure, it is now becoming recognized that the myocardial extracellular matrix (ECM) is a complex microenvironment containing a large

portfolio of matrix proteins, signaling molecules, proteases, and cell types that play a fundamental role in the myocardial remodeling process.<sup>28,176-178</sup>

Apart from the myocyte compartment, the chronically failing heart is characterized by iterations in the extracellular matrix (ECM), particularly by fibrous tissue formation.<sup>65</sup> Such an adverse accumulation of ECM raises myocardial stiffness and impairs contractile behavior.<sup>179</sup>

### Extracellular Matrix Remodeling (see Chapter 5)

The extracellular matrix of the heart is made up of a number of structural proteins including fibrillar collagen, smaller amounts of elastin, and the signaling peptides laminin and fibronectin. The complex collagen 3D weave, mainly consisting of type I collagen, interconnects individual myocytes through a collagen-integrin-cytoskeletal-myofibril arrangement. This network supports cardiac myocytes during contraction and relaxation, and also provides a mechanism for translating individual myocyte shortening and force generation into ventricular contraction; it is also responsible for much of the ventricle's passive diastolic stiffness.<sup>180</sup> In both human and animal studies, progressive LV remodeling and dysfunction are associated with significant changes in the ECM.<sup>181-184</sup>

The structural hallmark of prolonged pressure-overload hypertrophy is significantly increased collagen accumulation between individual myocytes and myocyte fascicles (Figure 15-7).<sup>185,186</sup> Thus the highly organized architecture of the ECM is replaced with a thickened, poorly organized ECM related to decreased capacity for ECM degradation and turnover. This “reactive” collagen deposition is characterized by both perivascular and interstitial fibrosis.<sup>180,187,188</sup> It is not clear whether the initiation of reactive fibrosis is triggered by myocardial ischemia or the local activation of trophic peptides such as angiotensin II, aldosterone, and catecholamines, which results in the sequential expression of transforming growth factor  $\beta_1$  and fibronectin, and a relative increase in collagen I.<sup>187-189</sup> While the accumulation of ECM with pressure-overload hypertrophy is not exclusive to collagen, these initial structural studies gave rise to the generic term for this extracellular remodeling process as myocardial fibrosis. Autopsy and biopsy studies of patients with severe chronic hypertension or aortic stenosis frequently show changes in collagen architecture, and a severe increase in the percentage of fibrosis occupying the myocardium.<sup>188,190</sup> Enhanced synthesis and deposition of myocardial ECM in pressure-overload hypertrophy is directly associated with increased LV myocardial stiffness properties, which in turn cause poor filling characteristics during diastole.<sup>186,191,192</sup> Indeed, clinical evidence suggests that progressive ECM accumulation and diastolic dysfunction are important underlying pathophysiological mechanisms for heart failure in patients with pressure-overload hypertrophy.<sup>193,194</sup>

In volume-overload hypertrophy due to the persistently elevated preload, a much different pattern of ECM remodeling occurs. In large-animal models of volume-overload hypertrophy due to chronic mitral regurgitation, the LV remodeling process is accompanied by a distinctive loss of collagen fibrils surrounding individual myocytes.<sup>87,195-198</sup> These changes in ECM support are associated with changes in isolated LV myocyte geometry where the cardiac cells increase in length. Representative scanning electron micrographs taken from a model of canine mitral regurgitation<sup>195</sup> are shown in Figure 15-8 and demonstrate the profound differences in ECM structure and composition compared with normal myocardium and that of volume-overload hypertrophy. Increased ECM proteolytic activity likely contributes to the reduced ECM content and support, and thereby facilitates the overall LV remodeling process.<sup>178</sup>

**FIGURE 15-7** Scanning electron micrographs taken from normal nonhuman primate left ventricular myocardium and following the induction of pressure overload hypertrophy (POH). These microscopic studies demonstrated thickening of the collagen weave and overall increased relative content between myocytes with POH. (From Abrahams et al. Myocardial hypertrophy in *Macaca fascicularis*. Structural remodeling of the collagen matrix. *Lab Invest* 1987;56:676-683.<sup>185</sup>)

Although the mechanisms by which increased degradation of collagen promote LV dilation and global LV dysfunction are not entirely clear, dissolution of the collagen weave may lead to increased elasticity and contribute to muscle fiber slippage and therefore an increase in chamber size.<sup>191</sup> Loss of collagen struts connecting individual myocytes could, as we will see later, prevent transduction of individual myocyte contractions into myocardial force development, resulting in reduced myocardial systolic performance.

The ECM and, particularly, collagen are under dynamic control of two sets of proteins: those that favor degradation and those that tend to inhibit it. The dissolution or degradation of collagen is predominantly related to the activation of matrix metalloproteinases (MMPs), a family of zinc-containing proteins that includes collagenases, gelatinases, stromelysins, and membrane types of MMPs.<sup>178</sup> Active MMPs can undergo auto-digestion and thereby lose proteolytic activity. However, the kinetics of this process are not fully understood and can be variable for different MMPs and conditions. A more critical control point for MMP activity is through the inhibition of the activated enzyme by the action of a group of specific MMP inhibitors termed *tissue inhibitors of metalloproteinases* (TIMP).<sup>178</sup> There are four known TIMP species of which TIMP-1 and TIMP-2 have been the most studied. The TIMPs are low-molecular-weight proteins that can complex noncovalently with high efficiency to active MMPs inhibiting their activity.<sup>199,200</sup>

While the contributory mechanisms for the changes in plasma MMP levels remain speculative, an association between changes in plasma MMP levels to adverse LV remodeling is beginning to emerge. For example, in a Framingham Heart substudy, it was demonstrated that increased plasma MMP-9 levels were associated with LV dilation.<sup>201</sup> Specifically, higher plasma levels of MMP-9 were associated with an approximately twofold higher risk of adverse LV remodeling.

**FIGURE 15-8** Scanning electron micrographs taken from normal canine left ventricular myocardium following chronic mitral regurgitation that causes a volume overload hypertrophy (VOH). In this model of VOH,<sup>195</sup> a loss of normal ECM architecture was demonstrated between individual myocytes (arrows), and the collagen supporting network is poorly organized. (Figure 2 from Dell'Italia, L. J., Balcells, E, Meng, Q. C., et al. Volume-overload cardiac hypertrophy is unaffected by ACE inhibitor treatment in dogs. *Am J Physiol Heart Circ Physiol* 273: H961-H970, 1997.)

Changes in the plasma levels of TIMP-1 have been studied in several large-scale cardiovascular studies.<sup>201,202</sup> Elevated TIMP-1 plasma levels have been shown to be associated with major cardiovascular risk factors and with the presence of LV hypertrophy in the Framingham Heart Study.<sup>201</sup> Furthermore, changes in plasma TIMP-1 levels were associated with increased mortality in another study.<sup>202</sup> However, it is likely that the changes in plasma MMP and TIMP levels observed in these studies will be influenced by the underlying cause of the cardiovascular disease process, and therefore, future studies will be necessary. Furthermore, these studies only measured MMP and TIMP plasma levels at one point in time, and how the temporal relation to the natural history of the LV remodeling process and progression to heart failure remains to be established. Nevertheless, these studies do provide further evidence to support the potential utility of plasma MMP and TIMP profiling in terms of prognosis.

## Myocardial Fibrosis

Fibrosis in heart failure is an ongoing active process of increasing collagen concentration and not simply a response to myocyte injury.<sup>179</sup> There are two types of fibrosis: reparative and reactive. Reparative fibrosis occurs in response to a loss of myocardial material and is mainly interstitial. In contrast, reactive fibrosis is observed in the absence of cell loss as a reaction to changes in myocardial load or inflammation, and is primarily perivascular. During ventricular remodeling,

reactive and reparative fibrosis usually coexist. After myocardial infarction, reparative fibrosis is organized as a scar and is surrounded by reactive fibrosis and myocyte hypertrophy.<sup>203</sup>

The mechanisms responsible for fibrosis are still controversial. Fibrosis is not directly induced by stretch or mechanical overload. Chronic volume overload due to exercise training, atrial septal defect, or aortic insufficiency is not accompanied by ventricular fibrosis.<sup>204,205</sup> In contrast, pressure overload is frequently associated with fibrosis. It has been proposed that ventricular fibrosis seen in arterial hypertension is caused by associated factors linked to this condition, such as ischemia<sup>206</sup> and neurohormones.<sup>179</sup> Humoral factors, particularly those of the renin-angiotensin-aldosterone system, are believed to be responsible for fibrosis. Angiotensin II and aldosterone have been implicated in the process as they stimulate collagen synthesis in cultured cardiac fibroblasts, and angiotensin II inhibits collagen degradation.<sup>207,208</sup>

Myocardial fibrosis has a number of deleterious effects on cardiac function. A twofold to threefold increase in myocardial collagen content alters ventricular filling properties particularly by increasing diastolic stiffness; a fourfold or greater increase in fibrosis also affects systolic function.<sup>209</sup> Fibrosis contributes to ventricular arrhythmias because disproportionate collagen accumulation creates myocardial electrical heterogeneity. Fibrosis is therefore one of the major biological determinants of fatal issues in cardiac remodeling, including congestive heart failure, severe arrhythmias, and sudden death.

### Coronary Microvasculature

Another factor that may contribute to progressive LV remodeling and dysfunction is the inadequate growth of myocardial microvasculature accompanying myocardial hypertrophy. This results in a reduction in capillary density in the hypertrophying remote noninfarcted myocardium and increases the average diffusion distance for oxygen from the capillary wall to the mitochondria of the myocytes.<sup>82,210</sup> These structural abnormalities are also accompanied by a functional decrease in coronary vascular reserve.<sup>211</sup> Thus both structural and functional abnormalities in the microvasculature could contribute to progressive LV dilation and remodeling that occurs during development of chronic heart failure.

## CHANGES IN MYOCYTE CONTRACTILE FUNCTION (see Chapter 3)

These abnormalities include changes in the contractile proteins or their regulatory elements,<sup>146</sup> alterations in the  $\beta$ -adrenergic receptor signaling pathway with downregulation of the  $\beta$ -adrenergic receptor,<sup>212</sup> an increase in  $\beta$ -adrenergic receptor kinase,<sup>213</sup> defects in energetics,<sup>214</sup> and alterations in cytoskeletal proteins.<sup>158</sup> In addition, calcium-handling proteins are altered with a decrease in sarcoplasmic reticulum  $\text{Ca}^{2+}$ -ATPase (SERCA2a), and an increase in the  $\text{Na}^+/\text{Ca}^{2+}$  exchanger.<sup>43,215,216</sup> Such changes would be expected to cause progressive myocyte contractile dysfunction. Indeed, the contractile function of myocytes isolated from end-stage heart failure in human and various animal models is often abnormal.<sup>81,217-219</sup> In models of concentric hypertrophy, the earliest change is slowing of myocyte relaxation that is manifest even before the appearance of overt heart failure.<sup>220</sup> Later, development of depressed myocyte peak contraction and slow relaxation is accompanied by alterations in  $\text{Ca}^{2+}$  transients.<sup>220-224</sup> These contractile defects have been related to underlying biochemical alterations in  $\text{Ca}^{2+}$  handling proteins, a decrease in SERCA2a, and an increase in the  $\text{Na}^+/\text{Ca}^{2+}$  exchanger.<sup>215,216</sup> In such conditions, therefore, global LV dysfunction could be explained on the basis of myocyte contractile defects.

Thus there is a considerable weight of evidence that one or another cellular function may be abnormal in the cardiac myocyte of different models of heart failure. However, there is no indication of any single final common pathway that is universally responsible for contractile dysfunction in the isolated myocytes of the failing heart. Indeed, in certain models of heart failure, myocyte contractile function may be preserved despite depressed global LV function. In one such model, rats 6 weeks following myocardial infarction developed significant remodeling and global LV dysfunction.<sup>85</sup> Myocytes isolated from these hearts showed eccentric hypertrophy, and an increase in length of the myocytes that correlated well with the LV volume. Despite global LV remodeling and dysfunction, however, these hypertrophied myocytes showed normal contractile function under a variety of conditions including increasing stimulation frequency, extracellular calcium, isoproterenol, and viscous loading.<sup>43,85,225</sup> Similarly, volume-overload hypertrophy associated with AV fistula in cats was reported to occur without changes in myocyte contractility.<sup>226</sup>

How can we explain global LV dysfunction despite preserved myocyte contractile function? The first way that pump function may be depressed with normal myocyte function is related to loss of cardiac myocytes. As we have seen, myocyte loss can occur acutely (e.g., following a myocardial infarction or chronically during the remodeling process through necrotic or apoptotic cell death). Either way, myocyte loss resulting in a thin-walled and dilated LV chamber with attendant increase in wall stress could be expected to develop pump dysfunction, independent of myocyte contractile function. A second possible mechanism is related to increased collagen disruption and loss of collagen struts connecting individual myocytes (see Figure 15-8). This would have the effect of under-tethering myocytes, preventing force generated by normally contracting myocytes to be transmitted to the wall, resulting in reduced global systolic performance. A recent study designed to test this hypothesis in papillary muscles isolated from normal rats and in pressure-overload hypertrophied cats found that acute disruption of the ECM fibrillar collagen, by plasmin-activated MMP, resulted in severe reduction in force generation.<sup>227</sup> However, myocytes isolated from these papillary muscles showed normal contractile function.<sup>227</sup> These data support the hypothesis that the ECM facilitates transduction of cardiomyocyte contraction into myocardial force development, and that ECM disruption could explain depressed LV systolic performance, despite the presence of normal myocyte contractile function.

## CHANGES IN GLOBAL STRUCTURE AND FUNCTION

The mechanical effects of LV remodeling set in motion several self-sustaining deleterious consequences. As the ventricle enlarges, LV geometry alters from a normal prolate ellipse to a mechanically disadvantageous spherical or globular shape (Figure 15-9). The result is an increase in meridional wall stress,<sup>228</sup> an abnormal distribution of fiber shortening, an increase in oxygen consumption,<sup>228,229</sup> and abnormal myocardial bioenergetics.<sup>214</sup> The spherical shape of the left ventricle leads to dilation of the atrioventricular ring and stretching of the papillary muscles, resulting in functional mitral regurgitation,<sup>230</sup> which contributes to a further decrease in forward cardiac output. Moreover, the high LV end-diastolic volume and pressure promote subendocardial ischemia that aggravates LV dysfunction and neurohormonal activation, decreases exercise capacity,<sup>231</sup> and increases the risk of ventricular arrhythmias.<sup>232</sup> Thus a downward spiral of worsening heart failure is initiated that ends in death of the patient.

**FIGURE 15-9** Left ventricular (LV) remodeling over time. Left ventricular angiogram in the right anterior oblique projection of a patient 1 month after acute myocardial infarction (March 1996) and 2 years later (April 1998). Note that 2 years after infarction, the end-diastolic volume (EDV) was three times normal, end-systolic volume (ESV) was five times normal, stroke volume (SV) was decreased, and there was a further decrease in ejection fraction (EF). There was a decrease in the ventricular mass-to-volume ratio over time, suggesting further increase in wall stress. The globular shape contributed to severe mitral regurgitation.

## STRUCTURAL BASES OF HEART FAILURE

In the preceding discussion we saw that the development and worsening of clinical heart failure is related to progressive ventricular dilation. It has been suggested that as the ventricle dilates, there may be an obligatory reduction of myocardial shortening or ejection fraction to maintain an optimal stroke volume.<sup>233</sup> An unchanged ejection fraction from a dilated left ventricle could deliver a large and potentially damaging stroke volume to the vasculature. The homeostatic mechanisms responsible for such a conceptual model are not clear but may be related to prevent a large pulse pressure from damaging the vasculature. According to this view, structural changes in LV architecture and increase in LV volume are the primary abnormalities that result in reduced wall motion mandated to generate a normal stroke volume from a large end-diastolic volume.<sup>233</sup> Therefore, this view challenges the traditional concept that contractile dysfunction leads to chamber dilation. The fact that the stroke volume is generally held constant, albeit at a lower than normal level, over a relatively large range of end-diastolic volumes supports this hypothesis (Figure 15-10).

## COMPENSATORY VERSUS MALADAPTIVE REMODELING

A fundamental question that must be addressed before embarking on a strategy to reverse the hypertrophic and structural myocardial remodeling is whether remodeling is good or bad. Distinction is often made between a compensatory (adaptive) and a decompensatory (maladaptive) process. The organism is not endowed with any mechanism to distinguish between the effect of its response to an acute stimulus and the ultimate effects of that response when the stimulus is maintained over a prolonged period of time. An adaptive component enables the heart to maintain function in response to pressure or volume overloading in the acute phase of cardiac injury.<sup>234</sup> Acute distention of the viable myocardium and the operation of the Frank-Starling mechanism, through an increase in sarcomere length, are therefore entirely appropriate beneficial responses. Likewise, augmentation of chronotropic and inotropic activity through adrenergic receptor stimulation that tends to maintain pump function during the abrupt loss of contractile tissue can be considered compensatory. Progressive left ventricle dilation after myocardial infarction can also help to maintain stroke volume in

**FIGURE 15-10** Lack of significant relationship between stroke volume and end-diastolic volume in 816 separate measurements of the left ventricle using magnetic resonance imaging techniques. The stroke volume is held relatively constant over a large range of end-diastolic volumes. (Unpublished data from IS Anand.)

the face of reduced contractile function, and has been considered an adaptive and compensatory response.<sup>3,235</sup> Under these circumstances, however, an increase in LV volume is not due to sarcomere stretch, but because of the addition of new sarcomeres in a series,<sup>85</sup> and therefore is not a mechanism of enhancing contractility on the basis of the Frank-Starling mechanism. Such a progressive remodeling and LV dilation does not normalize but increases wall stress and is associated with a poor prognosis.<sup>19,235</sup> Moreover, prevention of very early LV dilation with use of angiotensin-converting enzyme (ACE) inhibitors and  $\beta$ -blockers does not have any deleterious hemodynamic consequence.<sup>236-238</sup> Indeed, Sharpe et al<sup>236</sup> have demonstrated that attenuation of LV remodeling with early initiation of ACE inhibitors is actually associated with a greater increase in stroke volume as compared with a placebo. Furthermore, prevention of remodeling by early initiation of an ACE inhibitor or  $\beta$ -blocker, after myocardial infarction, in selected populations with LV dysfunction<sup>31,34</sup> and even in unselected populations<sup>239</sup> is associated with significant reduction in mortality and morbidity.<sup>34,237,240,241</sup> Hence, ventricular remodeling and dilation after myocardial infarction may be maladaptive from the very start, and should be a target for aggressive antiremodeling therapy.

In contrast, an increase in ventricular mass that helps to normalize wall stress in aortic stenosis and hypertension may be an appropriate compensatory response. Because systolic stress (afterload) is a major determinant of ejection performance, normalization of systolic stress helps to maintain a normal ejection fraction while generating high levels of systolic pressure.<sup>12</sup> However, LV hypertrophy has been shown to be an important independent risk factor for mortality and morbidity.<sup>17</sup> Similarly, a proportional increase in chamber volume, wall thickness, and mass in mitral and aortic regurgitation normalizes wall stress and is an obligatory response to maintain a large stroke volume that is necessitated by the regurgitant volume. Until the initial volume and pressure overload is matched by adequate hypertrophy, the process may be considered adaptive and compensatory. Eventually, with progressive dilation there is a mismatch and the process becomes maladaptive and decompensatory, and heart failure becomes clinically manifest.<sup>242,243</sup> There are no data to indicate when the transition from possible adaptive to maladaptive remodeling occurs; such a transition and its time course may be expected to vary greatly. However, once established beyond a certain phase, it is likely that remodeling actually

contributes to progression of heart failure. Thus whether remodeling is beneficial or deleterious cannot be viewed as a stereotypical process. Today's challenge is to be able to take advantage of the adaptive features of the hypertrophic response while eliminating, or at least minimizing, the maladaptive consequences.

## REVERSE REMODELING (see Chapter 8)

"Reverse remodeling" is a relatively new concept, where progressive LV dilation and deterioration in contractile function are not simply arrested, but partially reversed. Two important questions are related to the issue of reverse remodeling: "Do myocytes have the ability to remove sarcomeres?" and "Is there any time line beyond which reverse remodeling cannot be achieved?" A number of lines of evidence from surgical and pharmacological experiments have confirmed that regression of myocyte hypertrophy with removal of sarcomeres is possible. There are, however, insufficient data to address the second question. It is believed that early in the natural history of transition from hypertrophy to failure, remodeling is reversible, whereas later, with the development of extensive fibrosis, accumulation of cytoskeletal proteins, and loss of the contractile filaments, an irreversible process sets in.<sup>112</sup> Several therapeutic approaches for heart failure have been shown to halt or even reverse the remodeling process.

### Pharmacological Approaches

Several experimental studies, aimed primarily at modulating the neurohormonal responses, have been conducted to determine whether established remodeling of a damaged left ventricle could be reversed pharmacologically. It is well known that inhibition of the renin-angiotensin system improves cardiac remodeling.<sup>244,245</sup> McDonald et al<sup>246</sup> showed that ACE inhibition and  $\beta$ -adrenoreceptor blockade can reverse established ventricular remodeling in a canine model of discrete myocardial damage.<sup>246</sup> A significant reduction of LV mass and a trend in reduction of end-diastolic volume were found in both captopril- and  $\beta$ -blocker-treated groups compared with the control group.<sup>246</sup> Tamura et al<sup>247</sup> have reported that administration of angiotensin II type 1 receptor blockers produced significant reverse remodeling of myocyte volume, length, and cross-sectional area in rats with spontaneously hypertensive heart failure. In this study, myocyte dimensions were reduced below pretreatment values, suggesting true reverse remodeling rather than simply arrested progression of myocyte hypertrophy.<sup>247</sup> Xu et al<sup>248</sup> studied the effect of the angiotensin II receptor blocker losartan combined with exercise training in the postinfarction rat model and demonstrated that exercise training after myocardial infarction provides a beneficial effect on cardiac function and LV remodeling by altering the gene and protein expressions that regulate myocardial fibrosis, whereas such effects were only slightly improved by the combination of exercise and losartan.<sup>248</sup>

#### Angiotensin-Converting Enzyme (ACE) Inhibitors

The first class of medications shown to beneficially affect remodeling and clinical outcomes in patients with heart failure was ACE inhibitors. In several trials performed in both asymptomatic and symptomatic patients with reduced ejection fraction, ACE inhibitors attenuated the progressive increase in end-diastolic and end-systolic volume.<sup>32,236,249-251</sup>

#### $\beta$ -Blockers

In contrast to ACE inhibitors that attenuate LV remodeling, use of  $\beta$ -blockers is associated with significant reduction in ventricular volumes and improvement in global LV function

(reverse remodeling).<sup>30,31,33,252</sup>  $\beta$ -blockers were shown to reduce myocardial apoptosis, which at least in part could explain the favorable effect on ventricular remodeling.<sup>253</sup>

#### Aldosterone Receptor Blockers

Aldosterone receptor blockers have been shown to reverse LV remodeling following myocardial infarction and in patients with heart failure.<sup>254,255</sup> The 4E-Left Ventricular Hypertrophy Study<sup>256</sup> used cardiac MRI to compare LV mass regression by the selective aldosterone blocker eplerenone to the ACE inhibitor enalapril and the combination of eplerenone/enalapril in hypertensive patients with LV hypertrophy. Eplerenone was as effective as enalapril in regression of LV hypertrophy and control of blood pressure. The combination of eplerenone and enalapril was more effective in reducing LV mass and systolic blood pressure than eplerenone alone.<sup>256</sup> In a single-site clinical trial, Chan et al<sup>257</sup> have recently demonstrated with serial cardiac magnetic resonance (CMR) that the addition of spironolactone to candesartan has significant beneficial effects on LV reverse remodeling in patients with mild to moderate chronic systolic heart failure.

#### Angiotensin Receptor Blockers

Several recent trials demonstrated the beneficial effect of angiotensin receptor blockers (ARBs) on LV remodeling. In the Valsartan Heart Failure Trial (Val-HeFT),<sup>258,259</sup> valsartan therapy attenuated LV remodeling.<sup>260</sup> Stratification by baseline severity of remodeling showed that patients with worse LV enlargement and systolic function are at highest risk for an event, yet appear to gain the most antiremodeling effect and clinical benefit with valsartan treatment.<sup>261</sup> The Losartan Intervention For Endpoint (LIFE) study<sup>262</sup> showed that reduction in LV mass by angiotensin II blockade was independent of blood pressure reduction, indicating that inhibition of the renin-angiotensin-aldosterone system has added benefits beyond blood pressure control.<sup>262</sup>

#### Isosorbide Dinitrate/Hydralazine Combination

In the first Vasodilator-Heart Failure Trial (V-HeFT-I),<sup>263</sup> isosorbide dinitrate combined with hydralazine therapy compared with placebo in patients with heart failure treated only with digoxin and diuretic resulted in a sustained increase in LV ejection fraction that was quantitatively associated with improved survival.<sup>263</sup> The African American Heart Failure Trial (AHeFT) confirmed these findings, even on top of ACE inhibitors and  $\beta$ -blockers.<sup>264,265</sup>

## Cell Transplantation (see Chapter 4)

The past decade has seen an explosion of activity in the field of cell transplantation after myocardial injury. The first control-matched study using bone marrow stem cells was published by Strauer et al in 2002.<sup>266</sup> Ten patients were treated with intracoronary bone marrow mononuclear cells (BMMNCs) for 7 days after suffering a myocardial infarction. Three months later, the treated patients exhibited a decrease in infarct size when compared with controls. This study was followed by the TOPCARE-AMI (Transplantation Of Progenitor Cells And Regeneration Enhancement in Acute Myocardial Infarction) trial, which revealed improvement in ventricular function after treatment with either BMMNCs or circulating endothelial progenitor cells.<sup>267,268</sup> The first randomized trial, BOOST (Bone marrow transfer to enhance ST-elevation infarct regeneration), initially demonstrated improvement in ventricular function in myocardial infarction patients after treatment with BMMNCs; however, this effect was not sustained at 18 months.<sup>269,270</sup> The two largest randomized trials, ASTAMI<sup>271</sup> and Repair-AMI,<sup>272</sup> were published in 2006. Using similar protocols, the ASTAMI trial did not show any

improvement in LVEF at 6 months, whereas Repair-AMI showed a 5.5% increase in mean LVEF in the treated group compared with 3% in the controls at 4 months.<sup>271,272</sup> The BMMNC-treated group in the Repair-AMI study also demonstrated a statistically significant decrease in the combined endpoint of death, recurrence of myocardial infarction, and hospitalization for heart failure; however, the overall event rate in both groups were low (12 events in the control group, 2 events in the treated group).<sup>272</sup> Thus there is no consensus whether cell therapy works. Well-designed clinical trials are needed to further define the best cell population to be used, the delivery technique, and the most appropriate timing of cell therapy after an acute myocardial infarction.

## Surgical Approaches (see Chapter 55)

Several “conventional” surgical procedures have been developed to reverse the vicious cycle of ventricular remodeling that accompanies systolic heart failure with the goal to improve symptoms and survival of heart failure patients. The details of the most common surgical methods currently used to arrest or reverse cardiac remodeling are beyond the scope of this chapter and are discussed elsewhere.<sup>273</sup> In 2002, the National Heart, Lung, and Blood Institute funded the Surgical Treatment for Ischemic Heart Failure (STICH) trial<sup>275</sup> to address two pressing clinical questions regarding the management of patients with heart failure with surgically revascularizable coronary artery disease and left ventricular dysfunction. First, is contemporary coronary artery bypass graft (CABG) surgery superior to contemporary medical therapy in prolonging survival in these patients? Second, among patients with significant LV anterior wall dysfunction, does the addition of surgical ventricular reconstruction to CABG improve hospitalization-free survival? The primary outcomes of the first hypothesis are expected to be published in 2011. The results of the primary outcomes of the second hypothesis were recently published and showed that adding surgical ventricular reconstruction to CABG reduced the left ventricular volume, as compared with CABG alone. However, this anatomical change was not associated with a greater improvement in symptoms or exercise tolerance or with a reduction in the rate of death or hospitalization for cardiac causes.<sup>275</sup>

Removal of the hemodynamic stress in patients with either aortic stenosis or aortic insufficiency after aortic valve replacement has been shown to be associated with significant hemodynamic improvement and a decrease in LV mass.<sup>276</sup> Villari et al<sup>277</sup> analyzed serial LV hemodynamic and biopsy findings before and after valve replacement in patients with aortic valve disease. These patients initially had massive LV hypertrophy and severe collagen deposition. The results demonstrated that near-normalization of systolic load causes a rapid reduction in myocyte hypertrophy and LV mass within a few weeks after valve replacement.<sup>277</sup> In this early phase of regression of myocyte hypertrophy, little change in collagen and matrix was observed. However, after months and years following valve replacement, regression of interstitial fibrosis occurred, resulting in near-normalization of both muscle mass and fibrous tissue content. This initial rapid regression of hypertrophy and later regression of fibrosis was accompanied by an improvement in ventricular function and exercise capacity.<sup>277</sup> In an experimental model of aorto-caval fistula in rats, Gerdes et al<sup>278</sup> demonstrated that myocytes possess the necessary machinery to remove recently added sarcomeres in a series, returning altered pump function and dilated ventricular chamber geometry toward control values.<sup>278</sup>

There is now compelling evidence that prolonged, near-complete unloading of the left ventricle with the use of an LVAD is associated with reduced myocardial apoptosis<sup>279</sup> and structural reverse remodeling<sup>95,280-282</sup> that can be accompanied by functional improvement.<sup>283-285</sup> However, recovery that is sufficient

to permit explantation of the device has been observed in only 5% to 24% of patients in various series.<sup>286-291</sup> with a relatively high incidence of early recurrence.<sup>286</sup> Birks et al<sup>292</sup> have recently combined mechanical and pharmacological therapy (addition of the  $\beta_2$ -adrenergic-receptor agonist clenbuterol to standard heart failure therapy) in 15 patients with severe heart failure due to nonischemic cardiomyopathy and found an increased frequency and a sustained reversal of LV remodeling and heart failure.<sup>292</sup> The reproducibility and durability of these single-center findings, and the mechanisms contributing to the findings, require further study in different groups of patients.

## Cardiac Resynchronization Approach (see Chapter 47)

Beneficial effects of cardiac resynchronization therapy (CRT) on survival, New York Heart Association (NYHA) functional class, exercise capacity, and quality of life are associated with significant improvement in LV remodeling as early as 1 month after device implantation,<sup>293-295</sup> with further progressive reduction in LV volumes beyond 1 year in select patients.<sup>296,297</sup> The Cardiac Resynchronization-Heart Failure (CARE-HF) study demonstrated an early and sustained reduction in NT-pro-BNP with CRT that correlated with improvement in LV dimension and ejection fraction and mitral regurgitation.<sup>298</sup>

## Cardiac Constraint Devices

Preclinical studies have demonstrated that passive ventricular containment with cardiac constraint devices halts progressive ventricular remodeling<sup>299-301</sup> and improves myocyte function and structure, as characterized by enhanced myocyte contraction and relaxation, decreased myocyte hypertrophy, and decreased interstitial fibrosis.<sup>299,301</sup> Ventricular restraint prevents infarct expansion, improves border zone function, and favorably modifies LV geometry and myocardial structure after myocardial infarction.<sup>302-304</sup> Clinical studies showed amelioration of symptoms and improvement in left ventricle chamber dimensions and ejection fraction with the Acorn CorCap Cardiac Support Device.<sup>305,306</sup>

## Exercise Training Approach (see Chapter 57)

Although there is growing evidence that exercise training may beneficially alter the course of postmyocardial infarction remodeling and its attendant morbidity and mortality,<sup>307-309</sup> the question of when to start exercise training after myocardial infarction remains controversial. Experimental studies using a transmural myocardial infarction rat model showed that exercise beginning 24 hours to 7 days after myocardial infarction results in infarct thinning and expansion.<sup>310,311</sup> Other studies demonstrated that exercise training starting 7 days to 5 weeks after myocardial infarction causes hypertrophy of the noninfarcted wall and attenuates LV remodeling.<sup>312,313</sup> Wan et al<sup>314</sup> sought to determine whether starting exercise at 1 or 6 weeks after myocardial infarction would affect myocardial remodeling differently and found that exercise starting early or late after myocardial infarction affects myocardial remodeling and function similarly.<sup>314</sup>

In heart failure patients, exercise training was shown to improve peak oxygen consumption, muscle strength and mass, NYHA functional class, quality of life, and survival.<sup>315-319</sup> In the recently presented HF-ACTION trial (Heart failure and a controlled trial investigating outcomes of exercise training),<sup>320</sup> exercise training caused a nonsignificant reduction in all-cause mortality and all-cause hospitalization and was associated with a modest improvement in exercise capacity.<sup>320</sup> Exercise training is now recommended for patients with mild to moderate heart failure symptoms.<sup>321,322</sup> Haykowsky et al<sup>323</sup> performed a meta-analysis to determine

the effect of exercise training and type of exercise (aerobic vs. strength vs. combined training) on LV remodeling in heart failure and found that while aerobic training reverses patients with LV remodeling in clinically stable individuals with heart failure, this benefit was not confirmed with combined aerobic and strength training.<sup>323</sup>

## VENTRICULAR REMODELING AS A SURROGATE ENDPOINT IN HEART FAILURE

There is now a large body of evidence indicating that ventricular remodeling is independently associated with adverse clinical outcomes, and more importantly, that agents that have beneficial effects in heart failure also generally attenuate or reverse ventricular remodeling, whereas agents that have failed to improve clinical outcomes either had no effect on remodeling or have been associated with adverse remodeling. We believe that these findings are sufficient to warrant consideration of the impact of a therapeutic intervention on ventricular remodeling, in conjunction with other findings, as credible evidence in support of a claim for improved clinical outcomes.<sup>4,35</sup>

A number of studies have demonstrated strong, independent correlation between ventricular dilation and subsequent mortality, particularly among patients who have suffered a myocardial infarction.<sup>15,19,251,324</sup> In a meta-analysis, Kramer et al<sup>325</sup> reviewed 25 drug/device therapy trials and 88 remodeling trials of the same therapies in patients with LV dysfunction to examine whether the magnitude of remodeling effects is associated with the odd ratios for death across all therapies are favorable, neutral, or adverse. They found that the odds ratio for death in the mortality trials was correlated with drug/device effect on LV EF ( $r=-0.51$ ,  $p<0.001$ , EDV ( $r=0.44$ ,  $p=0.002$ ) and ESV ( $r=0.48$ ,  $p=0.002$ ). In logistic regressions, the odds for neutral or favorable effects in the mortality trials increased with mean increases in LVEF and with mean decreases in EDV and ESV in the remodeling trials. These data show that in patients with LV dysfunction, short-term trial-level therapeutic effects of a drug or device on LV remodeling are associated with longer-term trial-level effects on mortality. In the early Vasodilator-Heart Failure Trials (V-HeFT), hydralazine-isosorbide dinitrate combination and enalapril slowed remodeling compared with a placebo and improved survival, whereas prazosin had no effect on remodeling or outcomes.<sup>263</sup>

Table 15-2 compares the effect of a particular drug on ventricular remodeling and on clinical outcomes. In every case, the survival effects, unknown at the time that the volumetric data were acquired, paralleled the changes in ventricular remodeling. In the treatment and prevention arms of the Studies of Left Ventricular Dysfunction, the relative magnitude of an ACE inhibitor versus a placebo on ventricular remodeling approximated the relative magnitude of benefit on outcomes within the same population.<sup>249,250,326,327</sup> In the Metoprolol Randomized Interventional Trial in Heart Failure (MERIT-HF), the antiremodeling effects of metoprolol CR/XL on the left ventricle seen in the MRI substudy<sup>33</sup> paralleled the decrease in mortality from worsening heart failure.<sup>328</sup> In the Carvedilol Post-Infarction Survival Control in Left Ventricular Dysfunction (CAPRICORN) trial, carvedilol had a beneficial effect on ventricular remodeling<sup>31</sup> and reduced all-cause and cardiovascular mortality<sup>237</sup> in patients with LV dysfunction after acute myocardial infarction. In a meta-analysis, carvedilol showed greater benefits on LV remodeling compared with immediate-release metoprolol,<sup>329</sup> a finding which anticipated the subsequent results of the COMET trial showing improved survival for patients randomized to carvedilol, compared with those randomized to immediate-release metoprolol.<sup>330</sup> The Randomized Aldactone Evaluation Study (RALES) showed a 30% reduction in mortality with spironolactone in

patients with advanced heart failure.<sup>331</sup> A later study showed improvement in the LV volume and mass with spironolactone.<sup>255</sup> In the AHeFTt, therapy with an isosorbide dinitrate/hydralazine combination resulted in regression in LV remodeling<sup>264</sup> and increased survival among black patients with advanced heart failure.<sup>265</sup> Ibopamine was initially observed to increase ventricular volumes,<sup>332</sup> and later found to be associated with excess mortality.<sup>333</sup> The angiotensin receptor blocker losartan was initially found to have an adverse trend on LV volumes compared with the ACE inhibitor captopril,<sup>334</sup> and the dual vasopeptidase inhibitor, omapatrilat had an equivalent effect on LV remodeling.<sup>335</sup> In each case, the remodeling data closely predicted the subsequent result of a large-scale morbidity and mortality trial.<sup>336,337</sup> Despite favorable early clinical findings,<sup>338,339</sup> endothelin receptor antagonist use has been associated with neutral to adverse effects on clinical outcomes and no benefits on LV volume or mass.<sup>340</sup> We have earlier shown that chronic arginine vasopressin receptor blockade does not attenuate postmyocardial infarction ventricular remodeling in the rat model.<sup>341</sup> In the Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study With Tolvaptan (EVEREST) trial, tolvaptan initiated for acute treatment of patients hospitalized with heart failure had no effect on long-term mortality or heart failure-related morbidity.<sup>342</sup> Changes in LV remodeling over time also correspond to subsequent changes in mortality, independent of drug effect,<sup>251,263</sup> further reinforcing the role of remodeling as a surrogate marker in heart failure.

## Noninvasive Assessment of Left Ventricular Remodeling (see Chapter 36)

Since the initial angiographic-based methods for assessing ventricular remodeling in humans, a variety of techniques have been developed that have been used for assessment of ventricular size, shape, and function for both clinical and research studies. Two-dimensional echocardiography has emerged as the predominant noninvasive diagnostic method for clinical use in evaluating LV function; this modality has become the most widely used technique to assess ventricular remodeling. Nevertheless, nuclear techniques that have proven both reliable and highly reproducible have also been used in a clinical and research setting and, more recently, CMR imaging has offered the potential to obtain extremely high-quality images of the heart at much higher resolution than either of the other techniques.

### Echocardiography

Unlike cardiac MRI, echocardiography is not a true tomographic technique; the image obtained and the measurements made from the image are dependent on the imaging plane chosen by the sonographer. Three-dimensional measures of ventricular size—such as ventricular volume—are never derived directly from echocardiographic images but are estimated based on formulas that make assumptions about ventricular shape. Ventricular volume calculations are typically derived from 2D images and rely on some assumptions about ventricular geometry. Approaches that make the fewest assumptions about ventricular geometry—such as the modified Simpson's rule method—offer the most accurate estimations of ventricular volume.<sup>343</sup> Nevertheless, mistakes made on tracing a 2-D ventricular contour are amplified when volumes are calculated.

The reproducibility of echocardiography for measurement of LV dimensions, mass, and ejection fraction has been studied using a variety of study designs and statistical methods.<sup>344,345</sup> Although important information has been generated on interobserver and intraobserver variability, beat-by-beat variability, and interstudy (test-retest) variability in normal subjects,<sup>344,345</sup> similar data are not widely available in a heart failure population. Therefore the value by which

**TABLE 15-2 Relationship Between Drug Effects on Left Ventricular Remodeling and on Mortality in Heart Failure**

Study	Drug	LV Volumes	Mortality
SOLVD Treatment	Enalapril	Reduced <sup>250</sup>	Reduced <sup>326</sup>
SOLVD Prevention	Enalapril	Mildly reduced <sup>249</sup>	Mildly reduced <sup>327</sup>

LV mass and volume must change to exceed methodological variability on sequential examination in heart failure patients within a multicenter study is not well established.

The noninvasive echocardiographic examination is standardized throughout the world and can be performed in virtually all medical centers. The technique is relatively inexpensive, especially compared with the more invasive angiographic or MRI-based techniques. Finally, echocardiography can offer additional information about cardiac valvular function and diastolic function that are difficult to obtain with other modalities. Nevertheless, this technique suffers from marked variation in image quality that cannot be predicted, and approximately 10% to 15% of patients cannot be adequately imaged for quantitative purposes. For these reasons, the reproducibility and overall accuracy of echocardiography may not be as high as some of the other available techniques.

#### Radionuclide Ventriculography

Radionuclide ventriculography is a reliable technique for measurement of LV ejection fraction.<sup>346</sup> Background-corrected radionuclide counts within a region of interest are used to determine ejection fraction without the need to determine absolute volumes. However, calculation of absolute LV volume has proven more complex, requiring several corrections and assumptions regarding the relation between count activity as measured in a 2D picture of the left ventricle to the absolute volume.

A strength of the radionuclide ventriculography technique is the substantial reproducibility and the low intraobserver and interobserver variability that have been reported in the literature. Several studies have assessed the reproducibility of radionuclide ventriculography in both normal subjects and patients with heart diseases. Upton et al<sup>347</sup> determined the intrinsic variability of radionuclide measurements of LV function at rest and during exercise in 10 normal subjects. The interobserver variabilities for ejection fraction ( $2.1 \pm 1.0\%$ ) and for end-diastolic volume ( $7.5 \pm 4.7$  mL) at rest were considerably smaller than those reported in studies using contrast ventriculography.<sup>348,349</sup> The interstudy variability in ejection fraction in this study was  $4.0 \pm 3.8\%$  at rest and  $3.2 \pm 2.5\%$  during exercise, suggesting that at 95% confidence levels, repeat ejection fraction should not vary by more than 8% at rest and 5% during exercise. A difference in end-diastolic

volume of at least 20 mL between rest and exercise studies was suggested to be required for the change to be considered meaningful.<sup>347</sup> A similar variability in ejection fraction of  $4.4 \pm 3.6\%$  was reported by Marshall et al<sup>350</sup> in 20 patients with cardiac disease who had three resting radionuclide ventriculograms separated by an average of 4.3 days. Numerous studies using radionuclide techniques have documented that changes in LV volumes in heart failure patients determined by the radionuclide ventriculography technique appear to reflect long-term changes in natural history seen with this same drug therapy (see Table 15-2). Thus radionuclide ventriculography allows a relatively accurate, reproducible assessment of serial changes in LV volumetrics suitable for analysis in clinical trials of new therapies in heart failure and other cardiovascular diseases. It is less costly than Doppler echocardiography or MRI and is potentially widely available (at least in the United States), though the exact volumetric techniques are no longer widely practiced for purely clinical care purposes. A disadvantage of the radionuclide technique is that analysis of right and left ventricular volumes is not commonly undertaken in most clinical radionuclide laboratories. Moreover, the radionuclide ventriculography techniques require meticulous attention to detail and correction for attenuation.

#### Magnetic Resonance Imaging

In recent years, two tomographic techniques have been increasingly applied to the diagnosis of cardiovascular disease and the quantification of cardiac dimensions and function. These techniques, ultrafast computed tomography and MRI, could acquire tomographic images at multiple levels encompassing the entire heart and thereby yield a 3D data set. Computed tomography has, however, some major drawbacks in that it requires rapid infusion of intravenous contrast material and exposes patients to radiation, both of which carry an element of risk.<sup>351,352</sup> MRI does not have these limitations and can be performed in any imaging plane so that a data set parallel or perpendicular to the long axis of the ventricle is produced. Because a 3D data set is acquired, accurate LV volume and mass measurements can be obtained.<sup>346</sup>

Cardiovascular MRI has effectively become a reference standard for quantifying ventricular volumes and function and for measuring the myocardial scar burden after myocardial

infarction. Imaging of late gadolinium enhancement and microvascular obstruction carries strong prognostic information for identifying patients who would benefit from antiremodeling therapy.<sup>353</sup> Contrast-enhanced MRI can characterize acute myocardial infarction with two well-defined contrast-enhanced patterns as follows: (1) first-pass images performed immediately after contrast injection often demonstrate areas of reduced contrast-enhanced MRI or hypoenhancement in the endocardial core of the infarct, corresponding to microvascular obstruction,<sup>354,355</sup> and (2) delayed images (10 to 20 minutes after contrast injection) demonstrate regional signal hyperenhancement, corresponding to myocardial necrosis.<sup>356</sup> A combination of contrast-enhanced perfusion MRI with functional data might be useful for the identification of myocardial viability, allowing one to distinguish permanently dysfunctional myocardium from dysfunctional segments bound to recover contractile function and contribute to LV stroke volume after myocardial infarction.<sup>354,355,357,358</sup> MRI enables the study of myocardial deformation and strain evolution in precise regions of the myocardium with high levels of reproducibility and accuracy.<sup>359,360</sup> The data combination obtained with the delayed enhancement and the tagging images allows a precise monitoring of the functional variations in the different regions.<sup>361</sup>

MRI is now considered the reference technique for the non-invasive assessment of LV dimensions, mass, and function. This method is accurate to about 2%<sup>362</sup> and, because it is highly reproducible, offers an ideal means of serial assessment of disease progression or response to treatment in an individual patient.<sup>363</sup> MRI has been shown to be superior to echocardiography, contrast ventriculography, and radionuclide ventriculography with regard to accuracy,<sup>364,365</sup> and for interobserver and interstudy reproducibility of LV cavity volumes, ejection fraction, and mass both in normal and in diseased hearts,<sup>366-368</sup> including patients with heart failure.<sup>369</sup> For research purposes, this results in a considerable reduction in the sample size required to show a given change, when compared with echocardiography. Bellenger and colleagues<sup>370</sup> reported that to demonstrate a 10-mL difference in end-diastolic and end-systolic volumes and a 10-g difference in mass with 90% power and p value of 0.05, only 12, 10, and 9 patients would be required using MRI as compares with a sample size of 97, 53, and 190 patients for 2D echocardiography. Similar findings have also been reported in patients with hypertension.<sup>371</sup> Thus because of good accuracy and superior reproducibility, MRI may be considered the gold standard for quantification of LV mass, dimensions, and ejection fraction. Even though this method may be more expensive than 2D echocardiography, its greater reproducibility may make it suitable for research studies in which the greater cost could be offset by the savings from recruiting and studying fewer patients. The combination of gadolinium enhancement, perfusion, and cine imaging should make MRI the modality of choice in the assessment of LV dysfunction and remodeling.

Several factors are limiting the routine use of MRI for the evaluation of cardiovascular disease, including limited access to MRI imagers, expense of the studies, and the duration of the procedure required to achieve images of the entire heart. Claustrophobia is a problem with some patients but may be resolved with the newer open-sided scanners. Absolute contraindications to MRI are few, but patients with implantable devices such as pacemakers and defibrillators, cochlear implants, and cerebral aneurism clips usually cannot be scanned except under very controlled and clinically urgent circumstances.<sup>372</sup>

## CONCLUSIONS

Ventricular remodeling is a complex process that results from interactions between the initial myocardial injury or alteration in loading conditions and multiple mechanical and

neurohormonal factors that are capable of modifying the cardiomyocyte phenotype and of inducing changes in the extracellular matrix. Myocyte hypertrophy, cellular necrosis and apoptosis, interstitial fibrosis, and degradation of collagen are the major features of myocardial remodeling. Each of these components of the remodeling process contributes importantly to the development and progression of heart failure. At the level of the ventricular chamber, remodeling refers to changes in ventricular geometry, volume, and mass. Although initially it may be compensatory in certain pressure and volume overload conditions, progressive ventricular remodeling is ultimately a maladaptive process, contributing to progression of symptomatic heart failure and to an adverse outcome. After acute myocardial infarction, however, progressive hypertrophy and remodeling of noninfarcted myocardium may be harmful from the start. Ventricular remodeling is emerging as an important therapeutic target and a credible surrogate endpoint in heart failure. A variety of noninvasive techniques have been used for assessment of ventricular remodeling, CMR imaging being the gold standard for quantification of LV mass, dimensions, and ejection fraction. Treatment with the goal of slowing or reversing remodeling has been shown to improve long-term outcome. Remodeling of the dilated failing ventricle can also be partially reversed when hearts are “rested” using LVAD, but it is clear that currently available therapy remains palliative. Additional research is needed to identify the molecular processes responsible for remodeling, and to improve ways to inhibit this maladaptive growth response.

## FUTURE DIRECTIONS

Enormous effort has been directed toward identifying new therapeutic strategies with long-term efficacy in heart failure. The path is littered with successes and failures,<sup>4</sup> yet advances in myocardial biology, stem-cell research, pharmacological developments, and mechanical devices hold promise for future treatments. A comprehensive understanding of ventricular remodeling will be obligatory, since it reflects the basic mechanisms of heart failure development and progression. Although multiple studies have documented that interventions that have beneficial effects in heart failure also generally attenuate or reverse ventricular remodeling and that those that fail to improve clinical outcomes either have no effect on remodeling or have been associated with adverse remodeling, few studies have examined the mechanism by which LV reverse remodeling is mediated. Questions remain as to whether the reversal of myocyte structural remodeling is accompanied by normalization of the biology of the failing myocyte and what the mechanisms of changes are at the myocyte level. Further research should focus on the molecular and cellular mechanisms involved in adverse and reverse remodeling and on optimizing therapies to prevent remodeling and identifying appropriate patient groups to target. Major challenges remain, but patients with heart disease are likely to benefit from these efforts.

# Alterations in the Sympathetic and Parasympathetic Nervous Systems in Heart Failure

John S. Floras

Of the several identified markers of disease progression and premature mortality in heart failure, disturbances in the adrenergic and vagal regulation of the heart and circulation have received particular attention.<sup>1-4</sup> Before the prescription of contemporary therapy for heart failure due to left ventricular systolic dysfunction, long-term survival was found to relate inversely to plasma norepinephrine concentrations,<sup>3,5</sup> and in a cohort referred for consideration of cardiac transplantation,<sup>3</sup> more specifically to the appearance rate of norepinephrine in the coronary sinus.<sup>6</sup> Diminished tonic and reflex parasympathetic heart rate modulation is also associated with adverse prognosis.<sup>7-12</sup> However, in many people with asymptomatic or mild to moderate symptomatic left ventricular (LV) systolic dysfunction, plasma norepinephrine concentrations and sympathetic nerve firing rates are not elevated.<sup>13-16</sup> These observations raise sev-

eral as yet unresolved questions: (1) what mechanisms account for the presence and variable magnitude of sympathetic activation and parasympathetic withdrawal in heart failure; (2) do these adverse associations between disturbed neurogenic circulatory control and survival reflect causal relationships; and (3) will interventions that inhibit adrenergic activity or augment vagal tone improve outcome?<sup>17-19</sup>

This chapter will summarize evidence for disturbed autonomic neural regulation of the heart and circulation in human heart failure because of LV systolic dysfunction, and review mechanisms responsible for this derangement and their relevance to the pathophysiology and therapy of this relentlessly progressive condition. Heart failure patients with preserved systolic function (i.e., diastolic heart failure<sup>20</sup>) have been less well characterized, but the available data will also be reviewed. Reference to animal models will be limited to concepts that have not been tested in humans.

## ASSESSMENT OF SYMPATHETIC AND PARASYMPATHETIC NERVOUS SYSTEM ACTIVITY IN HUMANS

Several distinct yet complementary methods are available for the invasive and noninvasive assessment of specific aspects of sympathetic or parasympathetic function in conscious humans (Figure 16-1). Their application has yielded important insights into mechanisms of autonomic dysregulation in heart failure, but none has entered routine clinical practice. Each has specific advantages and limitations in the setting of heart failure that should be considered when interpreting information acquired with these techniques.

### Catecholamines

Sympathoadrenal activity may be determined indirectly, by quantifying plasma or urine catecholamine concentrations, or the rate of appearance of catecholamines in plasma. When obtaining basal values, blood should be withdrawn from an indwelling catheter after 30 minutes of quiet rest to minimize any excitatory effects of anxiety or antecedent activity.

Venous plasma norepinephrine concentrations relate significantly to outcome in large heart failure trials, but their predictive value for individual patients is low. This is for several reasons. Measurements obtained at rest provide little indication of the magnitude and duration of sympathetic nerve and adrenal responses to emotional and physical stimuli, such as exercise. These responses are often well differentiated and quite specific to the heart, kidney, or adrenal gland, whereas antecubital venous sampling reflects primarily neurotransmitter release from upstream forearm skeletal muscle.<sup>21-23</sup> Because of high neuronal and extraneuronal uptake, only a small fraction of norepinephrine released from sympathetic vesicles acts on postjunctional adrenoceptors or spills over into plasma. Under conditions of low cardiac output, plasma concentrations of norepinephrine increase due to reductions in neuronal and extraneuronal clearance. Without determining their impact on clearance, the effect of heart failure therapies on neurotransmitter release cannot be deduced with confidence from changes in the plasma concentration of catecholamines.<sup>23-25</sup>

The isotopic dilution method, developed by Esler's group in Melbourne,<sup>23</sup> overcomes several of these limitations but adds complexity and cost to the estimation of sympathoadrenal activity in a heart failure patient. Total body spillover into plasma can be determined from the dilution of tritium-labeled norepinephrine during its steady-state infusion in tracer concentrations, as follows:

$$\begin{aligned} \text{Total body NE spillover (pmol/min)} \\ = [^3\text{H}] \text{ NE infusion rate (dpm/min)} \end{aligned}$$

**FIGURE 16-1** Assessment of sympathetic and parasympathetic function in humans. Sympathetic function: arterial (A) or venous (V) or plasma norepinephrine (PNE) and epinephrine (PE) concentrations (*upper left*); sympathetic nerve traffic to muscle (MSNA) or skin (*lower left*); total body norepinephrine ( $[^3\text{H}]$  NE) spillover or regional norepinephrine spillover across the heart (A, aorta or arterial; CS, coronary sinus) (*upper right*), kidney (*lower right*) or leg (*lower left*); spectral analysis of heart rate variability (SA-HRV) (*upper right*). Parasympathetic function (*upper right*): bradycardic response to phenylephrine (BRS, baroreflex sensitivity); spectral analysis of heart rate variability (SA-HRV). (From Floras JS. Clinical aspects of sympathetic activation and parasympathetic withdrawal in heart failure. *J Am Coll Cardiol* 1993;22:72A-84A, with permission from the American College of Cardiology Foundation.)

plasma NE specific activity (dpm / pmol)

where NE = norepinephrine

$[^3\text{H}]$  NE = tritium - labeled NE, and

dpm = disintegrations per minute of tritium - labeled norepinephrine

If venous effluent from the heart, kidney, brain, or another vascular bed is collected simultaneously with an arterial sample, the difference in tritium-labeled norepinephrine between the vein and artery can be used to calculate its local extraction (Extr) by neuronal and extraneuronal transport mechanisms. Organ-specific norepinephrine spillover (NES) can then be determined by the equation:

$$\text{NES} = [(\text{NE}_v - \text{NE}_a) + (\text{NE}_a \times \text{Extr})] \times \text{PF}$$

where  $\text{NE}_a$  and  $\text{NE}_v$  represent arterial and venous concentrations of unlabeled norepinephrine and PF plasma flow.

Quantification of norepinephrine metabolites provides additional insight into neuronal and extraneuronal transport. For example, spillover of tritium-labeled dihydroxyphenylglycol (DHPG), the intraneuronal metabolite, provides an index of neuronal norepinephrine reuptake and storage.<sup>26,27</sup> Being complex, the organ-specific isotopic dilution method has been applied to human heart failure research in only a few laboratories. Unfortunately, the catheter required for assessment of venous plasma flow rate and blood sampling is no longer available commercially.

## Microneurography

Multifiber or single fiber microneurography permits direct recording from postganglionic sympathetic nerves supplying muscular or cutaneous vascular beds.<sup>28,29</sup> This method provides unique real-time insight into the dynamic nature of sympathetic activity and its reflex control. The peroneal and tibial nerves are the preferred sites for electrode insertion.

Muscle and skin sympathetic nerves exhibit different discharge characteristics under basal conditions and in response to a variety of physical and emotional stimuli. Sympathetic discharge directed at resistance beds in skeletal muscle (MSNA) is entrained by input from arterial and cardiopulmonary mechanoreceptors and therefore exhibits distinctive pulse-synchronicity, with bursts appearing 1.1 to 1.3 seconds after the preceding R wave of the electrocardiogram.<sup>18,28</sup> In healthy subjects, MSNA is activated by reductions in

diastolic<sup>30</sup> or cardiac filling pressure,<sup>31</sup> exercise,<sup>32</sup> hypoxia,<sup>33</sup> hypercapnia,<sup>33</sup> and arousal from sleep,<sup>34</sup> and is inhibited by lung inflation.<sup>17,35</sup> Skin sympathetic nerves (SSNA) fire in response to noise, touch, or cold independently of the cardiac cycle. MSNA therefore provides greater insight than SSNA into mechanisms responsible for sympathetic activation in the setting of heart failure.

In patients with heart failure due to systolic dysfunction, MSNA is more reproducible from one week to the next than is plasma norepinephrine concentration,<sup>36</sup> but microneurography has its own limitations. Training and experience are required to ensure the consistent acquisition of high-quality, stable MSNA recordings devoid of skin or motor unit discharge. Burst amplitude is critically dependent upon electrode placement. The presence, in subjects with normal ventricular function, of significant positive correlations between individual values for MSNA and both renal and cardiac norepinephrine spillover,<sup>37,38</sup> and proportionately similar increases in both MSNA and cardiac norepinephrine spillover (CNES) in response to isometric exercise<sup>38</sup> are observations consistent with the concept that a common mechanism influences the strength of resting sympathetic discharge to the heart, kidney, and skeletal muscle. However, because the sympathetic nervous system is capable of targeted outflow, the possibility that in heart failure muscle sympathetic burst firing characteristics might differ from those of sympathetic nerves directed at other hemodynamically important vascular beds must be considered.

## Baroreflex-Heart Rate Sequences

The arterial baroreflex regulation of heart rate by the parasympathetic and sympathetic nervous systems can be assessed in humans in several ways.<sup>39</sup> Because cardiac cycle length responds much more rapidly to changes in acetylcholine than to norepinephrine release, brisk sinus node responses to acute perturbations in blood pressure are mediated primarily by reflex vagal activation or withdrawal. Thus the strength, or gain, of reflex vagal heart rate regulation can be determined by quantifying the bradycardic response to a bolus of a vasoconstrictor drug such as phenylephrine or the tachycardic response to nitroprusside or nitroglycerin-induced hypotension. Responses to longer ("steady-state") infusions of these vasoactive agents are less specific because they represent the net of competing vagal and sympathetic influences.

The use of such drugs for this purpose has several limitations. Nitrate donors have direct effects on sinoatrial

discharge.<sup>40</sup> By causing sustained vasoconstriction or dilation, these drugs will themselves cause mechanical distortion of baroreceptor nerve endings. The impact of these infusions is not specific to the arterial baroreceptor reflex; they may also alter the discharge frequency of mechanoreceptors situated in the atria and pulmonary vasculature.<sup>41</sup>

To avoid such drugs, heart rate responses to carotid sinus baroreceptor stimulation by neck suction or unloading by neck pressure have also been studied,<sup>42</sup> recognizing that blood pressure changes evoked by these maneuvers will elicit counterregulatory responses from aortic arch baroreceptors. Algorithms have been developed to track spontaneous fluctuations in blood pressure and heart rate from continuous noninvasive or invasive recordings and identify within these brief sequences with concordant changes in systolic blood pressure and the subsequent R-R intervals (inverse of heart rate).<sup>39</sup>

Common to these methods is the construction of a regression equation relating changes in pulse interval (in msec) to changes in systolic blood pressure (in mm Hg) of immediately preceding cardiac cycles. The slope of this line estimates the gain of the arterial baroreflex control of heart rate. Values obtained using the spontaneous sequence method are similar to those derived when blood pressure is altered by bolus administration of vasoactive drugs.<sup>43,44</sup> Importantly, the available methods do not distinguish between impairments in baroreflex sensitivity caused by altered mechanical transduction of blood pressure due to increased vascular stiffness, changes in the neural transduction of baroreceptor distortion, or altered central processing of afferent input.<sup>45</sup>

## Baroreflex–Sympathetic Nerve Sequences

Although not specific to the arterial baroreflex, microneurographic recordings during graded infusions of pressor or vasodilator drugs have been used to evaluate the reflex regulation of central sympathetic outflow.<sup>46</sup> Blood pressure changes induced by such infusions are relatively slow in onset; studies in anaesthetized rabbits<sup>47</sup> and conscious humans<sup>48</sup> indicate that the arterial baroreceptors transduce high-frequency oscillations more effectively and at higher gain than low-frequency oscillations.<sup>49</sup>

## Heart Rate Variability

Tonic vagal modulation of heart rate may also be estimated by determining its beat-to-beat variation. Time domain variables used for this purpose include the standard deviation of all normal (i.e., excluding ectopic beats) pulse intervals within a defined period,<sup>50</sup> the standard deviation of beat-by-beat pulse interval variations, the arithmetic mean of standard deviations derived from 5-minute intervals over a 24-hour recording period (to reflect short-term variability of heart rate), the number of differences of successive RR intervals greater than 50 msec divided by the total number of intervals, and variations on these formulas.<sup>51</sup>

Spectral analysis has attracted considerable interest as a noninvasive frequency domain method of estimating non-neural and neural parasympathetic and sympathetic contributions to short- and long-term oscillations in heart rate.<sup>51–54</sup> The North American Society of Pacing and Electrophysiology and the European Society of Cardiology have proposed a standardized approach to the acquisition and interpretation of these power spectra.<sup>51</sup> The algorithms most commonly employed to develop power spectra are fast Fourier transformation, autoregressive analysis, and coarse-graining spectral analysis. The latter method was developed to address the observation that harmonic contributions to heart rate variability are superimposed on a broadband nonharmonic “noise,” which is most

prominent from 0.00003 to 0.1 Hz (i.e., across the very low-frequency range and extending into the low-frequency spectral band [0.05–0.15 Hz])<sup>55</sup> and is fractal in nature.<sup>56</sup> Nonharmonic power can be quantified by plotting the log of spectral power as a function of the log of frequency (a  $1/f_\beta$  plot).<sup>55,57</sup> Once the nonharmonic component is extracted, more precise estimates of the residual harmonic contributions to low- and high-frequency (0.15 to 0.50 Hz) power can be obtained.<sup>55,57</sup> This feature is a particular advantage in the study of heart failure patients, in whom, compared with healthy subjects, there is a greater concentration of heart rate spectral power with very low and low-frequency bands.<sup>52,58–63</sup>

Because vagal blockade abolishes high-frequency power, oscillations in heart rate within this band have been attributed to parasympathetic activity, with respiration as its primary rhythmic stimulus. In experimental preparations, low-frequency power increased during baroreceptor deactivation with nitroglycerin, and was prevented by prior bilateral stellectomy.<sup>53,64</sup> Therefore, heart rate fluctuations within these frequencies were at first considered useful representations of sympathetic neural modulation. Indeed, maneuvers known to increase central sympathetic outflow, such as standing,<sup>54</sup> tilt,<sup>53,57</sup> exercise,<sup>65</sup> and lower body negative pressure<sup>57</sup> were shown to increase low-frequency spectral power, whereas decreases were observed during sleep,<sup>66</sup> and after  $\beta$ -blockade<sup>54</sup> or central sympatholysis with clonidine.<sup>66</sup> However, below 0.15 Hz, the power spectrum is also influenced by parasympathetic oscillatory input.<sup>53,54,65–69</sup> To address this complexity, the ratio between low- and high-frequency power has been proposed as an estimate of the balance between these two simultaneously active neural influences.<sup>53</sup> Although this concept of “sympathovagal balance” has been adopted by many authors,<sup>51</sup> it has been rejected by others.<sup>60,61</sup>

Frequency domain analysis should be appreciated primarily for the insight it allows into mechanisms responsible for oscillations in regulatory systems, and for its prognostic value in populations with cardiovascular disease. At best, it provides an estimate of the extent to which parasympathetic and cardiac sympathetic nerves are capable of modulating heart rate variability within specific frequency bands. Unfortunately, because some authors do not make the important distinction between modulation of neural discharge and its intensity, and/or between sympathetic outflow directed at the heart and regional vascular beds, considerable confusion as to the research and clinical utility of this method persists, particularly within the heart failure literature.<sup>52,58,60–62,70</sup>

## Cross-Spectral Analysis

Algorithms used to derive power spectra for heart rate can also be applied to blood pressure and respiratory signals. The mean voltage neurogram also displays fluctuations in muscle sympathetic nerve discharge, responsive to changes in blood pressure, heart rate, and respiration. The presence, in normal subjects, of synchronous and concordant changes in low- and high-frequency oscillations in both heart rate and MSNA variability elicited by interventions that raise and lower sympathetic discharge suggest that sympathetic and parasympathetic outflow can be modulated by a shared brainstem mechanism.<sup>71</sup>

Cross-spectral analysis between two variables of interest can be performed to determine the magnitude or gain (ratio of output/input power) of the transfer function, the coherence, and the phase delay between these signals.<sup>72</sup> The gain of the transfer function between systolic blood pressure (input) and pulse interval (output) oscillations within the low- or high-frequency regions ( $\alpha$ -coefficient) has achieved widespread acceptance, for research purposes, as a noninvasive spectral index of the baroreceptor reflex control of heart rate,<sup>39</sup> but its agreement with the vasoactive drug method is weak.<sup>73</sup>

Similarly, the gain of the transfer function between blood pressure (input) and MSNA (output) can be calculated as an estimate of arterial baroreflex regulation of efferent sympathetic nerve traffic.<sup>72</sup>

## SYMPATHETIC ACTIVATION AND PARASYMPATHETIC WITHDRAWAL IN HUMAN HEART FAILURE (see also Chapters 13, 45, and 46)

### Heart Failure with Impaired Systolic Function

#### Sympathetic Activation

On average, plasma norepinephrine concentrations, sampled during supine rest, are elevated in patients with asymptomatic LV dysfunction and increase further with the progression to overt congestive heart failure.<sup>1,3</sup> Nonetheless, in a substantial proportion of patients with both symptomatic and asymptomatic LV systolic dysfunction, plasma norepinephrine concentrations are similar to those of age-matched control subjects.<sup>13,16</sup>

In health, approximately 25% of total body norepinephrine spillover arises from the kidney and about 2% from the heart.<sup>23</sup> Cardiac norepinephrine spillover is elevated in mild heart failure, before any obvious increase in total body norepinephrine spillover, renal adrenergic drive, or MSNA<sup>15</sup> (Figures 16-2 and 16-3). In patients with more advanced LV dysfunction, studied before the advent of contemporary heart failure therapy, norepinephrine clearance was a third lower, and total body norepinephrine spillover doubled, when compared with control subjects. Approximately 60% of the latter increase resulted from a twofold to threefold rise in renal norepinephrine spillover, and a fivefold to twentyfold elevation in cardiac norepinephrine spillover.<sup>23,74</sup> In the paced-ovine model of heart failure, such preferential activation of cardiac sympathetic nerve traffic results from one third lower resting cardiac than renal burst incidence in healthy sheep, affording much greater cardiac sympathoexcitatory capacity once heart failure develops.<sup>75</sup> Indeed, in human heart failure, mental stress and cycling exercise elicit further increases in cardiac neurotransmitter release, indicating that considerable adrenergic reserve remains.<sup>76</sup>

In advanced heart failure, plasma epinephrine concentrations also rise, indicating heightened adrenal sympathetic nerve activity and medullary catecholamine release.<sup>3</sup> Under these circumstances, epinephrine may be transported into sympathetic nerve terminals and incorporated, along with norepinephrine, into vesicles.<sup>77</sup> Esler et al<sup>77</sup> have documented cardiac epinephrine spillover, averaging 2 ng/min or 2% of the corresponding norepinephrine spillover, in untreated congestive heart failure but not healthy subjects. Neuronal release from the gut, liver, lungs, and kidneys, comprising approximately 25% of the total epinephrine plasma appearance rate, was also detected. The implication of these observations, as discussed later, is that epinephrine, a potent  $\beta_2$ -adrenergic receptor agonist, could come to exert both a neurotransmitter and a humoral role in heart failure.<sup>78</sup>

To determine whether this increased norepinephrine spillover results from greater central sympathetic outflow, or from alterations in its synthesis, release, or reuptake, Leimbach et al recorded MSNA in subjects with moderate to severe heart failure. The mean sympathetic nerve firing rate correlated with plasma norepinephrine concentrations and was significantly elevated as compared with both age-matched and younger subjects with normal ventricular function.<sup>79</sup> The latter observation was subsequently replicated in studies involving younger subjects with dilated cardiomyopathy.<sup>80</sup> Single fiber recordings in heart failure patients have demonstrated

**FIGURE 16-2** Individual and mean  $\pm$  SEM values for cardiac NE spillover in patients with mild to moderate and severe CHF, in healthy subjects, and in patients with stable angina pectoris.

\*Statistically significant difference ( $P < .05$ ) between severe chronic heart failure (CHF) and both control groups. †Statistically significant difference ( $P < .05$ ) between mild to moderate CHF and both healthy subjects and angina patients. (From Rundqvist B, Elam M, Bergmann-Sverrisdottir Y, et al. Increased cardiac adrenergic drive precedes generalized sympathetic activation in human heart failure. *Circulation* 1997;95:169-175.)

that these increases result not only from a higher nerve firing probability, but also multiple within-burst discharges, and the recruitment of previously silent fibers.<sup>81</sup> By contrast, skin sympathetic activity is not increased in patients with heart failure.<sup>82</sup> This dissociation indicates that systems such as the high- and low-pressure baroreceptor reflexes, which tightly regulate muscle but not skin neural discharge, elevate the set point for central sympathetic outflow in heart failure.

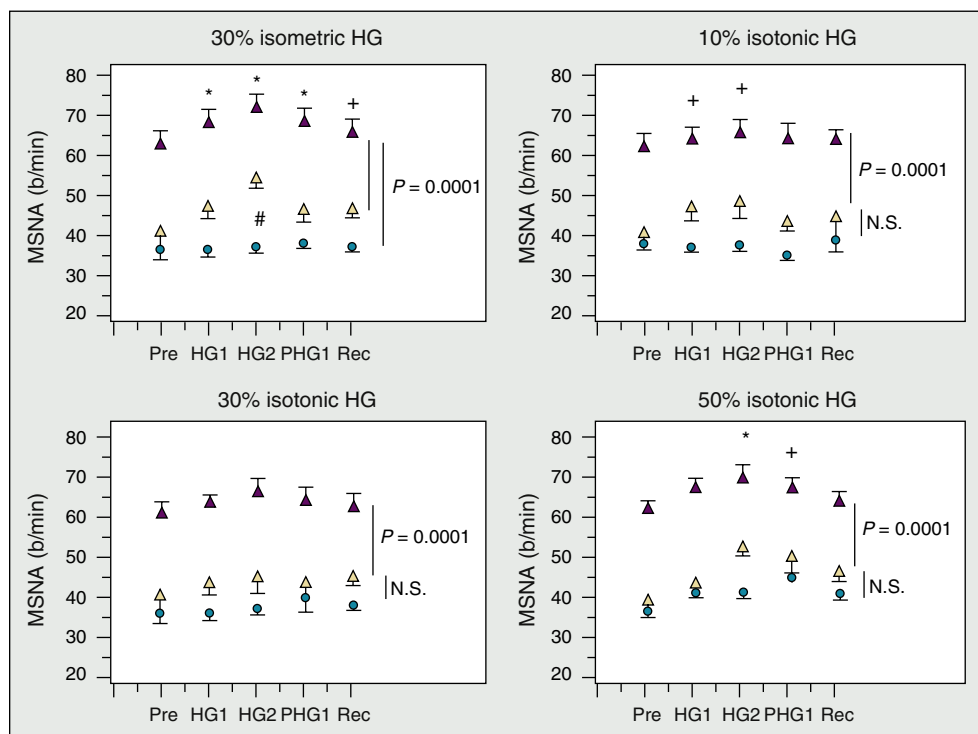

In subjects with mild depression of LV ejection fraction (down to 40%), group mean values for MSNA burst incidence are intermediate between those of patients with more severe heart failure and healthy control subjects.<sup>46</sup> There is little or no correlation with MSNA burst incidence once ejection fraction falls below 35%. Importantly, and in many patients with profound LV systolic dysfunction, muscle sympathetic nerve burst frequency or heart rate corrected burst incidence remains within the range observed in age-matched control subjects.<sup>14,15,83-85</sup> Notarius et al<sup>14</sup> recorded MSNA at rest, and during isometric and isotonic handgrip, of various intensities in age-matched subjects with normal and impaired LV systolic function (mean ejection fraction 19%). Patients with an MSNA  $\dot{V}O_2$  peak less than 56% of that predicted by their age, sex, and weight and height had consistently higher MSNA at rest and during exercise than age-matched healthy subjects. In contrast, MSNA in patients whose  $\dot{V}O_2$  peak was greater than 56% of their predicted value was remarkably similar to that of age-matched control subjects, despite their mean LV ejection fraction of 18% (Figure 16-4). These findings, coupled with the identification in patients with mild to moderate heart failure, by Rundqvist et al, of a selective increase in cardiac norepinephrine spillover, without any corresponding increase in mean values for muscle sympathetic nerve activity or total body norepinephrine spillover,<sup>15</sup> argue against generalized sympathetic activation as a cardinal characteristic of heart failure, or a consistent consequence of ventricular systolic dysfunction.

In the frequency domain, heart failure and age-matched control subjects display similar total MSNA power, harmonic power, nonharmonic power between 0 and 0.5 Hz and spectral density within the very low- (0 to 0.05 Hz) and high- (0.15 to 0.5 Hz) frequency bands.<sup>72</sup> However, low-frequency oscillations in the mean voltage neurogram were diminished

significantly or absent, despite near-maximal sympathetic burst incidence, suggesting progressive loss of central or reflex modulation of efferent sympathetic traffic with advancing heart failure.<sup>72,86</sup>

#### Parasympathetic Alterations

A blunted heart rate response to a rise in blood pressure was first described in human heart failure by Eckberg et al.<sup>87</sup> Bradycardic responses to carotid sinus baroreceptor stimulation by neck suction also are attenuated.<sup>42</sup> Subsequently, other investigators reported that slopes for baroreflex sensitivity (expressed either as ms/mm Hg or as beats per minute/

mm Hg) generated from infusions of phenylephrine and sodium nitroprusside to raise and lower systolic blood pressure, and thereby elicit reflexively increases and decreases in pulse interval, respectively, were shallower than in healthy controls, and diminished in proportion to the degree of LV systolic dysfunction.<sup>46</sup> New York Heart Association (NYHA) functional symptoms, the severity of mitral regurgitation, resting heart rate, and blood urea nitrogen.<sup>46,88,89</sup> Reflex and tonic vagal heart rate modulation, as assessed in the time domain (SDNN), correlate strongly.<sup>89</sup> Reductions in vagal modulation of heart rate appear to relate reciprocally to concurrent increases in sympathetic activity.<sup>90</sup>

### Parasympathetic and Sympathetic Contributions to Heart Rate Variability

Loss of vagal heart rate modulation can be detected in both the time and the frequency domain at the earliest stage of ischemic or dilated cardiomyopathy.<sup>91,92-94</sup> Soon after the onset of doxorubicin-induced cardiomyopathy, high-frequency spectral power decreases, whereas low-frequency spectral power increases, and there is a corresponding rise in plasma norepinephrine concentrations.<sup>95</sup>

However, this harmonic spectral index of cardiac adrenergic modulation is in general not increased, and is often attenuated in subjects with LV systolic dysfunction. Several groups have often demonstrated an inverse, rather than a direct relationship between low-frequency spectral power and discharge frequency in muscle sympathetic nerves or cardiac norepinephrine spillover.<sup>70,96</sup> Moreover, and as failure advances, heart rate often becomes invariant, and consequently refractory to analysis by most frequency domain methods.<sup>58,96,97</sup> Guazzi et al<sup>98</sup> observed a “predominance” of the low-frequency component of the heart rate power spectrum in NYHA class II patients, but not in class III or IV heart failure, which they attributed to functional sympathetic denervation in the latter groups.<sup>58,96</sup> It should be emphasized that power spectra reflect the fidelity with which postjunctional sinoatrial receptors respond to oscillations in nerve discharge, rather than the intensity of the sympathetic stimulus.<sup>58,99-101</sup> Whereas values for cardiac noradrenaline spillover are not affected by postsynaptic mechanisms, saturation or downregulation of cardiac postjunctional  $\beta$ -adrenoceptors and impairment of postsynaptic  $\beta$ -adrenoreceptor signal transduction will decrease sinoatrial responsiveness to neurally released norepinephrine.<sup>99</sup>

Nonharmonic contributions to the heart rate power spectrum are not attenuated in heart failure, but the complexity of the heart rate signal is less than in subjects with normal ventricular function, seemingly due to less in vagal modulation.<sup>97</sup>

### Heart Failure with Preserved Systolic Function (see Chapters 14 and 48)

Information as to sympathetic activation in heart failure with preserved ventricular systolic function is sparse. Benedict et al did not detect any increase in plasma norepinephrine concentrations of patients enrolled in the Studies of Left Ventricular Dysfunction (SOLVD) registry who had pulmonary congestion but a LV ejection fraction greater than 45%.<sup>102</sup> Although in a single center study of subjects 60 years or older, similar increases in mean values for plasma norepinephrine concentrations were found in cohorts with impaired and preserved systolic function<sup>103</sup> in general, the sympathetic nervous system would not appear to be as activated as in heart failure patients with systolic dysfunction,<sup>104</sup> and heart rate variability not as depressed.<sup>105</sup> MSNA has yet to be characterized in this specific population, but Grassi et al<sup>106</sup> have observed significantly higher MSNA burst incidence (but not plasma norepinephrine concentrations) in untreated men with hypertension-related LV diastolic dysfunction, as compared with hypertensive subjects with normal diastolic function or normotensive control subjects. Sudden increases in sympathoadrenal activity may be responsible for episodes of acute pulmonary edema in these individuals.<sup>107</sup>

## CLINICAL CONSEQUENCES

### Cardiac

In humans, the first manifestation of sympathetic activation is a selective increase in cardiac norepinephrine spillover.<sup>15</sup> Cardiac sympathetic activation and vagal withdrawal constitute adaptive mechanisms, engaged to maintain peripheral

tissue perfusion in the face of compromised cardiac performance. However, once congestion becomes manifest, the heart endures the greatest proportional increase in regional norepinephrine spillover.<sup>74</sup> Thus the failing heart is the organ exposed to the greatest magnitude and duration of sympathetic activation.

The direct myocardial consequences of this intense cardiac adrenergic drive include myocyte necrosis and apoptosis,<sup>108</sup> fibrosis,<sup>109</sup> decreased  $\beta$ -adrenergic receptor number, diminished  $\beta_1$ -adrenoceptor responsiveness to catecholamines, and altered  $\beta$ -adrenergic receptor signal transduction,<sup>110-113</sup> altered calcium regulation by the sarcoplasmic reticulum,<sup>114</sup> induction of proinflammatory cytokine expression,<sup>115</sup> oxidative stress,<sup>116</sup> destruction of sympathetic nerve terminals,<sup>117</sup> and depletion of myocardial norepinephrine content.<sup>26</sup> Non-uniform topography of myocardial norepinephrine depletion and sympathetic denervation should disturb the temporal coordination of right and left ventricular contraction and relaxation and alter the dispersion of refractoriness, promoting arrhythmogenesis. In advanced heart failure, cardiac norepinephrine becomes a potent marker of premature death,<sup>6</sup> and if cardiac norepinephrine stores are high, sudden death.<sup>26</sup>

The impact in heart failure of impaired vagal tone on heart rate modulation, regulation of LV performance, and inflammatory pathways has been reviewed recently in detail.<sup>118</sup>

### Peripheral

Excessive sympathetic drive to arteries, veins, and the kidney exacerbates the hemodynamic derangements of heart failure by increasing both preload and afterload. Stimulation of renal sympathetic nerves activates the renin-angiotensin-aldosterone axis, promotes tubular absorption of sodium and water, decreases glomerular filtration, increases renal vascular resistance, and blunts the renal responsiveness to atrial natriuretic peptide.<sup>119,120</sup> In young subjects with dilated cardiomyopathy, muscle sympathetic burst frequency correlates directly with resistance to blood flow in the calf, the vascular bed distal to the recording electrode.<sup>80</sup> This observation implicates sympathetically mediated vasoconstriction as an important mechanism for increased afterload in human heart failure. Increased sympathetic outflow may also raise ventricular afterload by decreasing conduit artery compliance.

### Exercise

A reduction in exercise capacity, whether due to dyspnea or fatigue, is a common heart failure symptom.<sup>121</sup> Several  $\beta_2$ -adrenoceptor polymorphisms associated with impaired exercise performance have been identified.<sup>122</sup> A central factor limiting exercise capacity is chronotropic incompetence due to decreased cardiac  $\beta$ -adrenergic receptor density or responsiveness to endogenous catecholamines,<sup>110</sup> whereas augmented neurogenic vasoconstriction represents one of several peripheral limitations.<sup>123,124</sup> In heart failure patients (but not in healthy age-matched control subjects) maximal oxygen uptake during exercise correlates inversely to resting MSNA<sup>83</sup> (Figure 16-5). Cardiac norepinephrine spillover, on the other hand, bears little relation to peak  $\dot{V}O_2$  in either group.<sup>125</sup> Reductions in blood flow below levels required to meet local metabolic demands during exercise may cause further reflexive increases in central sympathetic outflow by stimulating metaboreceptor afferents in skeletal muscle.<sup>14</sup>

### Mortality

Before the widespread use of angiotensin-converting enzyme inhibitors and  $\beta$ -adrenoceptor antagonists, the life expectancy of most heart failure patients with venous plasma

**FIGURE 16-5** Relationship between peak oxygen uptake ( $\dot{V}O_2$  peak) and muscle sympathetic nerve activity (MSNA) burst frequency and age in patients with heart failure. Three-dimensional graph shows individual data points and regression plane. Regression equation:  $\dot{V}O_2$  peak =  $40.5 - (0.347 \times \text{MSNA}) - (0.0570 \times \text{age})$ ; slope of the MSNA variable is significantly different from zero ( $P < .02$ ). By contrast there was no relationship between MSNA and  $\dot{V}O_2$  peak in healthy controls, in whom MSNA increased significantly with age ( $P < .04$ ) (not shown). (From Notarius CF, Ando SI, Rongen GA, et al. Resting muscle sympathetic nerve activity and peak oxygen uptake in heart failure and normal subjects.) *Eur Heart J* 2001;23:800-805.

norepinephrine concentrations greater than 800 pg/mL was less than 1 year.<sup>3,5</sup> Increased plasma norepinephrine concentrations also predict all-cause and cardiovascular mortality of asymptomatic patients with LV systolic dysfunction.<sup>126</sup> An inverse relationship between plasma norepinephrine concentrations and survival can still be detected in symptomatic patients receiving contemporary therapy, including  $\beta$ -blockade.<sup>127</sup> In a Brazilian study involving 122 heart failure patients, the level of MSNA was a significant independent predictor of mortality.<sup>128</sup>

A marked increased cardiac norepinephrine spillover rate, proportionally greater than corresponding increases in total body norepinephrine spillover, is a characteristic in the general population of survivors of sudden spontaneous ventricular arrhythmias,<sup>129</sup> and a particularly potent marker of 1-year mortality in advanced heart failure<sup>6</sup> (Figure 16-6). Estimating cardiac norepinephrine stores provides insight into the probable mode of death. In a group of 116 patients with a mean LV ejection fraction of 19%, followed on average for 18 months, those with greater than median estimated cardiac norepinephrine stores plus increased norepinephrine spillover had a twofold to threefold higher risk of sudden death, whereas patients with depleted myocardial norepinephrine stores and high cardiac norepinephrine spillover (reflecting chronically increased neurotransmitter turnover and reduced reuptake and storage) had a twofold to fourfold higher risk of death from progressive pump failure.<sup>26,130</sup> Noninvasive assessment of cardiac norepinephrine uptake using metaiodobenzylguanidine (MIBG) imaging has also been shown to identify heart failure patients at increased risk of death.<sup>131,132</sup>

Diminished baroreflex sensitivity and loss of heart rate variability are also associated with accelerated mortality from progressive myocardial failure and arrhythmias.<sup>7-9,11,12,133</sup> An attenuated reflex heart rate response to phenylephrine has similar prognostic implications in patients treated or not treated with  $\beta$ -adrenoceptor antagonists.<sup>89</sup> Loss of complexity in the heart rate signal, as estimated by nonharmonic

**FIGURE 16-6** Top, Histogram depicting the frequency distribution of cardiac norepinephrine (NE) spillover rates for patients with heart failure. Dashed line indicates group median (310 pmol/min). Data above indicates mean cardiac norepinephrine spillover rate for healthy subjects, with 95% confidence limits. Cardiac norepinephrine spillover was significantly higher in patients with heart failure ( $402 \pm 37$  vs.  $105 \pm 19$  pmol/min;  $P < .01$ ). Bottom, Survival curves for patients dichotomized by median cardiac norepinephrine spillover rate, with reduced survival ( $P = .01$ ) in patients with the highest values. (Data from Kaye DM, Lefkowitz J, Jennings GL, et al. Adverse consequences of high sympathetic nervous system activity in the failing human heart. *J Am Coll Cardiol* 1995;26:1257-1263, with permission from the American College of Cardiology Foundation.)

power-law regression parameters,<sup>133</sup> and low-frequency harmonic power may be the most sensitive predictors of sudden death.<sup>11</sup>

## MECHANISMS

Alterations in the neurogenic control of the circulation with the onset and progression of heart failure can arise from one or more elements responsible for the regulation of autonomic tone, such as inhibitory and excitatory input to brainstem vasomotor neurons, cortical modulation of central nervous system integration and catecholamine turnover, and efferent

**FIGURE 16-7** Updated synthesis illustrating mechanisms responsible for sympathetic activation and parasympathetic withdrawal in heart failure. As heart failure due to systolic dysfunction develops, inhibitory input from primarily ventricular mechanoreceptors decreases (*thin line*), whereas modulation of efferent sympathetic nerve traffic by the arterial baroreceptor and pulmonary stretch reflexes is preserved. Vagal contributions to heart rate variability and the efferent vagal and sympathetic heart rate responses to arterial baroreflex perturbations are attenuated. Excitatory (+) input from a normally quiescent atrial reflex, activated by increases in cardiac filling pressures, and from chemically sensitive ventricular afferent nerve endings, triggered by ischemia, adds to augmented sympathoexcitatory input from arterial chemoreceptors and from exercising skeletal muscle in heart failure (*thick lines*). Central excitatory mechanisms (*downward pointing arrow*) include an angiotensin II-AT<sub>1</sub> receptor-NADPH-superoxide axis, and the coexistence of sleep-related breathing disorders. Potential efferent mechanisms include prejunctional facilitation of NE release, and altered NE uptake. The time course through which these mechanisms are engaged differs between individuals. Relatively asymptomatic systolic dysfunction is characterized by a selective increase in cardiac NE release, and a reduction in tonic and reflex vagal heart rate modulation, whereas in advanced heart failure there is a generalized increase in sympathetic nerve traffic (*thick arrow shafts, thick lines*), blunted parasympathetic and sympathetic control of heart rate (*thin line*), and impairment of the reflex sympathetic regulation of vascular resistance. *Ach*, acetylcholine; *CNS*, central nervous system; *E*, epinephrine; *Na<sup>+</sup>*, sodium; *NE*, norepinephrine. Clinical implications of an updated model. *J Am Coll Cardiol* 2009;54:375-385.)

mechanisms determining the release rates of and receptor responsiveness to neurotransmitters (Figure 16-7).

### Afferent Influences

In healthy subjects, inputs from carotid sinus and aortic arch “arterial high pressure” and the cardiopulmonary “low pressure” mechanoreceptors provide the principal peripheral inhibitory influences on sympathetic outflow, with discharge from arterial chemoreceptors and muscle “metaboreceptors” providing excitatory information. The efferent vagal component of the baroreceptor heart rate reflex is also subject to arterial baroreceptor afferent input. At rest, healthy individuals display low sympathetic discharge and high heart rate variability. Reflex vagal and sympathoneural responses to acute perturbations in blood pressure are brisk.

#### Arterial Baroreceptor Reflexes

Arterial baroreceptor nerve discharge is activated by the pressure wave of systole, and diminishes or falls silent during diastole. Systolic stimulation of baroreceptor discharge will increase parasympathetic and decrease efferent sympathetic outflow reflexively. Baroreceptor silence during diastole eliminates the tonic inhibition of efferent sympathetic outflow, resulting, for example, in a burst of MSNA.<sup>30</sup>

Blunted arterial baroreflex control of heart rate is a characteristic feature of human heart failure.<sup>87</sup> Because baroreceptor afferent nerve discharge, which governs both sympathetic and vagal efferent limbs of this reflex arc, is less responsive to changes in local distending pressure in experimental models of ventricular systolic dysfunction, the prevailing view has been that arterial baroreflex regulation of vagal and sympathetic outflow in human heart failure are impaired equally.<sup>17,134-137</sup> However, assessment of the baroreceptor-heart rate reflex in humans relies upon the indirect estimation of sinoatrial responsiveness to two distinct and differentially regulated autonomic inputs. In heart failure, impaired efferent vagal ganglionic neurotransmission diminishes parasympathetic responsiveness to baroreceptor stimulation,<sup>138</sup> yet myocardial responsiveness to acetylcholine is intact in humans<sup>139</sup> and in experimental heart failure augmented.<sup>140</sup> By contrast, cardiac-specific sympathetic neural modulation is attenuated by downregulation or desensitization of  $\beta$ -adrenoceptors,<sup>141</sup> rendering the sinoatrial node less responsive to reflexively elicited changes in neurally released norepinephrine. Non-cardiac sympathetic efferent responses to arterial baroreflex perturbation upstream of the effector target can be measured directly and specifically by microneurography. Heart failure, by these several mechanisms, reduces the variability and complexity of heart rate but the variability of blood pressure

**TABLE 16-1** Evidence for Preserved Arterial Baroreflex Modulation of Sympathetic Activity in Human Heart Failure

Concept	Observation
MSNA pulse-synchronicity lost after sinoaortic baroreceptor denervation <sup>18</sup>	Pulse-synchronicity preserved, even in end-stage HF <sup>90</sup>
Pause with decay in DBP after pre-mature beat increases reflexively MSNA burst amplitude, duration, and area; rise in DBP after post-extrasystolic beat inhibits MSNA <sup>18</sup>	Extra-systolic augmentation of MSNA amplitude, duration, and area and post-extrasystolic suppression replicated in HF; duration or suppression proportional to magnitude of diastolic overshoot <sup>147</sup>
MSNA bursts track previous DBP with 1.2-1.3 sec lag <sup>30</sup>	Synchronization of sympathetic neural alternans with pulsus alternans <sup>49</sup>
Frequency domain estimate of arterial BR gain derived by cross-spectral analysis with BP oscillations as stimulus and MSNA oscillations as response	Transfer function gain in HF and healthy subjects similar across all frequency bands; calculated gain highest in high-frequency range <sup>72</sup>
Arterial BR unloading with SNP elicits reflex increase in TNES	Similar reflex increase in TNES in HF and healthy subjects <sup>25</sup>
LV pacing in HF increases DBP	Acute inverse DBP-MSNA relationship immediately upon conversion from to RV to LV pacing <sup>324</sup>
Muller maneuver increases acutely intrathoracic aortic and LV trans-mural pressure	MSNA inhibited similarly in HF and control subjects <sup>195</sup>

is similar in patients and age-matched healthy subjects,<sup>97</sup> suggesting relatively preserved modulation of sympathetic outflow in this condition.

Brandle et al<sup>142</sup> found no differences in the time course of changes in hemodynamics and plasma norepinephrine concentrations during the development of pacing-induced heart failure in dogs with and without sinoaortic baroreceptor denervation, and concluded that impairment of the arterial baroreflex could not be responsible for sustaining the increase in sympathetic outflow in this experimental model of heart failure. Reports, in heart failure, of significant inverse relationships between stroke work index and muscle sympathetic nerve activity<sup>143</sup> and between cardiac output and cardiac norepinephrine spillover<sup>144</sup> suggest that the arterial baroreflex regulation of efferent sympathetic discharge may actually be appropriate, when hemodynamic alterations present in this condition are considered. Grassi et al, using the vasoactive drug method, described an impairment of both limbs of the reflex control of MSNA that worsened with the progression of heart failure.<sup>46</sup> A second study also reported diminished arterial baroflex gain, but unfortunately in this report the mean age of patients was twice that of control subjects.<sup>88</sup> By contrast, Dibner-Dunlap et al<sup>145</sup> documented similar gains in the arterial baroreflex control of MSNA in healthy and heart failure subjects, whereas reflex responses to stimuli that raised and lowered cardiac filling pressure without affecting systemic blood pressure were markedly attenuated. These investigators concluded that impairment of the cardiopulmonary (not the arterial) baroreflex was the fundamental defect in the regulation of sympathetic outflow in human heart failure<sup>145,146</sup> (see Figure 16-7).

Two autonomic disturbances characteristic of advanced heart failure should be considered carefully when interpreting the results of experiments involving vasoactive drugs: (1) muscle sympathetic burst firing is pulse synchronous, and its incidence (i.e., bursts/100 cardiac cycles) approaches 100%; and (2) the heart rate response to arterial baroreceptor perturbation by phenylephrine or nitroprusside is markedly attenuated. If cardiac frequency hardly changes in response to these interventions, there is little opportunity arithmetically to modify a cardiac frequency-dependent representation of sympathetic nerve firing. If the reported effect of these drug interventions on MSNA burst frequency is reexpressed in terms of cardiac frequency (or as changes in absolute units, rather than as a percentage of baseline values) the gain of the arterial baroreflex regulation of MSNA is not appreciably impaired.<sup>18,19,46,88</sup>

**FIGURE 16-8** The electrocardiogram (ECG), mean voltage neurogram for (MSNA), blood pressure, and respiratory excursions in a young man with end-stage heart failure due to dilated cardiomyopathy. Paroxysms of ventricular bigeminy result in a doubling of the blood pressure cycle length, a longer diastolic period, and lower diastolic blood pressure. These changes are registered immediately by the arterial baroreceptors and result in a corresponding increase in the duration of the sympathetic burst and a marked increase in burst amplitude. These are reversed with restoration of sinus rhythm.

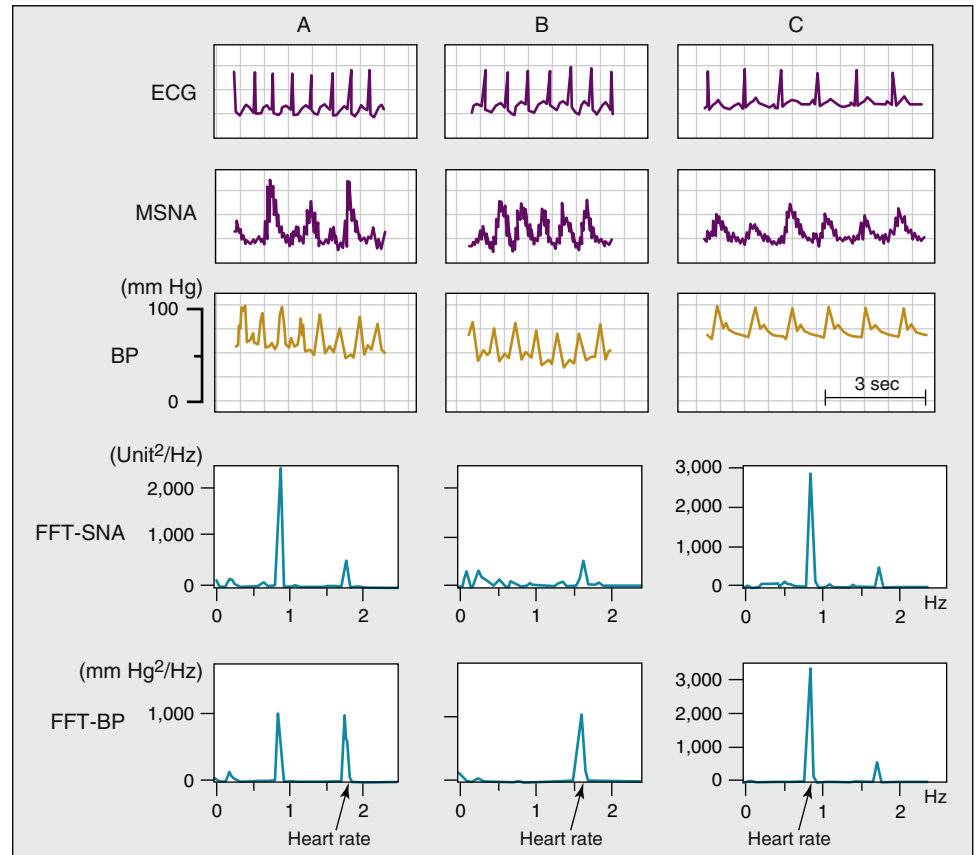

Several lines of evidence obtained using different approaches, and summarized in Table 16-1, are consistent with the concept that arterial baroreflex modulation of efferent sympathetic outflow is relatively intact in human heart failure\* (Figures 16-8 and 16-9). Further evidence for preserved functionality of the arterial baroreflex arises from recent experiments involving the paced-canine and paced-ovine heart failure models. In the former, electrical stimulation of the carotid sinus nerve to increase afferent input from the unloaded arterial baroreceptor caused a significant fall in plasma norepinephrine concentration and enhanced survival.<sup>148</sup> In the latter, directly recorded cardiac sympathetic nerve activity (CSNA) was significantly increased, and the baroreceptor regulation of heart rate was profoundly impaired, but the arterial baroreflex control of both CSNA and renal sympathetic nerve traffic did not differ from that of normal sheep.<sup>75,149</sup>

In human heart failure, the renal efferent response to arterial baroreceptor unloading behaves differently. In one study, hypotension induced by nitroprusside elicited an 85%

**FIGURE 16-9** **A**, The ECG, muscle sympathetic nerve activity (MSNA), systemic blood pressure (BP), and power spectra of sympathetic nerve activity (FFT-SNA) and blood pressure during pulsus alternans. **B**, Recordings during intravenous nitroglycerin with disappearance of pulsus alternans. During pulsus alternans, there were relatively small changes in BP yet large oscillations in the amplitude of nerve bursts. Each sympathetic burst followed the preceding diastolic BP by 1.2 to 1.3 seconds, with a fall in amplitude as diastolic BP rose and vice versa. Power spectra were derived by use of fast Fourier transformation (FFT) from all cardiac cycles during a 7-minute period. During alternans (**A**), there were two peaks in both the BP and the MSNA signal, one at the prevailing heart rate and a second at half this rate—that is, corresponding to the alternans frequency (0.9 Hz). MSNA power at the alternans frequency was greater than at the cardiac frequency, indicating that sympathetic alternans was present at this frequency throughout most of this 7-minute recording period. The lower frequency peak disappeared when pulsus alternans was abolished (**B**); the residual BP and MSNA peaks are at this patient's heart rate. **C**, Similar recordings of ECG, MSNA, and BP and the power spectra for MSNA and BP in a patient with heart failure but without pulsus alternans (for purposes of comparison with A and B). A single peak of high spectral power falls on the heart rate frequency (arrow) in both the MSNA and BP spectra. (From Ando S, Dajani HR, Senn BL, et al. Sympathetic alternans. Evidence for arterial baroreflex control of muscle sympathetic nerve activity in congestive heart failure. *Circulation* 1997;95:316-319.)

increase in renal NE spillover in healthy control subjects, but no net change in heart failure subjects, albeit from a nearly threefold higher baseline.<sup>150</sup> What could not be determined from these experiments is whether the absence of sympathoexcitation represents a ceiling effect (i.e., renal NE spillover cannot be increased further from these high baseline levels, as suggested by the ovine experiments of Ramchandra et al<sup>75</sup>) or the integrated response to the combination of arterial and cardiopulmonary receptor unloading with a concurrent reduction in renal venous pressure. In a more recent study, low dose nitroglycerin reduced pulmonary artery pressures selectively without altering renal NE spillover in either heart failure or healthy subjects, whereas a higher, hypotensive dose was accompanied by a significant reduction only in those with systolic dysfunction.<sup>151</sup>

#### Cardiopulmonary Reflexes

In healthy subjects, cardiopulmonary reflexes elicit sympathoinhibition and forearm vasodilation, when stimulated by increasing cardiac filling pressures, volume, or inotropic state, and sympathoexcitation when unloaded by interventions such as phlebotomy, or nonhypotensive lower body negative pressure (LBNP).<sup>41</sup> There is substantial evidence that such responses are altered in human heart failure. When Middlekauff et al<sup>152</sup> performed phlebotomy, the reflex forearm vasoconstrictor response to this stimulus was attenuated in heart failure patients, whereas the renal cortical vasoconstrictor response, as assessed by positron emission tomography, was preserved. In some patients, lower body negative pressure elicits forearm vasodilation rather than vasoconstriction.<sup>153</sup> Activation of vagal afferents with

inhibitory reflex effects on sympathetic outflow, as a result of acute increases in ventricular contractile force (possibly due to release of pericardial constraint) has been proposed as a potential mechanism for this paradoxical response.<sup>153,154</sup> However, sympathetic outflow was not quantified in these experiments. Subsequently, Dunlap et al reported greatly attenuated reflex MSNA responses to stimuli that raised and lowered cardiac filling pressure without affecting systemic blood pressure.<sup>145</sup> In our laboratory, nonhypotensive LBNP increased total body norepinephrine spillover significantly in subjects with normal ventricular systolic function, whereas there was only a trend, not significant, toward higher values in those with impaired ventricular systolic function.<sup>155</sup>

Such impairment would not be sufficient to account for two aspects of sympathoexcitation in heart failure: (1) a selective increase in cardiac norepinephrine spillover in mild to moderate human heart failure, without change in total body or renal norepinephrine spillover or in muscle sympathetic nerve activity,<sup>15</sup> and (2) the presence of direct correlations, in more advanced heart failure, between MSNA and pulmonary artery or capillary wedge pressure.<sup>79,143</sup> These observations suggest that a reflex that senses the degree of cardiopulmonary volume or pressure overload becomes active in heart failure. Indeed, in the pacing-induced canine model of congestion, Wang and Zucker documented sensitization of cardiac sympathetic afferents responsive to chemical stimulation, and speculated that enhancement of this reflex might contribute to increased sympathetic nerve traffic in chronic human heart failure.<sup>156,157</sup> This cardiac sympathetic afferent reflex was potentiated by acute volume expansion.<sup>158</sup>

**FIGURE 16-10** Cardiac norepinephrine spillover (CANESP) responses to nonhypotensive and hypotensive LBNP. ■ indicates normal LV function group; ●, CHF group; C, control; and RC, recovery. \* $P < .05$  vs. normal LV function group at control. (Data from Azevedo ER, Newton GE, Floras JS, et al. Reducing cardiac filling pressure lowers cardiac norepinephrine spillover in patients with chronic heart failure. *Circulation* 2000;101:2053-2059.)

Is there evidence in humans for activation, by increased filling pressure, of a cardiac-specific sympathoexcitatory reflex, perhaps arising from myelinated cardiac afferent nerves?<sup>159</sup> In patients with heart failure, there is a significant positive relationship between the pulmonary capillary wedge pressure and cardiac norepinephrine spillover.<sup>144</sup> Infusion of sodium nitroprusside in those with secondary pulmonary hypertension lowers cardiac norepinephrine spillover in addition to atrial and arterial pressure,<sup>160</sup> as does the brief application of positive airway pressure to reduce atrial and pulmonary venous transmural pressure (simultaneous reductions in intrathoracic aortic arch and LV transmural pressure should increase sympathetic outflow reflexively<sup>161</sup>). Nonhypotensive LBNP, applied to reduce selective cardiac filling and pulmonary pressure, decreases cardiac norepinephrine spillover in heart failure, but not in subjects with normal ventricular systolic function (Figure 16-10).<sup>155</sup> Because this maneuver lowers stroke volume and cardiac output, the reduction in cardiac norepinephrine spillover (but not total body norepinephrine spillover, which tends to increase) cannot be explained by activation of ventricular mechanoreceptors due to increases in systolic force.<sup>153,154</sup> Instead, Azevedo et al<sup>155</sup> attributed the sympathoinhibitory response to nonhypotensive LBNP to unloading of low-pressure mechanoreceptor afferents in the heart and lungs that reflexively and selectively excite cardiac adrenergic drive<sup>159</sup> (see Figure 16-7). Saline infusion causes a paradoxical increase in forearm vascular resistance in mild heart failure, an effect not seen in control subjects,<sup>162</sup> suggesting that in humans the efferent limb of this reflex, when stimulated acutely, might not be selective to cardiac sympathetic nerves.

Increasing the intensity of LBNP to induce systemic hypotension evoked a significant increase in cardiac norepinephrine spillover in the control group only (see Figure 16-10),<sup>155</sup> an observation concordant with these investigators' prior description of similar increases in total body norepinephrine spillover in heart failure and healthy subjects, yet attenuation of the reflex increase in cardiac norepinephrine spillover in response to a hypotensive infusion of sodium nitroprusside in those with impaired systolic function.<sup>25</sup> Together, these

findings suggest that the normal arterial baroreflex-mediated increase in cardiac norepinephrine spillover, evoked reflexively by a fall in systemic blood pressure, is tempered significantly in heart failure by concurrent removal of an excitatory stimulus arising from cardiac sympathetic afferents.

To summarize, the weight of present evidence indicates that arterial baroreceptor reflex regulation of muscle and cardiac sympathetic activity is not impaired in human heart failure. Consequently, the higher sympathetic nerve firing rate characteristic of the majority of patients with systolic dysfunction can be considered an appropriate reflex response to alterations in their systemic hemodynamics. The principal defect in baroreceptor regulation of the sympathetic nervous system appears, instead, to arise from reflexes originating in mechanoreceptors situated within the heart and pulmonary vasculature.<sup>146</sup> In some patients with heart failure, these baroreflex-mediated responses appear sufficient to account for the prevailing level of sympathetic activity, but in many others the contribution of nonbaroreflex-mediated excitatory reflexes also must be considered.

### Nonbaroreflex Mechanisms

**Pulmonary Stretch Reflexes.** A reflex arising from pulmonary stretch receptors distended by inspiration will inhibit sympathetic outflow.<sup>35</sup> In healthy subjects, breathing frequency correlates positively with MSNA burst frequency, and with reflex sympathoneural responses to hypoxia and hypercapnia.<sup>163</sup> The influence of breathing pattern on oscillations in adrenergic discharge is preserved in heart failure patients,<sup>72,164</sup> in whom decreased tidal volume, high respiratory frequency,<sup>165</sup> and brief periods of apnea elicit marked increases in MSNA (Figure 16-11). However, a greater tidal volume is required to inhibit completely MSNA in heart failure patients than in healthy subjects.<sup>164</sup> Rapidly adapting airway vagal sensory receptors, responding to inflation and deflation, are also stimulated by increases in left atrial pressure and extravascular pulmonary fluid volume.<sup>166</sup>

**Peripheral Chemoreceptor Reflexes.** The contribution of arterial chemoreceptors to sympathetic activation in experimental models of heart failure has been reviewed recently in detail by Schultz et al.<sup>167</sup> In healthy subjects, brief exposure to hypoxia can cause sustained increases in MSNA, persisting well after reoxygenation.<sup>168</sup> Augmented peripheral chemoreceptor sensitivity to hypoxia is reported to be present in approximately 40% of chronically treated heart failure patients<sup>169,170</sup> (see Figure 16-7). However, in two studies, inhalation of 100% O<sub>2</sub> to suppress peripheral chemoreceptor input had no effect on group mean values for MSNA, suggesting that chemoreceptor-mediated sympathoexcitation may not be this prevalent.<sup>171,172</sup> Di Vanna et al<sup>173</sup> described increased MSNA responses to hypoxic (peripheral) and hypercapnic (central) chemoreceptor stimulation in class II-III heart failure patients compared with control subjects. Carotid chemoreceptor reflex-induced sympathetic activation in heart failure may assume greater importance during exercise than in the resting state.<sup>174</sup>

Increased peripheral chemoreceptor sensitivity gives rise to several autonomic disturbances with adverse prognostic implications. These include higher plasma norepinephrine and brain natriuretic peptide concentrations, impaired arterial baroreflex control of heart rate, augmented very low-frequency heart rate and blood pressure spectral power, but loss of low-frequency heart rate variability, the development of periodic oscillations in breathing at very low frequency both during sleep and in the awake state, enhanced ventilatory responses to exercise, and a higher likelihood of developing nonsustained ventricular tachycardia.<sup>169,170,175-178</sup> In heart failure patients with coexisting chronic obstructive pulmonary disease, significantly higher plasma norepinephrine concentrations may reflect chronic hypoxemia.<sup>179</sup>

**FIGURE 16-11** Tidal volume ( $V_T$ ), esophageal pressure (Pes), heart rate (HR), the electrocardiogram (ECG), muscle sympathetic nerve activity (MSNA), and blood pressure (BP) in a young patient with dilated cardiomyopathy. Recordings taken during spontaneous breathing and spontaneous episodes of central apnea, while awake, only minutes apart, demonstrate marked activation of central sympathetic outflow and increased BP corresponding to periods of apnea.

### Sleep-related Breathing Disorders (see also Chapter 32)

Normally, nonrapid eye movement (non-REM) sleep is characterized by reductions in central sympathetic outflow, heart rate, stroke volume, and systemic vascular resistance. Blood pressure typically falls 20% to 25% from average waking levels.<sup>180-183</sup> Vagal activity, and in particular the arterial baroreflex control of heart rate, is augmented.<sup>184,185</sup> Paroxysms of sympathetic discharge provoking surges in heart rate and blood pressure occur during rapid eye movement (REM) sleep, but in general REM comprises only 15% of sleep time.<sup>182</sup> Systolic dysfunction itself is associated with briefer sleep duration and interrupted sleep,<sup>186,187</sup> resulting in a greater integrated daily adrenergic burden. However, sleep apnea is evident in the majority of chronic symptomatic heart failure patients studied in published reports, with approximately one third exhibiting obstructive sleep apnea (OSA) and one third central sleep apnea (CSA).<sup>188,189</sup>

By deactivating pulmonary stretch receptors and stimulating peripheral and central chemoreceptors by hypoxia and hypercapnia, each pause in breathing during sleep elicits profound increases in MSNA.<sup>33,190-193</sup> This sympathetic excitation is independent of and in addition to any reflex responses to mechanoreceptor unloading resulting from pump failure or systemic hypotension in heart failure. Inspiratory efforts against a collapsed upper airway, as occurs in obstructive sleep apnea (OSA), will generate extreme negative swings in intrathoracic pressure (i.e., an abrupt increase in LV afterload). Because the failing heart is more sensitive to increases in afterload, obstruction provokes an acute fall in stroke volume and diastolic blood pressure.<sup>194</sup> This unloading of arterial baroreceptors elicits a reflex increase in MSNA of greater intensity in heart failure than in control subjects with normal LV function, who are better able to maintain stable systemic blood pressure in the face of this mechanical stimulus.<sup>195</sup> Arousal from sleep, which terminates an apneic event, is accompanied by a further surge in central sympathetic outflow, a rise in blood pressure above awake levels, and a decrease in heart rate variability due to a concurrent reduction in vagal tone.<sup>182,195,196</sup> In severely affected patients, these cycles of apnea and arousal recur repeatedly over the course

of each night, exposing the failing heart and peripheral circulation during sleep to greater concentration of norepinephrine than is required to maintain circulatory homeostasis. Nocturnal and daytime exposure to heightened adrenergic drive<sup>168</sup> could lead, over time, to chronic hypertension.<sup>197,198</sup>

In patients with OSA but normal LV function studied while awake, the after-effects of these nocturnal sympathoexcitatory stimuli induce sustained increases in MSNA during wakefulness.<sup>190,199,200</sup> Coexisting obesity and hypertension<sup>189</sup> are important clues to the presence of obstructive sleep apnea in patients with LV systolic dysfunction. Grassi et al<sup>201</sup> described higher daytime MSNA in heart failure patients with obesity or hypertension, but did not report the prevalence of sleep apnea in this population. In a study involving 60 heart failure patients, of whom 43 had an apnea hypopnea index (AHI) of 15 events per hour,<sup>85</sup> MSNA during wakefulness was significantly higher in those with sleep apnea. In those with predominantly OSA, MSNA was increased by 11 bursts per 100 heartbeats. When OSA was abolished in a subset of such patients by 1 month of continuous positive airway pressure (CPAP), MSNA fell by 12 bursts per 100 heartbeats.<sup>85,202</sup> In the absence of sleep apnea, MSNA of treated heart failure patients is not appreciably greater than that of aged-matched control subjects (Figure 16-12). Such data provide important evidence in human heart failure for convergence on central sympathetic neurons of input from two independent sympathoexcitatory influences (heart failure and sleep apnea) that act in concert to increase MSNA through a process of additive summation<sup>203</sup> (Figure 16-13). Mortality rates in patients with untreated OSA and heart failure are greater than those of heart failure patients without OSA,<sup>204</sup> suggesting that this additional OSA-mediated sympathoexcitation has the independent potential to accelerate the progression of systolic dysfunction.

A transition from predominantly obstructive apnea at the beginning of the night to mostly central events toward waking has been observed in some patients.<sup>205</sup> Also observed is a prolongation of circulation time, and a reduction in  $P_{CO_2}$  below the threshold for apnea. These observations suggest that these repetitive increases in LV afterload during airway obstructions

**FIGURE 16-12** Scattergrams and means  $\pm$  standard errors for muscle sympathetic burst incidence (bursts per 100 cardiac cycles) in treated heart failure patients with and without sleep apnea, as compared with age-matched healthy laboratory controls. Note that MSNA in treated heart failure patients without sleep apnea is not significantly greater than that of healthy subjects, whereas the coexistence of sleep apnea with heart failure is accompanied by significantly higher MSNA ( $P = .005$ ). (Reproduced with permission of the American College of Cardiology Foundation from Floras JS. Sympathetic nervous system activation in human heart failure. Clinical implications of an updated model. *J Am Coll Cardiol* 2009;54:375-385.)

cause systolic function to deteriorate over the course of the night, with increased venous return and LV filling pressure stimulating hyperventilation and hypocapnia. Should this pattern progress over a period of months or years, the coexistence of obstructive apnea could predispose heart failure patients to worsening LV systolic function and central sleep apnea.

Compared with heart failure patients matched for ejection fraction and other clinical characteristics, but without sleep-related breathing disorders, those with CSA have higher nocturnal urinary norepinephrine excretion and increased plasma norepinephrine concentrations while awake. The magnitude of such activation is proportional to the frequency of arousal from sleep and the degree of apnea-related hypopnea.<sup>206</sup> MSNA during wakefulness is also greater in heart failure patients with, than without, CSA.<sup>85</sup> Mansfield et al<sup>207</sup> reported higher rates of cardiac and total body norepinephrine spillover in heart failure patients with CSA than in those without CSA or with OSA, and attributed these differences to greater hemodynamic decompensation in those with CSA. A direct comparison with the microneurographic literature is not possible because these investigators did not measure MSNA and used a quite low apnea-hypopnea index ( $>5$  events per hour) to define sleep apnea.

#### Myocardial Ischemia and Infarction (see also Chapter 23)

**Nonbaroreflex Mechanisms.** Myocardial ischemia and prior infarction, very common in the heart failure population, should also exert, via several mechanisms, an additional acute or chronic effect on sympathetic outflow that is both additive and independent of the magnitude of ventricular systolic function and consequent hemodynamic derangement.<sup>208,209</sup>

### Summation and interaction of reflexes causing directionally similar responses

**FIGURE 16-13** Convergence of afferent input from two sets of reflexes (in this example, heart failure and sleep apnea) eliciting directionally similar (in this example, excitatory) effects on muscle sympathetic nerve activity (MSNA) may summate and interact centrally through mutual inhibition (redundancy), simple additive summation, or mutual facilitation. The difference in MSNA recorded during wakefulness in heart failure patients with and without obstructive sleep apnea (OSA)<sup>85</sup> is eliminated when OSA is abolished.<sup>202</sup> This finding is consistent with the concept that these two sympathoexcitatory stimuli interact through a process of simple additive summation. (Reproduced with permission of the American College of Cardiology Foundation from Floras JS. Sympathetic nervous system activation in human heart failure. Clinical implications of an updated model. *J Am Coll Cardiol* 2009;54:375-385.)

Both anterior and inferoposterior wall ischemia elicit reflex sympathoexcitation by stimulating cardiac sympathetic afferent nerves.<sup>210</sup> Stimulation, by ischemia, of the vanilloid receptor-1 on cardiac spinal afferent nerves may represent one signaling pathway mediating this reflex response.<sup>211</sup>

Although cardiac sympathetic afferents may be stimulated by reductions in myocardial blood flow above the threshold for angina,<sup>159</sup> the reflex sympathoexcitatory response (which is reversed by stellectomy) is most evident during transmural ischemia.<sup>210</sup> If cardiac output and hence arterial blood pressure were to decrease as a consequence of ischemia, the resultant unloading of sinoaortic baroreceptors should elicit a further reflexive increase in sympathetic outflow. Vagal afferents arising from inferoposterior ventricular segments evoke a depressor response.<sup>212-214</sup> Prior myocardial infarction will interrupt the course of mechanoreceptor input to vagal afferents with inhibitory effects on sympathetic outflow.<sup>209,215</sup>

Consistent with this concept, 6 months after myocardial infarction, patients with relatively preserved ejection fraction (mean 52%) had significantly higher single fiber and multifiber MSNA burst incidences than patients with coronary artery disease or control subjects.<sup>216</sup> Do otherwise clinically similar patients with ischemic and nonischemic cardiomyopathy differ with respect to sympathetic activation? Higher plasma norepinephrine concentrations<sup>217</sup> and higher relative low-frequency heart rate spectral power<sup>218</sup> have been described for patients with ischemic as compared with dilated cardiomyopathy, whereas Grassi et al<sup>219</sup> reported virtually identical values for MSNA in these two cohorts. By contrast, in a comparative study of well-matched treated patients with ischemic and nonischemic dilated cardiomyopathy who were 5 to 10 years younger, and had much lower ejection fractions (22% vs. 33% for the Italian group), MSNA was significantly higher in those with an ischemic cardiomyopathy, and in addition, their  $\dot{V}O_2$  peak was significantly less.<sup>220</sup>

In advanced heart failure, metabolic disturbances, such as increased free radical production, and a shift from glucose to greater fatty acid oxidation by underperfused myocytes may stimulate sympathoexcitation in nonischemic cardiomyopathy.<sup>221,222</sup> An increase in efferent sympathetic drive will deplete cardiac glycogen stores and stimulate fatty acid oxidation and ketogenesis; blood ketone bodies in heart failure correlate directly with plasma norepinephrine concentrations.<sup>223</sup>

**Excitatory Reflexes Arising from Skeletal Muscle.** Several neural mechanisms, arising from skeletal muscle, have the capacity to increase the set point for central sympathetic outflow in heart failure (see Figure 16-7). These include (1) a sympathoexcitatory reflex, stimulated by adenosine, with the participation of angiotensin acting via the  $AT_1$  receptor as a neural intermediary<sup>224,225</sup>; (2) increases in local venous pressure<sup>226</sup>; (3) a muscle mechanoreflex<sup>227</sup> elicited by passive exercise, present in heart failure but not healthy control subjects; and (4) a muscle metaboreflex elicited by both isotonic and isometric handgrip.<sup>14,225</sup> The metaboreflex, which arises primarily from type IV sensory fibers, is activated at a lower workload in heart failure than in age-matched healthy control subjects. Importantly, the reflex MSNA response to exercise and postexercise skeletal muscle ischemia, elicited using a maneuver which traps ischemic metabolites in the forearm, is more prominent in heart failure patients with low peak  $\dot{V}O_2$  than in patients matched for ejection fraction (<20% in both groups) with a  $\dot{V}O_2$  peak greater than 56% of that predicted by their age, sex, weight, and height (see Figure 16-4).<sup>14</sup> This latter finding implies that comparisons between individuals of sympathetic activation obtained only under resting conditions underestimate the magnitude and adverse consequences of sympathetic activation when such heart failure patients are physically active.

**Excitatory Reflexes Arising from the Kidney.** An afferent signal from the uremic kidney has been shown to stimulate muscle sympathetic nerve activity of patients with chronic renal failure.<sup>228,229</sup> This sympathoexcitatory pathway may become active and functionally important in patients whose moderate to severe congestive heart failure is accompanied by renal insufficiency or increased venous pressure in the setting of right heart failure.

## Central Integration and Interactions

Baroreceptor and chemoreceptor afferent nerves terminate in the nucleus tractus solitarius, which sends excitatory information to cell bodies situated in the caudal ventrolateral medulla (VLM). Discharge from the caudal VLM has inhibitory effects on neurons located in the rostral VLM medulla which, in turn, increase the firing rate of sympathetic preganglionic neurons in the intermediolateral cell column of the spinal cord. Input from adjacent respiratory centers, and suprabulbar subcortical regions involved in cardiovascular regulation interact with these pathways at several sites to further modulate central sympathetic outflow. A wide range of neurotransmitters, including catecholamines, nitric oxide, and peptides, mediate these interactions.<sup>230</sup>

By measuring norepinephrine appearance rates in the internal jugular vein, along with those of its lipophilic metabolites, 3-methoxy-4-hydroxyphenylglycol (MHPG) and 3,4-dihydroxyphenylglycol (DHPG), Esler's group has demonstrated significant increases in human heart failure in internal jugular spillover of MHPG, DHPG, epinephrine, and of the serotonin metabolite, 5-HIAA,<sup>144,231</sup> and a significant positive correlation between brain norepinephrine turnover and cardiac norepinephrine spillover.<sup>231</sup> Sampling selectively venous effluent from cortical and subcortical regions, Aggarwal et al detected fourfold higher suprabulbar subcortical turnover of norepinephrine in treated heart failure patients than in control subjects.<sup>232</sup> Cortical norepinephrine turnover tended to be lower. Furthermore, there was a significant positive correlation between subcortical norepinephrine turnover, and total body norepinephrine spillover in the heart failure group, an observation consistent with these authors' hypothesis that activation of noradrenergic neurons projecting rostrally from the brainstem mediates sympathetic excitation in heart failure. Because of their participation in arousal, vigilance, and circulatory control in the rat, brain norepinephrine nuclei in the locus coeruleus have received particular attention.<sup>233</sup> Chronic sleep disruption in heart failure (even in the absence of nocturnal breathing disorders)<sup>187</sup> may establish a state of heightened arousal, increasing adrenergic drive as a consequence.

With the progression of heart failure symptoms, ventilatory and sympathetic neural responses to central chemoreceptor stimulation by hypercapnia are augmented<sup>170,173,175,234,235</sup> and within-breath sympathoinhibition attenuated.<sup>235</sup> An increase in the gain of the central chemoreflex response to  $CO_2$  could assist in establishing the cyclical breathing oscillations characteristic of central sleep apnea<sup>236</sup>; apneas act, in turn, to further stimulate central sympathetic outflow, with exaggerated sympathoexcitation<sup>235</sup> and carryover of high MSNA into the awake state.<sup>85,206</sup> In the most recently published series, involving of 60 consecutive patients with class I-III heart failure (mean LVEF 31%) receiving contemporary therapy, the prevalence of increased sensitivity to hypercapnia was 47%.<sup>170</sup>

The concept that the central nervous system simply integrates information from these several afferent inputs, and then transmits output passively has been superseded by experimental and clinical evidence demonstrating an active contribution to the autonomic disturbances of heart failure.<sup>142</sup> Central alterations in the gain of the arterial or

cardiopulmonary baroreflex modulation of sympathetic outflow are not accessible to study in humans, but in experimental heart failure models, Zucker's group has documented central augmentation of cardiac sympathetic afferent reflex regulation of renal sympathetic nerve activity, arising from increases in central angiotensin II, decreases in local synthesis of neuronal NO, which exerts sympathoinhibitory actions at several brain sites,<sup>237</sup> and generation of reactive oxygen species. These actions and interactions have important sympathoexcitatory consequences.<sup>238,239</sup> Overexpression of inducible NO synthase in the RVLM by adenoviral vectors also increases sympathetic activity by generating reactive oxygen species.<sup>240</sup>

Angiotensin II inhibits vagal discharge, increases central sympathetic outflow, and interacts with the arterial baroreflex at several sites within and outside the blood-brain barrier.<sup>241-245</sup> In dogs without heart failure, the hypotensive response to chronic carotid baroreceptor stimulation is attenuated if angiotensin II is infused concurrently.<sup>246</sup> The cardiac sympathetic afferent reflex in dogs is potentiated by chronic central infusion of angiotensin II<sup>247</sup>; in rats with chronic heart failure this reflex can be normalized by central administration of antisense oligodeoxynucleotides to AT<sub>1</sub> receptor mRNA.<sup>248</sup> Sympathetically mediated increases in renal renin release in heart failure could therefore generate a positive feedback loop, amplifying adrenergic discharge through these central actions of angiotensin II.

In rats with congestive heart failure, an increase in renal sympathetic outflow and resetting of its regulation by the arterial baroreceptor reflex could be reversed by intracerebroventricular infusions of Fab fragments (as inhibitors of ouabain-like activity), the angiotensin II AT<sub>1</sub> receptor antagonist, losartan,<sup>248-252</sup> or an angiotensin-converting enzyme inhibitor<sup>253</sup> and was not observed in transgenic rats deficient in brain angiotensinogen.<sup>254</sup> In a rabbit heart failure model, sympathoexcitation resulted from increased rostral VLM angiotensin AT<sub>1</sub> receptor and NAD(P)H oxidase subunit gene expression with consequent upregulation of superoxide production.<sup>238,255</sup> This group has proposed that increased central angiotensin II in heart failure initiates a positive feedback loop involving a reactive oxygen species pathway that may regulate neuronal excitability by modulation of ion channel function.<sup>256</sup> In this model, increased central enhancement of the gain of the cardiac reflex, rather than loss of arterial baroreceptor input,<sup>142</sup> contributes to the increased set point for sympathetic outflow in chronic heart failure.<sup>257-259</sup> Central mineralocorticoid receptors also participate in the regulation of sympathetic outflow. In rats with experimental heart failure, intracerebroventricular infusion of spironolactone reduced renal sympathetic nerve firing and augmented its arterial baroreflex regulation.<sup>260</sup> Aldosterone of adrenal origin has also been reported to stimulate the brain renin-angiotensin system by increasing paraventricular (hypothalamic) nucleus angiotensin AT<sub>1</sub> receptor mRNA, protein, and NAD(P)H oxidase subunit gene expression, and concurrently plasma NE concentrations.<sup>261</sup> Recently described is an additional central cytokine-mediated sympathoexcitatory pathway that can be attenuated by antiinflammatory cytokines<sup>262</sup> or by mineralocorticoid receptor blockade.<sup>263</sup>

## Efferent Mechanisms

### Ganglionic Neurotransmission

The principal defect in the parasympathetic modulation of heart rate in experimental heart failure appears to lie at the level of vagal ganglionic neurotransmission.<sup>138</sup> Conversely, by stimulating sympathetic ganglionic and adrenomedullary neurotransmission, increases in angiotensin II in heart failure could augment norepinephrine and epinephrine release.<sup>241</sup>

### Prejunctional Mechanisms and Efferent Sympathovagal Interactions

In the hamster model of dilated cardiomyopathy, early increases in cardiac norepinephrine turnover, tyrosine hydroxylase and dopamine  $\beta$ -hydroxylase activity, and cardiac dopamine stores are followed by depletion of myocardial norepinephrine content and destruction of sympathetic nerve terminals.<sup>117</sup> In a rabbit model of pacing-induced heart failure, ventricular systolic dysfunction and an increase in plasma norepinephrine were followed by a reduction in cardiac norepinephrine uptake and transporter density, and a subsequent decrease in myocardial  $\beta$ -receptor density, with gradual normalization after pacing ended.<sup>264</sup>

Radioligand-binding experiments in ventricles derived from patients with class II-IV heart failure detected a significant decrease of up to 30% in norepinephrine uptake-1 carrier density.<sup>265</sup> Isotopic dilution studies have identified reduced efficiency of norepinephrine uptake, such that its spillover into the coronary sinus was increased disproportionately more than its neuronal release.<sup>130</sup> Rundqvist et al<sup>15</sup> calculated the fractional extraction of norepinephrine to be 87% in healthy controls, but only 60% in heart failure patients. These abnormalities of cardiac norepinephrine uptake can be improved with chronic  $\beta$ -adrenoceptor blockade<sup>266</sup> and, in patients with heart failure and preserved systolic function, with the angiotensin II AT<sub>1</sub> receptor antagonist, candesartan.<sup>267</sup>

The release of norepinephrine from sympathetic nerve endings and the discharge of acetylcholine from vagal nerves also can be augmented or suppressed by endogenous or exogenously administered agonists, acting on a wide variety of prejunctional receptors. Norepinephrine release from cardiac, intrathoracic, and peripheral sympathetic nerve endings, and catecholamine release from the adrenal medulla can be facilitated through stimulation of prejunctional  $\beta_2$ -adrenoceptors by its endogenous agonist, epinephrine.<sup>77,78,268-272</sup> In more advanced heart failure, circulating epinephrine may be transported into sympathetic nerve terminals, incorporated into vesicles along with norepinephrine, and released as a cotransmitter<sup>77,273</sup> with a potential prejunctional sympathofacilitatory action.<sup>78</sup>

In contrast,  $\alpha_2$ -adrenoceptor agonists, such as clonidine, inhibit norepinephrine release. Observations concerning the functional importance of such inhibition in human heart failure suggest regional selectivity, with left ventricular<sup>274</sup> but not forearm  $\alpha_2$ -adrenoceptors<sup>275</sup> retaining this inhibitory capacity.

Polymorphisms of prejunctional adrenergic receptors might contribute to interindividual variation in norepinephrine release. In a retrospective genetic-association study, Small et al<sup>276</sup> detected a sixfold increase in the risk of developing heart failure in black subjects homozygous for the hypofunctioning prejunctional  $\alpha_{2C}$  Del322-325 polymorphism, and a tenfold increase in those who were also homozygous for the hyperfunctional postjunctional  $\beta_1$ Arg329 receptor, which demonstrates greater affinity, in vivo, for adenylyl cyclase, and augmented generation of contractile force in right ventricular trabeculae of nonfailing and failing hearts exposed to isoproterenol.<sup>277</sup> These authors proposed that this increased risk for heart failure resulted from a synergistic enhancement of polymorphisms within these two adrenergic signal-transduction pathways. However, in this initial report, no direct functional data concerning cardiac norepinephrine release, or postjunctional responsiveness, such as heart rate were provided.<sup>276</sup> By contrast, in healthy subjects, variability in the blood pressure and plasma norepinephrine response to the selective  $\alpha_2$ -agonist dexmedetomidine was unaffected by this genotype,<sup>278</sup> and in a cohort of patients with severe heart failure, Kaye et al<sup>279</sup> detected no relationship between the  $\alpha_{2C}$  Del322-325 or  $\beta_2$ -adrenoceptor polymorphisms and the rate of cardiac norepinephrine release. Curiously, the relationship

between norepinephrine release and heart rate was steeper in  $\beta_2$ -adrenoceptor Arg 16 homozygotes, implying increased postjunctional responsiveness.

Muscarinic  $M_2$  receptors on adrenergic nerve endings also attenuate norepinephrine release when stimulated by acetylcholine.<sup>280-282</sup> Intracoronary infusion of acetylcholine into subjects with LV systolic dysfunction and increased cardiac adrenergic drive decreased cardiac norepinephrine spillover, an effect not seen in control subjects with normal LV systolic function. Receptor blockade with atropine had no effect in the heart failure group, but increased cardiac norepinephrine spillover in control subjects.<sup>283</sup> Conversely, increased norepinephrine release from sympathetic nerve endings inhibits acetylcholine release by stimulating prejunctional  $\alpha_1$ -adrenoceptors on vagal nerve endings.<sup>284</sup> More recent experiments have identified neuregulin-1 signaling as an important antiadrenergic pathway, requiring eNOS-mediated muscarinic cholinergic receptor activation.<sup>285</sup> Neuregulin-1 expression initially increases and then decreases with the development of congestive heart failure.<sup>285</sup> Other sympathetic neurotransmitters, such as NPY, that inhibit acetylcholine release<sup>228,286,287</sup> may also exert a vagolytic action in advanced heart failure.

In experimental preparations, prejunctional  $AT_1$  receptors have been shown to facilitate neural and adrenal release of catecholamines when stimulated by angiotensin II<sup>241,288-290</sup> but it has proven difficult to replicate this action in human heart failure.<sup>291</sup>

Circulating activating antibodies against  $\beta_1$  and/or  $\beta_2$  adrenoceptors, present in some patients with dilated cardiomyopathy, can mimic a state of marked sympathoexcitation.<sup>292</sup>

## THERAPEUTIC IMPLICATIONS

Parenteral catecholaminergic positive inotropic agents were among the earliest therapies for heart failure. Acutely, dobutamine infusion causes a significant reduction in cardiac norepinephrine spillover, an effect attributed to reductions in cardiac filling pressures, and activation of ventricular mechanoreceptors.<sup>293</sup> However, the long-term administration of sympathomimetics has been shown, consistently, to increase mortality, and the application of isotope dilution methodology to heart failure patients disproved the concept that the failing heart required inotropic support to compensate for sympathetic denervation. Use of these agents is now restricted to short-term palliation.

From the perspective of the autonomic nervous system, current pharmacological and nonpharmacological management of heart failure is predicated upon the following hypotheses: (1) in most patients, the magnitude of sympathetic activation is in excess of that required to maintain cardiovascular homeostasis; (2) as evident from the transplantation literature<sup>294</sup> and the device literature,<sup>259</sup> many of the mechanisms contributing to sympathetic activation and parasympathetic withdrawal in heart failure result from functional, reversible alterations rather than irreversible damage; and (3) interventions that counter cardiac sympathetic overactivity will improve both symptoms and prognosis. Several therapeutic strategies have been pursued, with varying degrees of success: (1) attenuation of sympathoexcitatory stimuli, (2) modulation of sympathetic nerve traffic and norepinephrine release, (3) adrenoceptor blockade, (4) central sympatholysis, and (5) augmentation of vagal tone.

By modulating sympathetic nerve traffic and NE release, opposing adrenoceptor stimulation by either neurally released or circulating catecholamines, or attenuating sympathoexcitatory stimuli such as high cardiac filling pressure and myocardial ischemia, several contemporary disease-based heart failure therapies counter, directly or indirectly, the adverse effects of excessive cardiac and systemic sympathetic activity

and augment vagal tone to improve symptoms, prognosis, or both. These include relief of congestion and central sleep apnea through diuresis<sup>295,296</sup> (but avoiding bladder fullness<sup>297</sup>) prescription of angiotensin-converting enzyme inhibitors,<sup>145,298</sup> angiotensin receptor antagonists,<sup>224,225,243,299,300</sup> amiodarone,<sup>301</sup> antagonists of prejunctional  $\beta_2$ -adrenergic receptors that facilitate NE release,<sup>302</sup> and digitalis glycosides.<sup>303,304</sup> Antagonism of  $\beta_1$ -adrenergic-mediated stimulation of renin release, resulting in lower circulating concentrations of angiotensin II, should provide additional therapeutic benefit.<sup>305</sup> Although not formally tested in randomized controlled trials, chronic cardiac resynchronization therapy also appears to lower MSNA<sup>306</sup>; whether this adaptation represents an appropriate reflex response to atrial mechanoreceptor unloading or arterial baroreceptor stimulation has yet to be clarified. Importantly, neither these drug nor device therapies address directly nonbaroreflex stimuli to sympathetic nervous system activation, such as skeletal muscle mechanoreflexes and metaboreflexes that augment sympathoneural responses to exercise, the co-existence of sleep-related breathing disorders, or adrenoceptor polymorphisms, such as that of the hyperfunctional postjunctional  $\beta_1$ Arg329 receptor, which influences the response to  $\beta$ -adrenoceptor blockade.<sup>277</sup> The identification of such conditions in individual patients affords the opportunity to add, as adjunctive treatment, new therapeutic strategies targeted at their specific sympathoexcitatory pathophysiology.

While  $\alpha_1$ -adrenoceptor antagonists might be expected to counter the adverse effects of NE on the kidney and peripheral vasculature, this drug class has not been demonstrated to alter mortality rates in heart failure,<sup>307</sup> possibly due to the absence of a sustained effect on neurogenic vasoconstriction.<sup>308</sup>

The symptomatic, hemodynamic, and mortality benefits of long-term  $\beta_1$ - and nonselective  $\beta$ -blockade for patients with heart failure due to depressed LV systolic function have been proven in a series of landmark placebo-controlled trials involving carvedilol, bisoprolol, and metoprolol (see also Chapter 46).<sup>156,309-312</sup> In a randomized, double-blind comparative investigation in heart failure patients (mean LV ejection fraction of 20%), 4 months of therapy with carvedilol decreased total body and cardiac norepinephrine spillover by more than 35%. These changes did not occur in metoprolol-treated patients.<sup>302</sup> Because neither drug affected postganglionic MSNA, these reductions were attributed to the blockade of prejunctional neural  $\beta_2$ -adrenoceptors capable of facilitating norepinephrine release. Moreover, there was a significant inverse relationship between changes in CNES and reflex vagal heart rate modulation. In contrast,  $\beta$ -blockade had no effect on arterial baroreflex modulation of MSNA. Together, these latter findings are best explained by an efferent sympathetic-parasympathetic interaction (i.e., blockade of cardiac sympathetic prejunctional  $\beta_2$ -adrenoceptors), rather than by any augmentation of afferent or central components of the baroreflex arc, resulting in withdrawal of the inhibitory effects of excess cardiac norepinephrine release on vagal modulation of sinoatrial discharge.<sup>313</sup> Thus, in addition to protecting myocytes from the toxic effects of high local concentrations of catecholamines,<sup>108</sup>  $\beta$ -adrenoceptor antagonists such as carvedilol and metoprolol address the earliest autonomic disturbances identified in heart failure by countering the adverse effects of cardiac sympathetic overactivity and by augmenting tonic and reflex heart rate modulation while preserving normal homeostatic oscillations in MSNA.<sup>314</sup>

Some patients receiving the combination of angiotensin-converting enzyme inhibition,  $\beta$ -adrenoceptor blockade, and aldosterone antagonism continue to demonstrate persistently high sympathoadrenal activity. Moreover,  $\beta$ -blockade does not shield the heart, kidney, or periphery from  $\alpha$ -adrenoceptor-mediated vasoconstriction or renal sodium retention, or from vasoconstriction caused by neurotransmitters co-released with norepinephrine such as ATP<sup>315</sup> or

neuropeptide Y (NPY), which has a more sustained effect than NE<sup>316</sup> and is also a potent inhibitor of efferent vagal neurotransmission.<sup>317</sup> Not unexpectedly, myocardial spillover of NPY also is increased in heart failure.<sup>318</sup> More aggressive neuro-humoral blockade, or central abolition of sympathetic outflow, or both, have been proposed therefore as means of further reducing mortality rates. Importantly, these strategies presume that peripheral sympathetic drive is excessive in all treated heart failure patients, and its antagonism will benefit all patients. Both assumptions should be questioned critically.

Central sympathetic outflow can be attenuated directly, by stimulating  $\alpha_2$  and imidazoline  $I_1$  receptors located within the rostral VLM using either clonidine, an  $\alpha_2 + I_1$  receptor agonist, or  $I_1$  agonists such as moxonidine. Acutely, the intravenous administration of 0.1 mg clonidine lowered arterial norepinephrine concentrations, cardiac norepinephrine spillover, and left ventricular  $+dP/dt$  by 47%, 58%, and 15%, respectively.<sup>319</sup> When administered for 2 months by transdermal patch, 0.1 mg of daily clonidine reduced muscle sympathetic burst frequency by 26% and plasma norepinephrine concentrations by 47%.<sup>320</sup>

Unfortunately, both in a pilot study,<sup>321</sup> and in a large-scale mortality trial,<sup>322</sup> there was an excess of deaths in patients allocated moxonidine. In retrospect, this outcome may relate more to the specific aspects of these clinical trials, than the validity of the underlying hypothesis.<sup>19</sup> In many of the patients recruited, plasma norepinephrine concentrations were not markedly elevated, perhaps because of prior optimization of their medical therapy for their heart failure. The dose of moxonidine selected for study may have been sympathoablative, reducing residual central sympathetic outflow to levels insufficient to support cardiac output or peripheral resistance at rest, and unlike  $\beta$ -adrenoceptor antagonists, preventing appropriate increases in neurotransmitter release in response to exercise or other stimuli. An excess of mortality and sudden death might have resulted from a rebound during periods of non-adherence. In the MOXSE pilot study, there were twofold to threefold increases in plasma norepinephrine concentrations, and corresponding rebound elevations in heart rate, blood pressure, and ventricular ectopy during tapered withdrawal from active therapy.<sup>321</sup> The fundamental question raised by these two studies is whether the adverse effect of this therapy on outcomes should be attributed to the drug strategy itself, to excessive sympatholysis, or to intense rebound surges in central sympathetic outflow. A similar concern was raised by a trial of bucindolol in heart failure, in which a marked fall in plasma norepinephrine concentration with treatment was accompanied by an increase in mortality; although described as "sympatholysis," whether this effect was due to decreased sympathetic nerve traffic, decreased norepinephrine release, or increased clearance cannot be established.<sup>323</sup> This line of investigation is unlikely to advance unless these issues are resolved, and a method of identifying patients with residual sympathetic activation more reliable than venous norepinephrine concentrations or HR spectral analysis,\* can be deployed routinely within the clinical setting.

Future approaches may address the central angiotensin II-AT<sub>1</sub> receptor-reactive oxygen species-sympathoexcitatory hypothesis of heart failure by administering centrally acting antioxidants,<sup>325</sup> mineralocorticoid receptor antagonists,<sup>261,326</sup> or statins<sup>327-329</sup> or by stimulating neuregulin-1/ErbB signaling to reduce cardiac sympathetic and augment vagal tone.<sup>285</sup> In heart failure patients, infusion of 2.5 mg of vitamin C augmented the reflex vagal heart rate modulation by approximately 30%.<sup>330</sup> There may be a role for nicotinic agonists<sup>331</sup> or vagal nerve pacing<sup>332</sup> to preserve parasympathetic tone as heart failure progresses, and for chronic afferent baroreceptor

nerve pacing,<sup>148</sup> or for novel approaches to attenuate or reverse the loss of norepinephrine carrier density and augment its reuptake at cardiac sympathetic nerve endings.<sup>333</sup> In a rabbit model of heart failure, overexpression of the norepinephrine transporter uptake-1 protein by adenoviral gene transfer resulted in recovery of norepinephrine uptake throughout the left ventricle, greater  $\beta_1$ -adrenoceptor and sarcoplasmic reticulum  $Ca^{2+}$  ATPase protein expression, and improvement in cardiac structure and contractile function.<sup>334</sup> Direct injection of nerve growth factor into the left stellate ganglion of rats with experimental heart failure also resulted in augmented norepinephrine uptake and an increase in fractional shortening.<sup>335</sup>

Conversely, if directed evaluation identifies coexisting conditions that augment adrenergic outflow to the heart and periphery in excess of that needed to maintain hemodynamic stability, then therapy individualized so as to attenuate patient-specific sympathoexcitatory pathophysiology may be added to conventional disease-specific treatment. In addition to attenuating myocardial ischemia surgically, mechanically, or pharmacologically, this goal might be achieved by (1) normalizing cardiac filling pressure and relieving pulmonary congestion with natriuretic peptide infusion<sup>155,336,337</sup> or ultrafiltration,<sup>338</sup> but without inducing systemic hypotension and thereby increasing reflexively sympathetic activity and norepinephrine release<sup>336,339,338</sup>; (2) physical conditioning<sup>84,340</sup>; and (3) abolishing coexisting OSA with nocturnal continuous positive airway pressure (CPAP).<sup>341,342</sup> Each of these interventions has been demonstrated to both diminish sympathetic tone and augment the tonic or reflex vagal modulation of heart rate.<sup>84,340,342-350</sup> By contrast, if deployed prematurely (i.e., when filling pressures are not elevated diuretic therapy would have adverse consequences-activating both the sympathetic nervous and renin-angiotensin systems. However, as yet none of these interventions has been demonstrated in large clinical trials to reduce mortality rates.

Conventional pharmacological approaches to heart failure have no impact on OSA. By contrast, nocturnal nasal CPAP abolishes upper airway obstruction and four of its sympathoexcitatory consequences: apnea, hypoxia, hypercapnia, and arousal from sleep. In patients with heart failure and obstructive sleep apnea, CPAP reduces nocturnal blood pressure and heart rate (see also Chapter 32),<sup>351</sup> and increases the arterial baroreflex modulation of heart rate.<sup>348</sup> Thus the sympathoinhibitory and vagotonic effects of CPAP during sleep, alone, may be sufficient to benefit heart failure patients with co-existing OSA. Consequently, there is increasing recognition of the importance of identifying and treating OSA when present in heart failure patients.

In addition, in patients with elevated LV end-diastolic pressure, studied while awake, the acute application of CPAP augmented stroke volume,<sup>352</sup> increased total spectral power, nonharmonic power, low- and high-frequency power, and the ratio of high to total power<sup>353</sup> and diminished cardiac norepinephrine spillover.<sup>161</sup> In randomized trials of 1 month duration involving heart failure patients with OSA, nightly use of CPAP abolished apnea, improved LV structure and ejection fraction,<sup>341</sup> lowered systolic blood pressure, heart rate, and MSNA during wakefulness,<sup>341,342</sup> and reduced ventricular ectopy during sleep.<sup>354</sup> A randomized controlled trial involving patients with milder OSA (apnea-hypopnea index >5 events per hour) and an LV ejection fraction less than 55% also observed a significant increase in LV ejection fraction in conjunction with a reduction in urinary norepinephrine excretion after 3 months of CPAP treatment.<sup>355</sup> Data from non-randomized observational studies, involving OSA subjects without<sup>356</sup> and with,<sup>204</sup> heart failure suggest that the abolition of apneas by CPAP may also reduce mortality rates.

In a 3-month randomized trial involving heart failure patients with CSA, the nightly application of CPAP suppressed

the apnea-hypopnea index and reduced nocturnal urinary norepinephrine by 41%, to values similar to those obtained in clinically matched heart failure patients without CSA. CPAP also reduced plasma norepinephrine during wakefulness by 22%.<sup>206</sup> In a long-term trial involving 258 heart failure patients with CSA, CPAP did not improve transplant-free survival overall,<sup>357</sup> but this intervention reduced the apnea-hypopnea index only from 40 to 20 events per hour. However, in a post hoc efficacy analysis, CPAP improved significantly transplant-free survival of those patients in whom the apnea-hypopnea index was suppressed below 15 apneic or hypopneic events per hour. The threshold required for recruitment into the CANPAP trial.<sup>187</sup>

## SUMMARY

In this chapter we have (1) reviewed methods for assessing sympathetic and parasympathetic function in conscious humans; (2) summarized evidence for adrenergic activation and vagal withdrawal in human heart failure, and the adverse consequences of these disturbances; and (3) discussed, in detail, mechanisms that underlie both these alterations in neurogenic circulatory control and the actions of current and emerging pharmacological and nonpharmacological interventions for this condition. Several key concepts should be reemphasized.

Patients with LV systolic dysfunction have in common impaired vagal modulation of heart rate, but differ considerably in the magnitude and mechanisms of sympathetic activation. Although the set point for central sympathetic outflow is increased in the majority of patients, in a substantial minority of those with asymptomatic or symptomatic LV systolic dysfunction values for plasma norepinephrine concentrations, muscle sympathetic nerve activity and total body norepinephrine spillover remain within the range described for control subjects. Therefore, sympathetic activation cannot be considered a defining characteristic of LV systolic dysfunction. Many current therapies for heart failure attenuate adrenergic drive and augment vagal tone. The therapeutic implication of these findings is that patients without evidence for sympathetic activation are unlikely to benefit from multiple neurohumoral antagonists or from sympatholytic interventions.<sup>19,358</sup>

Alterations in both inhibitory and excitatory influences on autonomic outflow contribute to these disturbances in neurogenic circulatory control. The extent to which each of these regulatory systems is impaired or activated is subject to considerable interindividual variation. Early activation of adrenergic drive to the diseased myocardium appears to be the principal mechanism linking altered neural regulation of the heart and circulation to adverse outcomes.

The currently available evidence in humans allows five conclusions with respect to mechanoreceptor reflex regulation of heart rate and sympathetic nervous system activity in human heart failure due to impaired systolic function (see Figure 16-7): (1) the arterial baroreceptor reflex regulation of heart rate by the vagus nerve is impaired; (2) in contrast, the arterial baroreflex regulation of muscle sympathetic nerve activity is rapidly responsive to changes in diastolic blood pressure; (3) pulmonary mechanoreceptor-mediated inhibition of sympathetic outflow is preserved; and (4) cardiopulmonary reflex control of muscle sympathetic nerve activity is blunted. As a consequence, efferent sympathetic outflow to the skeletal muscle is not suppressed by increased cardiac filling pressure. Rather, (5) elevated filling pressures in heart failure can increase cardiac norepinephrine spillover by stimulating a cardiac-specific sympathoexcitatory reflex.

Viewed from this perspective, the heterogeneity and time course of organ-specific sympathetic activation and parasympathetic withdrawal can be considered appropriate to

Table 16-2

**Summary and Proposed Construct Relating Time Course and Heterogeneity of Autonomic Disturbances in Human Heart Failure to Hemodynamic and Nonhemodynamic Abnormalities**

Primary Abnormality	Autonomic Consequence
Acute heart failure with pulmonary congestion and hypotension	Generalized activation of sympathetic and renin-angiotensin-aldosterone systems; parasympathetic withdrawal
Chronic increase in left atrial pressure	Activation of cardiac sympathetic afferents causing reflex increase in efferent cardiac SNA
	Decrease in tonic +/- reflex vagal HR modulation
	Decreased pre-junctional muscarinic receptor-mediated inhibition of NE release
Chronic increase in left ventricular end diastolic pressure and volume	Reflex inhibition of sympathetic outflow to kidneys, skeletal muscle, and other systemic vascular beds
Chronic exposure to increased cardiac SNA	Impaired cardiac $\beta$ -mediated signal transduction
	Increased pre-junctional $\alpha_1$ -mediated inhibition of Ach release
Chronic reduction in stroke volume and systemic blood pressure	Impaired arterial baroreflex regulation of HR
	Reflex sympathetic activation resulting from intact and responsive arterial baroreflex regulation of muscle SNA, total body NE spillover, $\pm$ cardiac NE spillover, $\pm$ renal NE spillover
Pulmonary congestion	Decreased inhibition of central sympathetic outflow by pulmonary stretch reflexes stimulated by lung inflation
	Decreased respiratory sinus arrhythmia (vagal)
Chemoreceptor and muscle metaboreceptor activation	Increased muscle SNA
	Decreased tonic and reflex vagal HR modulation
Co-existing sleep apnea	Increased muscle SNA and decreased vagal HR modulation during sleep
	Increased daytime plasma NE

Ach, Acetylcholine; HR, heart rate; NE, norepinephrine; SNA, sympathetic nerve activity.

individual hemodynamic profiles (Table 16-2). Patients will progress from asymptomatic to end-stage heart failure by different pathways and at different rates. In some, the initial insult may be a sudden drop in cardiac output and blood pressure, which will reflexively activate the sympathetic nervous and renin-angiotensin systems and decrease vagal tone so as to achieve a state of relative compensation.<sup>16</sup> If, on the other hand, relatively normal stroke volume and blood pressure can be maintained by increases in LV end-diastolic volume, rather than cardiac filling pressure, such patients would be less likely to manifest evidence, at rest, for hemodynamically mediated sympathetic activation. Indeed, by increasing the ventricular mechanoreceptor firing rate, such remodeling might even depress, reflexively, sympathetic outflow to the kidney and skeletal muscle, maintaining renal responsiveness to natriuretic influences and relatively normal peripheral resistance. Impaired cardiac reserve in such patients might only be evidenced by abnormal adrenergic or heart rate responses to exercise or mental stress.

From this compensated state, heart failure may progress along several pathways, with corresponding disturbances of neural regulation. If cardiac filling pressures rise initially, as required to maintain stroke volume and systemic arterial pressure, the anticipated response would be activation of the cardiac sympathetic reflex<sup>159</sup> and a decrease in tonic vagal heart rate modulation<sup>359</sup> without any corresponding changes in MSNA or total body norepinephrine spillover. Any withdrawal of muscarinic tone will release its restraining influence on cardiac norepinephrine.<sup>283</sup> This hypothetical scenario would account for the selective increase in cardiac norepinephrine spillover documented in mild to moderate symptomatic LV systolic dysfunction,<sup>15</sup> and for the positive correlation noted between cardiac norepinephrine spillover and pulmonary capillary wedge pressure.<sup>144</sup> Chronic exposure to increased cardiac norepinephrine release would initiate the process of sinoatrial adrenoceptor downregulation and altered  $\beta_1$ -adrenoceptor signal transduction. In some individuals genetic polymorphisms involving adrenergic receptors may accelerate this process.<sup>276</sup> Similar alterations in autonomic regulation may occur in diastolic heart failure, but this hypothesis has yet to be formally tested.

As myocardial contractile performance deteriorates, heart rate will rise through arterial baroreflex-mediated vagal withdrawal and sympathetic activation to maintain cardiac output. Over time, further unloading of arterial baroreceptors by a decline in systolic or pulse pressure will elicit further diminution of cardiac vagal modulation, generalized neurohumoral activation resulting from reflex increases in sympathetic outflow to the heart, kidney, and skeletal muscle, and loss of low-frequency MSNA spectral modulation due to impaired neuroeffector transduction. By removing the inhibitory or restraining effect of lung inflation on central sympathetic outflow—pulmonary congestion—altered lung mechanics and increased work of breathing will cause a further step-up in nerve traffic; indeed, it is those patients with short shallow breaths who display the highest values for MSNA.<sup>165</sup>

Arterial baroreceptor reflex-mediated increases in cardiac or peripheral sympathetic outflow (in response to decreases in stroke volume, ventricular inotropy, or blood pressure) are present in the majority of patients with LV systolic dysfunction, but the intensity of this response will differ between individuals, depending upon the magnitude of hemodynamic compromise. Other sympathoexcitatory stimuli that act to elevate the set point for central sympathetic outflow or neurotransmitter release above levels required to maintain hemodynamic stability, such as elevated atrial pressures, the coexistence of sleep-related breathing disorders, and chemoreceptor or muscle metaboreceptor activation will vary from patient to patient. The induction of inflammation may initiate an additional cascade of catecholamines.<sup>360</sup> Without characterizing the extent of these several sympathoexcitatory mechanisms, one cannot be certain that the magnitude of adrenergic activation in a particular patient is best can be managed solely with sympatho-modulatory therapies, such as  $\beta$ -adrenergic antagonism and angiotensin-converting enzyme (ACE) inhibition, or requires additional specific pharmacological and nonpharmacological interventions.

## FUTURE DIRECTIONS

Therapies that modulate sympathetic and vagal outflow or antagonize the postjunctional actions of neurally released and circulating catecholamines lower mortality rate and decrease morbidity. Whether there is a direct causal relationship between these neural effects of therapy and improved outcomes and whether patients with heart failure but preserved

systolic function exhibit similar alterations in sympathetic and parasympathetic function by these several baroreflex and nonbaroreflex-mediated mechanisms are two important hypotheses for future investigation.

## CARDIOVASCULAR EFFECTS OF SUSTAINED NEUROHUMORAL ACTIVATION IN HEART FAILURE

Systemic perfusion pressure is determined by cardiac output and vascular tone of peripheral arteries. When cardiac output decreases, systemic perfusion pressure is maintained mainly by peripheral vasoconstriction and sodium retention, which are both characteristic findings in patients with overt heart failure and attributable to the interaction of hemodynamic and neurohumoral factors. Several neurohumoral systems are activated in patients with chronic heart failure that cause peripheral vasoconstriction. The sympathetic nervous system is activated very early in the disease process, whereas the renin-angiotensin system is usually activated when clinical symptoms develop. Vasopressin is released mainly in very advanced stages of chronic heart failure when systemic perfusion is already threatened.<sup>1</sup> Furthermore, chronic severe heart failure is associated by an increased endothelial release of locally acting vasoconstricting factors such as endothelin.

These endogenous vasoconstricting factors are counterbalanced in part by endogenous vasodilators. In normal individuals, natriuretic peptides attenuate the release of norepinephrine, renin, and vasopressin and their actions on peripheral blood vessels

and within the kidneys. In addition, the continuous release of endothelium-derived relaxing factor (nitric oxide) from the endothelium normally counteracts the vasoconstricting factors. In fact, the continuous basal release of nitric oxide keeps the peripheral vasculature in a dilated state. In patients with heart failure, however, the effects of circulating and locally active vasodilators are attenuated. The release of atrial natriuretic peptide is blunted in chronic heart failure and the effects of both atrial (ANP) and brain natriuretic peptide (BNP) lose their ability to suppress the release of renin or dilate peripheral blood vessels (see also Chapter 18).<sup>2</sup> In addition the vascular availability of nitric oxide is severely diminished in patients with chronic heart failure.<sup>3</sup> Thus diminished vasodilator forces leave the actions of vasoconstrictors unopposed. It is important to note that the interaction of the sympathetic and renin-angiotensin systems even amplifies their vasoconstricting effects. Increased sympathetic activity increases the release of renin and vice versa and angiotensin enhances the release of both norepinephrine and vasopressin.

## BLOOD FLOW TO SKELETAL MUSCLE IN CHRONIC HEART FAILURE

Impaired cardiac contractility is not necessarily associated with clinical signs of heart failure but may be present in an asymptomatic patient. The clinical symptoms of heart failure are apparently not related to cardiac dysfunction but to activation of compensatory mechanisms such as activation of the sympathetic nerve system, renin-angiotensin system, or activation of cytokines such as tumor necrosis factor (TNF)- $\alpha$  or interleukin-6. In most cases of well-treated chronic heart failure, cardiac output remains close to normal during resting conditions<sup>4</sup> and only a minority of patients have an impaired increase of cardiac output during exercise testing that appears to be associated with a poor prognosis, particularly when peak oxygen consumption is severely reduced.<sup>5</sup> Muscle blood flow during exercise, however, is reduced in patients with chronic heart failure as compared with normal individuals because of diversion of blood flow away from the muscles.<sup>6</sup> In addition, the size and vascularization of the skeletal muscle is reduced in heart failure patients,<sup>6</sup> contributing to the clinical symptom of premature muscular fatigue during physical activity or exercise. Attempts to augment muscle blood flow by increasing the pumping capacity of the heart during exercise have produced only mild increases in blood flow to exercising skeletal muscle and did not result in acutely improved exercise tolerance. One explanation may be that the increased cardiac output was associated with increased skin rather than skeletal muscle perfusion; moreover, there is evidence that skeletal muscle is unable to use increased oxygen supply acutely due to impaired oxidative capacity of skeletal muscle.

In many patients with chronic heart failure, the increase in blood flow to working muscle with exercise is attenuated for each given workload compared with that in normal persons.<sup>7</sup> Peak oxygen consumption is also lower in patients with chronic heart failure and is accompanied

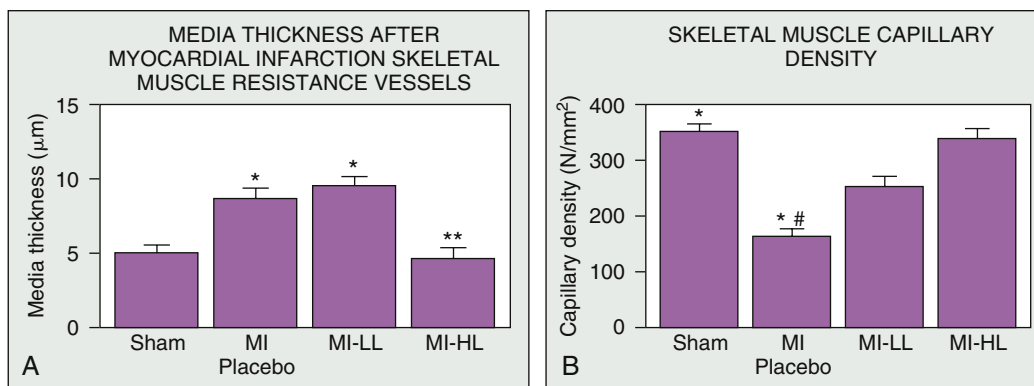

by an early increase in plasma lactate concentration.<sup>7</sup> The reduced maximal blood flow to working muscle occurs predominantly in oxidative working muscle<sup>8</sup> and is primarily caused by an abnormality of arteriolar vasodilation during exercise. Patients who exhibit improved exercise capacity after therapy with angiotensin-converting enzyme (ACE) inhibitors also exhibit improved leg blood flow.<sup>9</sup> The failure of muscle blood flow to increase normally during exercise in patients with chronic heart failure is primarily because of an abnormality of peripheral arteriolar vasodilation. During exercise, blood flow to working muscles increases largely due to two mechanisms: increase in cardiac output and redistribution of blood flow. Both mechanisms are altered in chronic heart failure. This increase in cardiac output with exercise is impaired. In addition, normally arterioles within the exercising muscle dilate, a mechanism that is also impaired in many patients with heart failure,<sup>7,10,11</sup> in part due to excessive sympathetically mediated vasoconstriction, activation of the plasma renin-angiotensin system, and possibly to increased plasma concentrations of endothelin<sup>12</sup> both in the pulmonary<sup>13</sup> and systemic circulation.<sup>14</sup> Although these neurohumoral factors exert potent systemic and regional vasoconstriction, they do not completely explain the impaired vasodilating capacity within skeletal muscle in patients with chronic heart failure. Impaired metabolic vasodilation during exercise cannot be restored by  $\alpha$ -adrenoreceptor blockade with phentolamine.<sup>1,15</sup> Similarly, ACE inhibition does not restore impaired metabolic vasodilation during exercise after acute administration, despite a substantial reduction of plasma angiotensin II and norepinephrine concentrations.<sup>9,16</sup> Chronic treatment with an ACE inhibitor over several months, however, leads to a significant increase in femoral blood flow during exercise in patients with chronic heart failure and is associated with an improved oxygen consumption.<sup>9</sup> Chronic ACE-inhibitor therapy reverses therefore the inability of peripheral vessels to dilate.<sup>17</sup> These findings are in line with previous observations in large clinical trials that the full beneficial effect of ACE-inhibitor therapy emerges slowly over time.<sup>18</sup> Similarly, the restoration of peripheral perfusion and skeletal muscle function takes weeks to months after cardiac transplantation, suggesting that chronic heart failure leads to alterations of arterial function and structure.

## STRUCTURAL ALTERATIONS OF PERIPHERAL ARTERIES IN CHRONIC HEART FAILURE

Experimental evidence indicates that angiotensin II induces hypertrophy of cultured rat aortic smooth muscle cells<sup>19</sup> and may be involved in the proliferative process of tissues during growth. Recent experimental observations suggest that structural vascular alterations emerge in the chronic phase of heart failure and can be reversed by high-dose ACE inhibition<sup>20</sup> (Figure 17-1, A). Unfortunately, clinical studies indicating structural alterations in peripheral resistance arteries are scarce and usually confined to skin resistance vessels that may not be representative for skeletal muscle resistance vessels. Small skeletal muscle biopsies often allow only examination of very small arterioles (<50  $\mu$ m), which may not play a major role in the regulation of blood flow such as resistance vessels in the range of 80 to 200  $\mu$ m. A further potential mechanism that contributes to structural alterations of peripheral arteries in chronic heart failure is a “vascular stiffness factor” owing to the increased vascular sodium content, which can be, in part, reduced with diuretic therapy in decompensated heart failure.<sup>21</sup> The stiffness factor represents a mechanical factor that may impair the vasodilator capacity of peripheral blood vessels either because of an increase of sodium content within the vascular wall or because edema enhances the compressive forces of perivascular tissues. A reduced density of skeletal muscle capillaries may represent another structural abnormality in experimental models<sup>20</sup> (Figure 17-1, B) and patients with chronic heart failure<sup>22</sup> that may contribute to the reduced vasodilator capacity in chronic heart failure, since reduction of capillary density leads to a reduction of total peripheral vascular cross-sectional area.

## ALTERATION OF ENDOTHELIUM-DEPENDENT VASODILATION IN HEART FAILURE

The endothelium plays an important role in the control of vascular tone by releasing both vasodilating and vasoconstricting factors.<sup>23</sup> These mechanisms are important for the regulation of the microvasculature<sup>24</sup> and for the larger conduit arteries.<sup>3,25</sup> Patients with chronic heart failure are

**FIGURE 17-1** A, Media thickness of skeletal muscle resistance vessels from rat skeletal muscle 1 year after myocardial infarction. Bar graphs indicate media thickness in sham-operated animals (sham), placebo-treated animals with myocardial infarction (MI placebo), animals treated with low-dose lisinopril (MI-LL), and animals treated with high-dose lisinopril (MI-HL). Data are mean  $\pm$  SEM, \* $P$  < .01 vs. Sham; \*\* $P$  < .01 vs. MI placebo, and MI-LL; B, Skeletal muscle capillary density determined from quadriceps femoris muscle 1 year after myocardial infarction. Bar graphs indicate skeletal muscle capillary density in sham-operated animals (sham), placebo-treated animals with myocardial infarction (MI placebo), animals treated with low-dose lisinopril (MI-LL), and animals treated with high-dose lisinopril (MI-HL). Data are mean  $\pm$  SEM, \* $P$  < .05 vs. MI-LL; # $P$  < .01 vs. Sham, MI-LL, and MI-HL. (Modified from Schieffer B, Wollert K, Berchthold M, et al. Development and prevention of skeletal muscle structural alterations after experimental myocardial infarction. *Am J Physiol* 1995;269:H1507-H1513.)

characterized by increased systemic vasoconstriction and a reduced vasodilator response during physical exercise. While neurohumoral factors undoubtedly are involved in alterations of the peripheral vasculature, there is good evidence that abnormal function of the endothelium contributes to the abnormal vasodilator response in chronic heart failure. In this respect, the role of endothelium-derived relaxing factor (i.e., nitric oxide<sup>26</sup>) has received considerable attention. Nitric oxide is synthesized in the endothelial cell by the endothelial cell NO synthase from the amino acid L-arginine<sup>27</sup> (Figure 17-2) in the presence of cofactors such as tetrahydrobiopterin.<sup>28</sup>

The endothelium releases NO in response to a variety of stimuli including increased shear stress<sup>3,25</sup> during increased blood flow such as during physical activity, or receptor stimulation such as muscarinic or bradykinin  $\beta_2$ -receptors.<sup>23,29</sup> Following its release from the endothelial cell and uptake into the vascular smooth muscle cell, NO stimulates the guanylate cyclase to form cyclic guanosine monophosphate (cGMP), resulting in smooth muscle relaxation and vascular dilation (see Figure 17-2). With the assumption that an impaired vasodilator response to acetylcholine reflects endothelial dysfunction,<sup>29,30</sup> evidence for an impaired endothelium-dependent vasodilation was found in the *microcirculation* of the myocardium, leg, and forearm of patients with chronic heart failure.<sup>31-35</sup> These observations suggest that the impairment of endothelium-dependent, NO-mediated vasodilator function is a generalized phenomenon in patients with chronic heart failure. Yet, beyond the impaired response to endothelium-dependent stimuli, basal release of nitric oxide may be altered in chronic heart failure. In normal individuals, the arterial vasculature is kept in a somewhat dilated state by constant basal release of nitric oxide<sup>36</sup> as demonstrated by decreased peripheral blood flow following inhibition of NO synthesis by L-monomethyl-L-arginine (L-NMMA). However, this basal release of nitric oxide may be enhanced in patients with severe chronic heart failure. In some but not all studies, the reduction of blood flow following L-NMMA was enhanced in heart failure as compared

to normal individuals. These observations raised the concept that severe heart failure is associated with increased basal release of nitric oxide to counterbalance the excessive vasoconstrictor forces jeopardizing tissue perfusion. Severe heart failure is associated with increased levels of cytokines, which may induce the expression of inducible nitric oxide within the vascular wall. This concept is supported by the observation that peripheral venous nitrate, the product of NO metabolism in blood, also has been found to increase in heart failure.<sup>37,38</sup> However, these observations were not made in all patient populations studied, in particular, basal release of nitric oxide may be normal in patients with more compensated states of heart failure without substantial cytokine activation.

One consequence of impaired endothelium-mediated vasodilation of peripheral *resistance arteries* may include reduction of tissue perfusion during physical exercise, thereby contributing to impaired exercise capacity in heart failure. The disturbance of microvascular dilation within the coronary artery circulation may result in ischemia and further myocardial damage and dysfunction in patients with chronic heart failure.

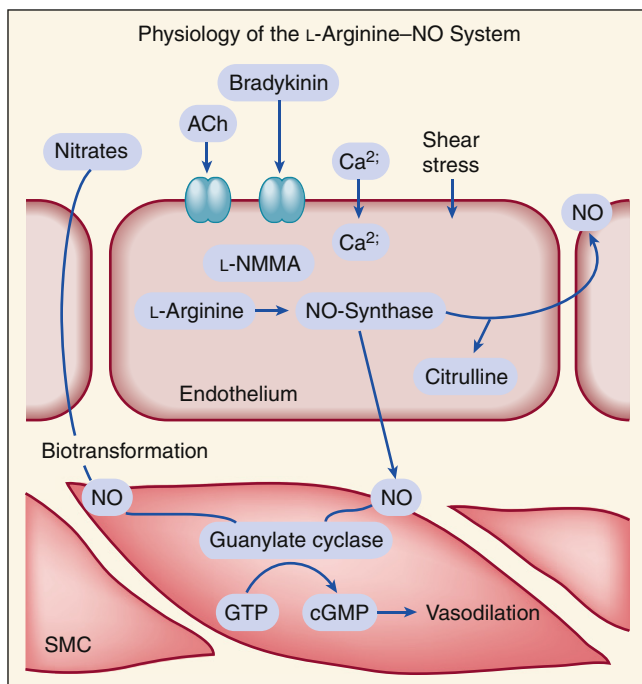

Alterations in endothelial function emerge not only in peripheral resistance vessels but also in *peripheral conduit arteries*; flow-dependent vasodilation of conduit arteries in humans is to a large extent mediated by endothelial release of nitric oxide.<sup>3,25</sup> However, flow-dependent vasodilation is impaired in patients with chronic heart failure as compared with healthy control subjects.<sup>3,39</sup> Following blockade of the NO synthase by L-NMMA, flow-dependent dilation is similar in patients with heart failure and healthy subjects, suggesting that the impairment in patients is due to reduced bioavailability of nitric oxide. Importantly, the impairment of flow-dependent vasodilation is similar in patients with ischemic and dilated cardiomyopathy, suggesting that heart failure per se rather than the etiology of heart failure determines the extent of endothelial dysfunction. Because large arteries are more than just passive conduits,<sup>40</sup> it is possible that the impairment of flow-mediated vasodilation during exercise might lead to increased impedance to the left ventricular ejection and thereby contributes to the hemodynamic derangements characteristic of chronic heart failure.

## MECHANISMS OF ENDOTHELIAL VASODILATOR DYSFUNCTION IN HEART FAILURE

Preclinical experiments suggest that endothelial dysfunction is a progressive, time-dependent process that probably plays a minor role early in heart failure. Rats in whom heart failure was induced by coronary ligation with subsequent myocardial infarction demonstrated no evidence of endothelial dysfunction 1 week after myocardial infarction. Four and 16 weeks after myocardial infarction, however, a reduced vasorelaxation was observed in aortic rings in response to acetylcholine as compared with sham-operated control animals.<sup>41</sup> Moreover, endothelial dysfunction in the rat infarct model appears to emerge only in rats with large myocardial infarctions, markedly impaired left ventricular function, and evidence of heart failure.<sup>24</sup> Several pathophysiological mechanisms appear to contribute to the impaired NO-dependent vasodilation in chronic heart failure and many of these aspects have now been studied in humans (Box 17-1).

### Nitric Oxide Synthase in Heart Failure

The reduced endothelium-dependent nitric oxide-mediated vasodilator response to acetylcholine may be, in part, caused by reduced gene expression and activity of the nitric oxide

**FIGURE 17-2** The physiology of the L-arginine-nitric oxide (NO) system: Nitric oxide is synthesized in the endothelial cell from the amino-acid L-arginine by the endothelial NO-synthase. Following uptake into the vascular smooth muscle cell (SMC), NO stimulates the guanylate cyclase to form cyclic guanosine monophosphate (cGMP) resulting in vasodilation.

### Box 17-1 Potential Mechanisms for Endothelial Dysfunction in Heart Failure

- Reduced eNOS gene expression and activity, including TNF- $\alpha$  induced shortening of eNOS mRNA half life.
- Activation of the RAAS, including increased ACE-activity and increased aldosterone concentrations
- Inactivation of NO by superoxide anions
- Endogenous inhibitors of eNOS
- Alteration of vascular signal transduction
- Impaired endothelial repair mechanisms

forming enzyme NO synthase (eNOS). Pulsatile flow<sup>42</sup> and the associated shear stress<sup>40,43</sup> are important regulators of NO production, thereby providing a potential link between impaired cardiac and vascular function as represented by impaired endothelial vasodilator function in patients with chronic heart failure. In fact, experimental and clinical studies have shown that eNOS gene expression in aortic endothelial cells and myocardial tissue is reduced in heart failure.<sup>44,49</sup> Moreover, nitric oxide production from cardiac microvessels from patients with end-stage heart failure is reduced as compared with normal hearts.<sup>48</sup> Taken together, impaired expression and activity of endothelial cell NO synthase may represent one factor contributing to impaired endothelium-dependent dilation in patients with heart failure. There is good evidence that gene expression of endothelial nitric oxide synthase is upregulated by shear stress,<sup>43</sup> raising the possibility that chronically reduced blood flow in chronic heart failure may be involved in the development of reduced nitric oxide synthase gene expression.

### Impact of Cytokines (see also Chapter 11)

Plasma concentrations of cytokines, such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), are increased in patients with chronic heart failure<sup>47</sup> and may represent a further mechanism contributing to impaired endothelium-dependent vasodilation in patients with chronic heart failure by diminishing the availability of NO.<sup>48</sup> Experimental evidence suggests that TNF- $\alpha$  can inhibit the stimulated release of nitric oxide from the endothelium<sup>49</sup> and that TNF- $\alpha$  impairs the stability of eNOS mRNA by shortening its half-life.<sup>50</sup> TNF- $\alpha$  has also been shown to increase endothelial and vascular smooth muscle cell production of superoxide anions, which decrease the half-life of nitric oxide.<sup>51</sup> Thus TNF- $\alpha$  may inhibit endothelium-dependent nitric oxide-mediated vasodilation by decreasing the bioavailability of nitric oxide through enhanced destruction and reduced synthesis of NO-synthase, although data derived from human studies are limited. It is interesting to note that TNF- $\alpha$  plasma concentrations were closely related with forearm blood flow responses to intrabrachial infusions of acetylcholine.<sup>47</sup> Moreover, the administration of etanercept, a recombinant TNF receptor that binds to and functionally inactivates TNF- $\alpha$ , has been shown to improve vasodilator capacity in patients with advanced heart failure, suggesting the important role of TNF- $\alpha$  for impaired endothelial vasoreactivity in CHF.<sup>47a</sup>

### Inactivation of Nitric Oxide by Superoxide Anions

Another mechanism that appears to play a role in the development of endothelial dysfunction in chronic heart failure is an enhanced oxidant stress (i.e., superoxide anion production) that can rapidly inactivate nitric oxide and tetrahydrobiopterin, an important cofactor of the endothelial NO synthase.<sup>47b,47c</sup> There is accumulating evidence that the production of oxygen-free radicals is enhanced in chronic heart failure<sup>52</sup> which, in turn,

**FIGURE 17-3** Reduced bioavailability of NO in heart failure. Restoration of arterial diameter by high-dose intraarterial infusion of vitamin C (acute) or 2 g vitamin C (orally) indicating inactivation of NO by radicals. Bar graphs represent the NO-mediated vasodilation of the radial artery in healthy controls (Normals), patients with chronic heart failure (CHF) and the effect of placebo (CHF-placebo), intraarterial infusion of vitamin C (CHF-vitamin C acute), and oral therapy with vitamin C over 4 weeks (CHF vitamin C chronic) in patients with chronic heart failure. (Modified from Hornig B, Arakawa N, Kohler C, et al. Vitamin C improves endothelial function of conduit arteries in patients with chronic heart failure. *Circulation* 1998;97:363-368.)

would contribute to a reduced bioavailability of nitric oxide and endothelial dysfunction in these patients. Antioxidant therapy with ascorbic acid improves endothelium-mediated vasodilation in patients with chronic heart failure by increasing the bioavailability of nitric oxide<sup>53</sup> (Figure 17-3), supporting the role of oxidative stress in heart failure.

The underlying mechanisms leading to increased production of oxygen-free radicals in chronic heart failure likely include increased NAD(P)H oxidase<sup>54a</sup> and xanthine oxidase activation.<sup>54b</sup> There is experimental evidence that the redox state of the vascular wall is influenced by angiotensin II and TNF by increasing the production of superoxide anions in vascular smooth muscle cells by activating the NADH/NADPH-oxidases.<sup>54</sup> Moreover, there is increased vascular activity of NAD(P)H oxidase<sup>54a</sup> and increased binding of xanthine oxidase to the endothelium in patients with CHF that is related to endothelial dysfunction.<sup>54b</sup> Other potential sources of increased radical formation in chronic heart failure may include the failing cardiac myocyte<sup>55,56</sup> and leukocytes.<sup>57</sup> Moreover, there is evidence that the activity of antioxidative enzyme systems, such as superoxide dismutase, are reduced within the arterial wall in heart failure.<sup>54b</sup>

### Role of the Renin-Angiotensin System (see also Chapter 9)

Another mechanism involved in endothelial dysfunction in chronic heart failure might be an increased activity of the angiotensin-converting enzyme (ACE)<sup>58</sup> in the face of an activated renin-angiotensin system in chronic heart failure. ACE is identical to kininase II and degrades bradykinin. Increased activity of ACE is therefore associated with increased formation of angiotensin II and enhanced inactivation of endogenous bradykinin. The deleterious effects of angiotensin II on radical formation has been described above. The consequence of increased degradation of bradykinin results in impaired bioavailability of NO by reducing its release and synthesis from the endothelium. In addition, bradykinin exerts its vasodilating properties by endothelial release of endothelium-derived hyperpolarizing

factor<sup>59</sup> and prostacyclin.<sup>60</sup> Numerous experimental studies have indicated that bradykinin tissue levels are altered in heart failure and that ACE inhibitors can improve bradykinin availability. There is also clinical evidence that ACE inhibition is associated with an increase in bradykinin plasma concentrations.<sup>61</sup> Moreover, there exists a specific interaction of ACE inhibitors with the bradykinin  $\beta_2$ -receptor.<sup>62</sup> Interestingly, the bradykinin  $\beta_2$ -receptor can act as an inverse receptor,<sup>63</sup> which may also play a role in interventions with ACE inhibitors. By using a specific bradykinin  $\beta_2$  receptor antagonist, we recently have shown in humans that bradykinin is involved in the regulation of vascular tone *in vivo*.<sup>64</sup> In addition, the beneficial effect of ACE inhibition on endothelium-dependent vasodilation is mediated by bradykinin and/or a bradykinin  $\beta_2$ -receptor-mediated mechanism<sup>65</sup> (Figure 17-4) after acute administration. Long-term ACE inhibition improves endothelial function and the bioavailability of NO in patients with heart failure.<sup>66</sup> In fact, recent data would suggest that bradykinin may contribute to the vasodilation associated with chronic ACE-inhibitor therapy in patients with heart failure via the  $\beta_1$ -receptor.<sup>67,67a</sup>

Interestingly, while the antioxidant ascorbic acid improves endothelium-dependent vasodilation before starting ACE-inhibitor therapy, the beneficial effect of ascorbic acid was lost after long-term ACE inhibitor therapy<sup>68</sup> (Figure 17-5, A). Thus the beneficial effect of chronic ACE inhibition on endothelium-dependent vasodilator function may involve, indirectly, antioxidative effects (i.e., mediated by reduced formation of superoxide anions by vascular NADP/NADPH-oxidases<sup>68</sup>) and increased activity of extracellular superoxide dismutase (EC-SOD), a major antioxidative enzyme system within the human arterial vascular wall degrading superoxide anions. In fact, there is evidence that EC-SOD activity increases substantially after long-term therapy with an ACE inhibitor or an  $AT_1$ -receptor antagonist<sup>68</sup> (see Figure 17-5, B), including a close relationship between the increase of EC-SOD activity and the increase of the availability of nitric oxide.<sup>68</sup> These intervention studies in patients would suggest that increased oxidative stress in patients is related to both enhanced radical formation by NADPH oxidase, xanthine oxidase, and others, but also to impaired degradation of superoxide anions by antioxidative enzyme systems (Figure 17-6).

It should be noted that intervention studies also suggest that endothelial function of peripheral *resistance arteries* is impaired and chronic heart failure is modulated by the renin-angiotensin system: for example, ACE inhibitors affect forearm blood flow, in an endothelium-dependent matter, by mediating prostaglandins.<sup>69</sup> It appears that the contribution of

**FIGURE 17-4** Contribution of bradykinin to the effect of ACE inhibition on flow-dependent dilation. Bar graphs represent the percent change of radial artery diameter during flow-dependent, endothelium-mediated vasodilation of the radial artery in healthy controls during control conditions (control), after intraarterial infusion of the bradykinin  $\beta_2$ -receptor antagonist HOE 140 (HOE 140), after infusion of the ACE-inhibitor quinaprilat (Quinaprilat) and after co-infusion of quinaprilat together with HOE 140 (Quinaprilat + HOE 140).

**FIGURE 17-5** A, Antioxidative effects of pharmacological interference with the renin-angiotensin system: bar graphs indicate the effect of intraarterial infusion of vitamin C on flow-dependent, endothelium-mediated vasodilation of the radial artery of patients with coronary artery disease before and after 4 weeks of therapy with ramipril (10 mg/d) or losartan (100 mg/d). B, Effect of ACE inhibition and  $AT_1$ -receptor antagonism on EC-SOD activity in patients with coronary artery disease: bar graphs show the activity of endothelial-bound activity of extracellular superoxide dismutase (EC-SOD) before and after 4 weeks of therapy with ramipril (10 mg/d) or losartan (100 mg/d) in patients with coronary artery disease.

**FIGURE 17-6** The activated renin-angiotensin system in heart failure leads to increased inactivation of bradykinin, resulting in impaired release of NO by endothelial cells. Since extracellular superoxide dismutase (SOD) is regulated by NO, the impaired release of NO by bradykinin is associated with reduced SOD-activity. In addition, activation of the renin-angiotensin system results in increased formation of free radicals by NADH/NADPH oxidases. The resulting increase in cellular radicals leads to enhanced inactivation of NO. Thus activation of the renin-angiotensin system results in impaired NO availability due to both reduced production and increased inactivation of NO.

prostaglandins is operative only in individuals and patients with mild heart failure, whereas such an effect is not observed in patients with severe heart failure.

Intervention studies with angiotensin-II type 1 ( $AT_1$ -) receptor and aldosterone antagonists revealed that the renin-angiotensin system has a very complex impact on vascular functions including the endothelium. At the first glance, it may be surprising that the  $AT_1$  receptor affects endothelial function. However, both experimental and clinical studies have shown the blockade of the  $AT_1$  receptor is associated with improved endothelium-dependent relaxation,<sup>64,70</sup> suggesting a role for the  $AT_1$  receptor in modulating endothelium-dependent mechanisms (i.e., indirectly by preventing inactivation of NO by superoxide anions). In this respect, we have demonstrated that the beneficial long-term effect of  $AT_1$  receptor blockade on flow-dependent, endothelium-mediated vasodilation is blocked by the NO-synthase inhibitor L-NMMA, suggesting that therapy with an  $AT_1$ -receptor antagonist increases the bioavailability of NO.<sup>68</sup> Concomitantly, the  $AT_1$ -receptor blockade antagonist abolished the beneficial effect of antioxidant interventions. Based on experimental data, it is possible that the blockade of angiotensin II actions via the  $AT_1$  receptor reduces NADH-oxidase activity and formation of superoxide anions.<sup>71</sup> The experimental observations in this respect are supported by our observation that 4 weeks of therapy with an  $AT_1$ -receptor antagonist increased the antioxidative potential of the vessel wall in patients with coronary artery disease by increasing the activity of EC-SOD<sup>68</sup> (see Figure 17-5, B). In addition, experimental data suggest that angiotensin II stimulates the  $AT_2$  receptor during blockade of the  $AT_1$  receptor,<sup>72</sup> which may cause bradykinin-mediated release of NO from endothelial cells.<sup>72,73</sup> In fact, long-term therapy with an  $AT_1$  receptor has been shown to improve the vasodilation of peripheral resistance arteries in response to intraarterial infusion of bradykinin, an effect that was significantly smaller as compared with the effect of a comparable dose of an ACE inhibitor.<sup>67</sup>

It has recently been demonstrated by the RALES study that therapy with spironolactone on top of standard therapy, including diuretics and ACE inhibitors, improves the prognosis in patients with chronic heart failure.<sup>74</sup> In this respect it is interesting to note that there is evidence that spironolactone improves impaired endothelium-mediated vasodilation in patients with chronic heart failure. The beneficial effect of spironolactone was observed in patients on top of standard therapy with an ACE inhibitor and diuretics in a prospective, placebo-controlled cross-over study.<sup>75</sup> The improved endothelium-mediated vasomotion of forearm resistance arteries was inhibited by L-NMMA, supporting the concept that spironolactone increases bioavailability of NO consistent with experimental data that aldosterone inhibits endothelial release of NO.<sup>76</sup> In addition, aldosterone plasma concentrations in patients with chronic heart failure correlate inversely with arterial compliance,<sup>77</sup> which is in part related to endothelial release of nitric oxide.<sup>78</sup> Moreover, aldosterone may increase oxidative stress in the vascular wall, which, in turn, would then be attenuated by spironolactone.

Thus there is increasing evidence that the renin-angiotensin-aldosterone system can affect endothelial function in patients with chronic heart failure. Blockade of this neurohumoral activation by inhibition of ACE, aldosterone, and/or  $AT_1$  receptors may well contribute to the beneficial long-term effects of these agents on prognosis in these patients. It is less clear to what extent blockade of the renin-angiotensin system affects other functions of the peripheral circulation, including the vascular structure of peripheral resistance vessels. However, some experimental data support that at least ACE inhibitors are capable of reversing vascular remodeling of the vasculature in heart failure,<sup>79,80</sup> consistent with the notion that the activated renin-angiotensin system has a profound impact on vascular function and structure in heart failure.

## Alterations of Vascular Signal Transduction in Heart Failure

It has been suggested that abnormalities in vasodilator responsiveness in studies with the use of acetylcholine may be, in part, explained by a defect at the endothelial muscarinic receptor level or its signal transduction pathway. The majority of patients with heart failure have underlying ischemic heart disease and risk factors that are known to affect adversely the vascular responses to acetylcholine.<sup>29,30,81</sup> However, a reduced response to acetylcholine was found in chronic heart failure patients with nonischemic cardiomyopathy and without cardiovascular risk factors.<sup>82</sup> Because acetylcholine has direct smooth muscle contracting properties,<sup>23</sup> the response to this agonist represents the net effect of the release of vasodilating substances from the endothelium and direct smooth muscle contraction. Accordingly, the use of a pure endothelium-dependent vasodilator without effects on vascular smooth muscle might provide a clearer picture of endothelial vasodilator capacity. Substance P is a peptide that stimulates endothelial NO synthase through a different endothelial receptor, for example, the tachykinin receptor,<sup>83</sup> and has no direct effect on vascular smooth muscle cells. Substance P has been shown to dilate epicardial coronary arteries and coronary microvessels in humans<sup>84</sup> and forearm resistance and conduit arteries.<sup>85</sup> This vasodilator effect can be attenuated significantly by the NO-synthase inhibitor L-NMMA in normal subjects.<sup>86</sup> Interestingly, the acetylcholine-induced vasodilation of forearm resistance arteries was reduced significantly in patients with chronic heart failure, whereas the increase in blood flow in response to substance P was preserved and not impaired as compared with healthy controls. Similarly, intracoronary infusion of acetylcholine caused significantly less of an increase in coronary blood flow in heart failure patients as compared with control subjects, whereas substance P resulted in a similar increase in coronary blood flow in both groups.<sup>87</sup> Furthermore, the epicardial vasodilator response to substance P was also similar in both groups.<sup>87</sup> Thus it is possible that chronic heart failure may be associated with an abnormality of the muscarinic receptor and/or postreceptor coupling mechanisms, which could contribute to the observed reduction of the response to acetylcholine. However, it is established that endothelium-dependent dilation in response to increased flow, the most physiological test of endothelium-dependent relaxation, is markedly impaired in chronic heart failure. Moreover, vasodilation in response to stimulation of vasopressin type II (V2) receptors<sup>88</sup> is dependent on endothelial nitric oxide release and can be blocked by L-NMMA but not by indomethacin.<sup>89,90</sup> When the V2 receptor agonist desmopressin was infused into the brachial artery of heart failure patients and control subjects, the ensuing vasodilation was attenuated significantly in patients.<sup>91</sup> Moreover, inhibition of nitric oxide synthesis by L-NMMA reduced desmopressin responses to a significantly greater extent in control subjects as compared with patients.<sup>91</sup> Accordingly, these data clearly indicate that impaired endothelium-dependent vasodilation in patients with chronic heart failure is not limited to a specific defect of the muscarinic receptor or its signal transduction pathway.

## Abnormalities of L-arginine Use in Chronic Heart Failure

L-arginine is the amino acid from which the endothelial NO-synthase synthesizes NO. Therefore, it has been supposed that an L-arginine deficit contributes to impaired NO-dependent vasodilation. Some experimental and clinical studies suggest that L-arginine has a beneficial effect on peripheral endothelial function, blood flow, and even exercise capacity. However, L-arginine improved endothelium-mediated

vasodilation only in some, but not in all, studies performed in patients with chronic heart failure.<sup>92-94</sup> The effect of L-arginine may not be limited to improvements in endothelium-dependent relaxation; in fact, there is some evidence that L-arginine supplementation inhibits monocyte adhesion and platelet aggregation.<sup>95,96</sup> Yet, the potential beneficial effect of L-arginine is difficult to explain, since L-arginine plasma concentrations are sufficiently high for a maximal saturation of endothelial NO synthase.<sup>97</sup> This phenomenon is called the “L-arginine paradox.” There are, however, experimental<sup>98</sup> and clinical data suggesting that endogenous competitive L-arginine antagonists such as asymmetrical dimethyl-L-arginine (ADMA) inhibit NO-synthesis from L-arginine as demonstrated in hypercholesterolemia and chronic heart failure.<sup>99,100</sup> Furthermore, data from our group suggest that ADMA plasma concentrations are inversely related to endothelium-mediated vasodilation and exercise capacity in patients with chronic heart failure.<sup>101</sup> In this respect, the bioavailability of NO may be determined by the ratio between L-arginine and ADMA. ADMA is inactivated by DDAH, an enzyme that is redox-sensitive.<sup>102</sup> Oxidative stress contributes to increased ADMA plasma concentrations and L-arginine supplementation might develop antioxidative effects. In hypercholesterolemia, intracellular ADMA levels are increased and L-arginine availability is impaired, despite normal L-arginine plasma concentrations.<sup>103</sup> However, little is known about the expression and activity of DDAH in heart failure, nor do we have data on intracellular L-arginine and ADMA levels in endothelial cells in this condition. However, the markedly increased ADMA levels show a profound alteration of the L-arginine-NO system in heart failure, which may have additional implications beyond endothelium-dependent mechanisms (i.e., impact on the bioavailability of NO in skeletal muscle, which could affect muscle contraction and oxygen consumption [see later discussion]). In addition, oxidant stress-sensitive arginase activity may explain a limited L-arginine availability.<sup>101a</sup> In the clinical setting, the supplementation of high dosages of L-arginine (5 to 20 g/day) during long-term therapy are necessary to achieve an effect and may be associated with altered taste and gastrointestinal side effects. Thus L-arginine supplementation may represent a “proof of the principle” rather than a practical therapeutic option.

### Role of Physical Activity for Endothelial Function in Chronic Heart Failure (see also Chapter 57)

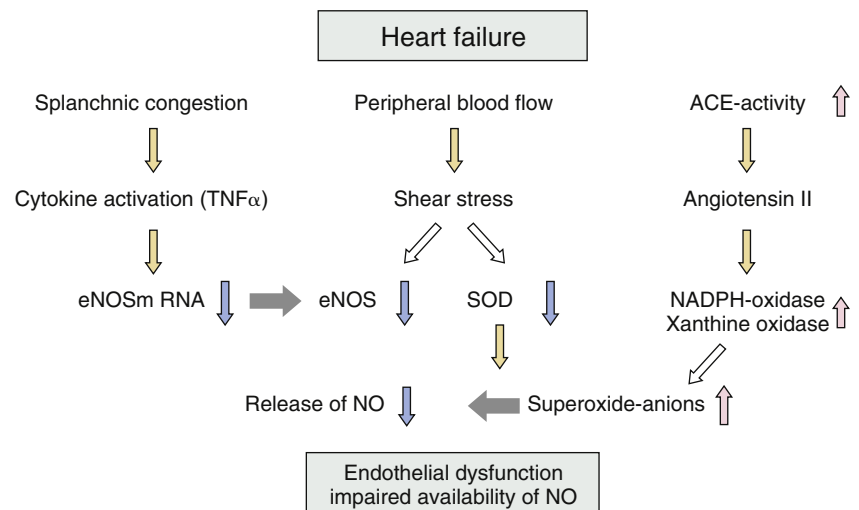

One functional consequence of an impaired endothelial function is that the vessels lose their ability to release NO in response to increased blood flow such as during physical
